Cognitive Function and Hyponatremia: Baseline Data from the SPRINT Trial Daniel E. Weiner,[4] S. Gaussoin,[8] Manjula Kurella Tamura,[3] Alfred K. Cheung,[6] William C. Cushman,[2] Anthony A. Killeen,[5] Mahboob Rahman,[1] Barry M. Wall,[2] Jamie P. Dwyer,[7] Kausik Umanath.[9] *[1]Case Western Reserve University, Cleveland, OH; [2]Memphis VA Medical Center, Memphis, TN; [3]Stanford University, Palo Alto, CA; [4]Tufts Medical Center, Boston, MA; [5]University of Minnesota, Minneapolis, MN; [6]University of Utah, Salt Lake City, UT; [7]Vanderbilt University Medical Center, Nashville, TN; [8]Wake Forest, Winston-Salem, NC; [9]Henry Ford, Derroit, MI.*

Background: Hyponatremia is stated as a reversible cause of cognitive impairment despite very limited data exploring this association.

Methods: To explore the relationship between serum sodium concentration and cognitive function, we evaluated baseline data from the Systolic Blood Pressure INTervention (SPRINT) cognition substudy, SPRINT-MIND. Five cognitive domains were defined from 11 cognitive tests using z-scores, and the association of serum sodium with cognitive performance and brain abnormal white matter volume quantified by MRI were evaluated using linear and quantile regression, respectively.

Results: Among 9361 SPRINT-MIND participants, 2853 were administered an expanded cognitive battery at baseline, 664 of whom had brain MRI. Mean age was 68 years; 20% had known CVD and 29% eGFR <60 ml/min/1.73m^2. There were 120 participants with serum sodium ≤135 mEq/L, 485 with sodium 136-138, 983 with 139-140, 891 with 141-142, and 374 with ≥143 mEq/L. In analyses adjusted for age, sex, SPRINT network, education, race, diabetes, CVD, BMI, smoking, ACEi/ARB use, systolic and diastolic BP, lipids, eGFR, and albuminuria, lower serum sodium was associated with significantly worse executive function (p=0.002) and a trend to worse attention (p=0.08) and global cognitive function (p=0.12). Associations were unchanged following adjustment for thiazide and anti-depressant use. When examining thresholds, participants with Na ≥143 mEq/L also demonstrated worse cognitive test performance in most domains, consistent with a 'J'-shape relationship between sodium and cognition. In the MRI subgroup, sodium was not associated with brain abnormal white matter volume in adjusted analyses (p=0.77).

Conclusions: In older adults with hypertension, lower serum sodium is associated with worse cognitive function, particularly executive function. This does not appear to reflect structural brain disease.

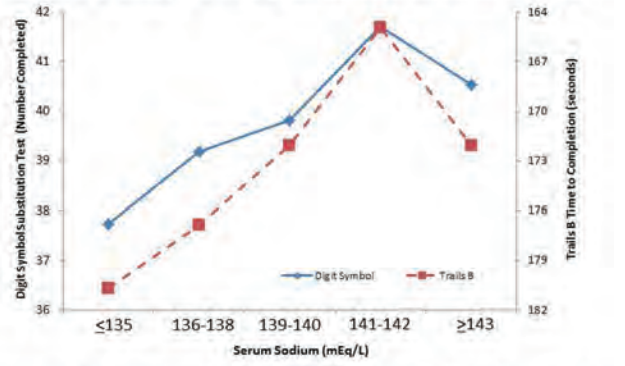
Figure. Adjusted least squares means for performance on Trailmaking Test Part B (p=0.005) and the Digit Symbol Substitution Test (p<0.001)



Adjusted for age, network, education, race, sex, diabetes, cardiovascular disease, BMI, use of ACE inhibitors or angiotensin receptor blockers, thiazide diuretics, loop diuretics, antidepressant medication use, SBP, DBP, Total cholesterol, HDL, LDL, eGFR, and albuminuria. For the Digit Symbol Substitution Test, a higher score is better while, for Trails B, a lower time is better.

Atrial Fibrillation and Risk of Decline in Cognitive Function in CKD Mark D. Mccauley,[9,13] Jesse Y. Hsu,[12] Ana C. Ricardo,[9] Dawood Darbar,[10] Mayank Kansal,[9] Alan S. Go,[3] Manjula Kurella Tamura,[5] Harold I. Feldman,[12] John W. Kusek,[4] Jonathan J. Taliercio,[1] Panduranga S. Rao,[11] Tariq Shafi,[2] Jiang He,[6] Xue Wang,[8] Kristine Yaffe,[7] James P. Lash.[9] *[1]Glickman Urological and Kidney Institute, Cleveland, OH; [2]Johns Hopkins University School of Medicine, Baltimore, MD; [3]Kaiser Permanente Northern California, Oakland, CA; [4]NIDDK, Bethesda, MD; [5]Stanford University, Palo Alto, CA; [6]Tulane School of Public Health and Tropical Medicine, New Orleans, LA; [7]UCSF, San Francisco, CA; [8]UNIVERSITY OF PENNSYLVANIA, Philadelphia, PA; [9]University of Illinois at Chicago, Chicago, IL; [10]University of Illinois at Chicago, Chicago, USA, Chicago, IL; [11]University of Michigan Health System, Ann Arbor, MI; [12]University of Pennsylvania, Philadelphia, PA; [13]Medicine/Cardiology, Jesse Brown VA Medical Center, Chicago, IL.*

Background: Studies in the general population suggest that atrial fibrillation (AF) is an independent risk factor for decline in cognitive function, however this relationship has not been examined in persons with chronic kidney disease. We investigated the association between AF and changes in cognitive function over time in men and women enrolled in the Chronic Renal Insufficiency Cohort Study.

Methods: AF status was determined annually using 12-lead electrocardiogram and/or participant self-report. Global cognitive function was assessed biannually with the Modified Mini-Mental State Exam (3MS). Linear mixed effect regression was used to compare the association between time-updated AF status and longitudinal change in 3MS.

Results: Compared to individuals without AF (n= 3120) at baseline, individuals with AF (n=673) were older, had lower socioeconomic status, increased prevalence of cardiovascular disease, and lower estimated glomerular filtration rate. Baseline 3MS scores were similar (90.6 vs 91.3) in AF and non-AF groups. Median follow-up time was 5.8 years. Table below summarizes multivariable analyses.

Conclusions: Despite a greater burden of cardiovascular disease at baseline in individuals with AF, there was no independent association between AF and longitudinal changes in cognitive function.

Metabolomics Study Identifies Several Metabolites Associated with Uremic Symptoms in Advanced CKD Jiun-Ruey Hu,[1,5] Andrew S. Levey,[3] Josef Coresh,[1,4] Morgan Grams,[1,4] Eugene P. Rhee,[2] Tariq Shafi.[1,4] *[1]Epidemiology, Johns Hopkins School of Public Health, Baltimore, MD; [2]Massachusetts General Hospital, Boston, MA; [3]Tufts Medical Center, Boston, MA; [4]Welch Center for Prevention, Epidemiology, and Clinical Research, Johns Hopkins University, Baltimore, MD; [5]Vanderbilt University School of Medicine, Nashville, TN.*

Background: Uremic symptoms are common in patients with advanced CKD, but the toxins that cause these symptoms are unknown.

Methods: We measured metabolites in participants of the Modification of Diet in Renal Disease (MDRD) with measured GFR < 20 ml/min/1.73 m^2 (N=216), using an untargeted LC/MS/MS platform. We determined the association of 667 metabolites with uremic symptom scores using linear regression adjusting for clinical factors and accounting for multiple comparisons.

Results: The mean age of the participants was 52 years and 81% were white. Uremic symptoms were common. 80% of participants had at least 1 uremic symptom. Metabolites associated with uremic symptoms are presented in the accompanying table.

Conclusions: We identified several metabolites associated with uremic toxins. Metabolomics has the potential to identify toxins that cause uremic symptoms.

Near-Infrared Spectroscopy Measured Muscle Haemoglobin O2 Saturation Kinetics and Physical Performance in CKD Thomas J. Wilkinson,[2] Alice e. White,[2] Daniel Nixon,[2] Douglas W. Gould,[2] Emma L. Watson,[2] Alice C. Smith.[1] *[1]John Walls Renal Unit, Leicester General Hospital, Leicester, United Kingdom; [2]University of Leicester, Leicester, United Kingdom.*

Background: CKD patients have poor exercise capacity. A possible factor may be an imbalance in muscle oxygen (O_2) supply and utilisation, moderated by mitochondrial and endothelial dysfunction. Near-infrared spectroscopy (NIRS) can be used to measure *in vivo* muscle oxidative metabolism. Using NIRS we investigated gastrocnemius skeletal muscle O_2 kinetics in non-dialysis CKD patients during exercise.

Methods: 30 patients (59±16 yrs; 11 female; eGFR: 54±26 mL/min/kg/1.73m^2) completed the incremental shuttle walk test. NIRS measured light attenuation in the near-infrared spectrum and determined chromophores, primarily % of oxygenated haemoglobin present in the muscle (SMO_2%). SMO_2% was assessed before, during, and after (recovery) exercise. Resting cardiac parameters were assessed, along with habitual physical activity (PA). Patients were divided into aerobic capacity tertiles to determine SMO_2% differences.

Results: From baseline, SMO_2% declined by 12±7% during exercise before rapidly recovering upon cessation (Fig 1). Controlled for age, sex and eGFR, patients with higher aerobic capacity took 258 (56-461) secs (55%) longer (P=.016) to reach minimum SMO_2%, and recovered 49 (2-96) secs (75%) quicker (P=.040) than those with lower aerobic capacity. Better SMO_2% kinetics were associated with higher stroke volume and PA levels, and lower peripheral resistance.

Conclusions: Superior SMO_2% kinetics (i.e. slower deoxygenation rate, quicker recovery) are associated with greater exercise capacity, better vasculature, and higher PA in CKD. The dysfunctional kinetics observed may indicate endothelial dysfunction and an inability of mitochondria to efficiently carry out oxidative phosphorylation. Accordingly, NIRS is a low-cost and non-invasive means to evaluate O_2 kinetics and could be a useful tool to measure oxidative metabolism mechanisms in CKD.

SA-PO449

Exercise Improves Self-Reported Physical Symptom Burden and Fatigue in Non-Dialysis CKD Thomas J. Wilkinson,[3] Soteris Xenophontos,[3] Douglas W. Gould,[3] Amy L. Clarke,[3] Barbara P. Vogt,[2] Joao L. Viana,[4] Emma L. Watson,[3] Alice C. Smith.[1] *[1]John Walls Renal Unit, Leicester General Hospital, Leicester, United Kingdom; [2]Universidade Estadual Paulista UNESP, Botucatu, Brazil; [3]University of Leicester, Leicester, United Kingdom; [4]University Institute of Maia, Porto, Portugal.*

Background: CKD patients suffer from a variety of physical symptoms due to the disease and its treatments. Symptoms include fatigue, muscle weakness, pain, and sleep disruption, and these can negatively affect quality of life (QoL) and discourage physical activity. Whilst intradialytic exercise may help ameliorate some symptoms in dialysis patients, research on whether exercise can reduce symptom burden in non-dialysis patients is lacking.

Methods: 36 patients (62±12 yrs; 22 female; eGFR: 26±8 mL/min/kg/1.73m^2) completed supervised aerobic exercise (AE) (n=18) or combined aerobic plus resistance exercise (A+RE) (n=18) 3x/week for 12 weeks. Self-reported symptom burden and fatigue measures were taken pre- and post-exercise. The Leicester Uraemic Symptom Scale (LUSS) measured the frequency and intrusiveness of 11 symptoms. Fatigue was measured using the Functional Assessment of Chronic Illness Therapy-Fatigue Scale (FACIT-F); the total FACIT-F score and Trial Outcome Index (TOI) were used.

Results: AE reduced the total mean number of symptoms from 6.3 to 5.4 (14% P=.014) and the frequency of itching by 35% (P=.004). AE also reduced the intrusiveness of sleep disturbance by 14% (P=.001) and experience of muscle spasm/stiffness by 29% (P=.021). In the A+RE group, only a reduction in the frequency (41% P=.001) and intrusiveness (39% P<.001) of a feeling in loss of muscular strength/power was seen. Exercise improved fatigue; total FACIT-F score was improved in the AE and A+RE groups by 9% (P=.028) and 23% (P=.068) respectively, whilst the TOI was improved by 10% (P=.067) and 27% (P=.048).

Conclusions: Exercise can significantly reduce physical symptom burden and fatigue in non-dialysis CKD. Patients performing AE experienced less symptoms overall, with itching, sleep disturbance, and muscle stiffness symptoms improving specifically. Unsurprisingly, patients performing additional strength training felt stronger. Fatigue was improved following both exercise modalities. Symptom burden contributes to physical inactivity and a reduction in QoL, and as such exercise should be encouraged to help improve patient's health status.

"It's Opened Up My Eyes to How Much I Can Actually Do": A Mixed Methods Study Exploring the Feasibility of a Physical Activity Education Programme in CKD Amy L. Clarke, Heather J. Mackinnon, James Burton, Alice C. Smith. *University of Leicester, Leicester, United Kingdom.*

Background: Physical activity (PA) can improve the quality of life (QoL) and health of patients with chronic kidney disease (CKD). However, patients exhibit minimal PA, and currently, no specific pathways exist to target physical inactivity in CKD. "PACT" is a 3.5-hour structured group education programme designed to initiate PA by eliciting illness perceptions, providing basic disease education, highlighting health risks, and promoting the benefits of PA and self-regulation.

Methods: A mixed methods 'before and after' feasibility study of the PACT intervention to explore recruitment, retention and engagement; and patient acceptability of intervention and outcome measures. Semi-structured interviews were conducted to gain an understanding of patient experience.

Results: Overall, 75 non-dialysis CKD patients were approached and 19 (25%) were consented. 17 (90%) attended the group session, and 4 withdrew due to unrelated reasons, resulting in a 68% completion rate. Engagement with step monitoring was good during the 8 weeks of walking;11 returned PA diaries completed at a rate of 61-100%. There was a mean (CI 95%) increase in daily steps from pre-to post-intervention of 1947(-445, 4349) which produced a small-moderate effect *(d=0.47)*. Positive changes were observed for: physical function, QoL, activation and knowledge. Our qualitative analysis found that participants enjoyed the interactive session and would recommended it; outcome assessments were for the most acceptable, and self-monitoring steps enhanced engagement. However, some participants felt that real time monitoring on a mobile app, further guidance for exercise intensity, and a greater emphasis on psychological strategies related to disease adjustment and PA motivation could improve the intervention.

Conclusions: The purpose of this trial was to determine acceptability of and engagement with the PACT protocol. Findings were positive, with some areas for refinement indicated. The trial was not powered to assess efficacy, but demonstrated potential to improve PA, and domains related to QoL. This approach to lifestyle management has great promise in CKD and deserves further attention.

SA-PO451

Prevalent Depression and Associated Factors in a Disadvantaged CKD Population Carl P. Walther, Jingbo Niu, Sai Kaumudi Saridey, Wolfgang C. Winkelmayer, Sankar D. Navaneethan. *Baylor College of Medicine, Houston, TX.*

Background: Depression is common among individuals with CKD and associated with adverse outcomes. In the US population, prevalence is lower in older persons and varies with race/ethnicity. We studied factors associated with depression in a diverse non-dialysis CKD cohort, which could help to identify high-risk patients and disparities.

Methods: We identified adults with eGFR <60 for ≥90 days who received care through a safety-net health system from 2006-16. Depression was determined from ICD codes prior to or within 2 weeks of cohort entry. Comorbidities were identified using a similar method. We categorized CKD into stages 3A, 3B, 4, and 5. Race/ethnicity was recorded in 5 mutually-exclusive categories. We used multivariate logistic regression to analyze associations with demographics, comorbidities, and CKD stage, and calculated predicted probabilities and 95% CIs.

Results: We included 13678 CKD patients of whom 39.4% were Hispanic, 40.9% black, 11.5% white, 5.9% Asian/Pacific Islander, and 2.2% other/unknown race. Depression prevalence was 11.6% overall, and 23.9% among whites, 11.1% among blacks, 9.8% among Hispanics, and 5.3% among Asians/PIs. Interactions between age and race/ethnicity, and between age and number of comorbidities were observed.

Conclusions: Depression prevalence varied with race/ethnicity, age, and comorbidities. Depression decreased markedly with age in blacks and whites, but not Hispanics. The association of comorbidities with depression decreased with age.

Stratified Odds Ratios [95% CIs] for Depression*

Age category (years)	Hispanic (versus black or white)†	One additional comorbidity‡
18 to 34	0.30 (0.11-0.87)	2.63 (1.56-4.43)
35 to 49	0.50 (0.36-0.69)	1.70 (1.49-1.93)
50 to 64	0.76 (0.65-0.89)	1.59 (1.50-1.68)
65 to 79	0.87 (0.68-1.11)	1.59 (1.56-1.73)
80 or older	1.61 (0.94-2.77)	1.23 (1.03-1.46)

SA-PO452

Prevalence and Associated Factors of Depressive Symptoms among Predialysis CKD Patients in China: Results from the Chinese Cohort Study of CKD (C-STRIDE) Lei Pu,[2] Li Wang,[2] Guisen Li.[1] *[1]Renal Division and Institute of Nephrology, Sichuan Academy of Medical Sciences and Sichuan Provincial People?s Hospital, Chengdu, China; [2]Sichuan Provincial People's Hospital, Chengdu, China. Group/Team: C-STRIDE study group.*

Background: Depression was reported to be the most common mental disorder in patients with chronic kidney disease (CKD). Previous studies found that depression could accelerate the progression of CKD disease, and was an independent risk factor of hospitalization and death among patients with CKD. The objective of this study is to investigate the prevalence of depression in Chinese patients with predialysis CKD, and to identify factors associated with depression.

Methods: Baseline data of a multicenter prospective cohort study, Chinese cohort study of chronic kidney disease(C-STRIDE)study were used. Altogether 2995 participants with CKD stage 1 to 4 who completed a survey of depressive symptoms were included. The depressive symptoms were assessed by Zung Self-Rating Depression Scale (ZSDS). ZSDS≥50 was used as thecutoff score of the presence of depressive symptoms. MultivariableLogistic regression models were used to identify factors associated with depression.

Results: Mean eGFR level was 51.59±29.49ml/min/1.73m2. The prevalence of depressive symptoms was 37.8% and increased significantly with advanced CKD stages. Female, higher education level, low income, larger economic impact of disease cost, comorbid cardiovascular disease, anemia, lower physical activity ability were independently associated with depressive symptoms.

Conclusions: Our study revealed that depressive symptoms were common among Chinese predialysis CKD population. Socioeconomic factors andclinical characteristics of severity of disease were strongly associated with the depressive symptoms.

SA-PO453

The Impact of CKD on Disability and Health-Related Quality of Life (HR-QOL) of Children and Adolescents Anna Francis,[1] Madeleine Didsbury,[2] Anita Van zwieten,[1] Kerry Chen,[7] Laura J. James,[7] Siah Kim,[6] Tonya Kara,[5] Natasha Nassar,[1] Allison Tong,[7] Steven Mctaggart,[9] David W. Johnson,[4] Jonathan C. Craig,[8] Kirsten Howard,[1] Germaine Wong.[3] *[1]University of Sydney, Sydney, NSW, Australia; [2]Centre for Kidney Research, Westmead, NSW, Australia; [3]None, Auambie, NSW, Australia; [4]Princess Alexandra Hospital, Brisbane, QLD, Australia; [5]Starship Children's Hosptial, Auckland, New Zealand; [6]Sydney Children's Hospital, Newtown, NSW, Australia; [7]The University of Sydney, Westmead, NSW, Australia; [8]University of Sydney/ Children's Hospital, Sydney, NSW, Australia; [9]Children's Health Queensland, Brisbane, QLD, Australia.*

Background: Children with CKD suffer from reduced HR-QOL. The extent of impairment and risk factors for poorer HR-QOL and disability are under-studied. The study aimed to compare overall HR-QOL and severity of disability in children and adolescents with different stages of CKD and to determine factors associated with lower HR-QOL scores.

Methods: HR-QOL data were collected from children and adolescents (age 6-18 years) across five paediatric units in Australia and New Zealand. The Health Utilities Index 3 survey was used to measure overall utility based HR-QOL (where 0 represents being dead and 1 represents full health). A score of 1.00 represents no disability, 0.89-0.99 represents mild disability, 0.70-0.88 represents moderate disability and less than 0.70 represents severe disability. HR-QOL scores and disability stages were compared between CKD stages using the Mann-Whitney-U test. Multivariable linear regression assessed factors associated with decline in HR-QOL.

Results: There were 377 children with CKD (median age 12.6 years). The median unadjusted HR-QOL score for those with CKD stages 1-4 was 0.88 (interquartile range

[IQR] 0.61-0.97), higher than those on dialysis (0.67, IQR 0.39-0.91, p<0.001), but similar to kidney transplant recipients (0.83, IQR 0.59-0.97, p=0.4). Severe disability was more common in dialysis patients (20/35, 57%), compared to transplant recipients (37/114, 33%) or those with CKD stages 1-4 (57/176, 32%) (c2=8.4, p=0.02) (table 1). The factors associated with decrements in HR-QOL were being on dialysis (compared to CKD stages 1-4: reduction by 0.13, 95%CI 0.02-0.24) and lowest quartile family income (compared to highest income quartile: reduction by 0.10, 95%CI 0.01-0.20), when adjusted for age and gender.

Conclusions: HR-QOL children with CKD was significantly related to stage of disease and family income, with children on dialysis and those the lowest family income having significant lower HR QOL.

Funding: Private Foundation Support

Disability in children with CKD

	None to mild disability	Moderate disability	Severe disability

Posttraumatic Stress Disorder and Outcomes among US Veterans Who Transition to Renal Replacement Therapy: A Transition of Care in CKD Study Vanessa A. Ravel,[1] Elani Streja,[1] Connie Rhee,[1] Csaba P. Kovesdy,[2] Kamyar Kalantar-Zadeh.[1] [1]*UC Irvine, Orange, CA;* [2]*University of Tennessee Health Science Center, Memphis, TN*.

Background: End stage renal disease (ESRD) patients starting dialysis treatment often experience worse mental health and quality of life. While poor mental health has been associated with a higher risk of mortality and hospitalization in studies of veteran patients, there is a dearth of research specifically evaluating the association of posttraumatic stress disorder (PTSD) and these outcomes in veterans transitioning to dialysis.

Methods: From a nationwide contemporary cohort of 79,331 US veterans transitioning to dialysis between 10/2007 and 3/2014, we identified 5,464 (6.9%) veterans with a PTSD diagnosis prior to transition. The association between pre-ESRD (prelude) PTSD and 1-year all-cause mortality was examined via adjusted Cox regression, and Poisson regression was used to evaluate the association between PTSD and 1-year hospitalization rate. Models were hierarchically adjusted for case-mix and laboratory covariates.

Results: Patients were 71±12 years old and included 5% women, 24% African-Americans, 61% diabetics and 9% were homeless. Patient with prelude PTSD had a higher a risk of 1-year all-cause mortality [aHR: 0.89 (0.84-0.95)], but a lower 1-year hospitalization incident rate ratio [aIRR: 1.05 (1.02-1.07)] in fully adjusted models.

Conclusions: While prelude PTSD is associated with reduced risk of post-ESRD mortality in veterans transitioning to dialysis, it is also associated with a higher hospitalization rate. Studies are warranted to examine the role of psychosocial factors between prelude PTSD and post-ESRD outcomes, and whether an increased hospitalization rate mediates better survival for veterans with PTSD transitioning to ESRD.

SA-PO455

Impact of Multimorbidity on Patient-Reported Quality of Life – Analysis of a Real World CKD Patient Population James Jackson,[1] Anna Hadfield,[2] Rebecca Moon.[1] [1]*Adelphi Group, Macclesfield, United Kingdom;* [2]*Adelphi Real World, Macclesfield, United Kingdom*.

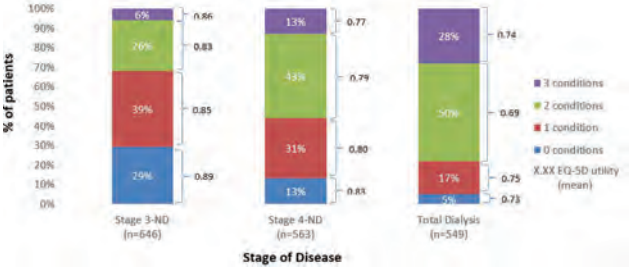
Background: It is widely accepted that the prevalence of anemia, secondary hyperparathyroidism (SHPT) and hyperkalemia amongst chronic kidney disease (CKD) patients increases as CKD worsens. The objective of this analysis was to determine whether an increase in the number of CKD related comorbidities has an impact on patient quality of life (QoL).

Methods: Data were drawn from the Adelphi CKD Disease Specific Programme (DSP), a real-world, cross-sectional survey of consulting non-dialysis (ND) and dialysis CKD patients across 5EU and USA. Patients were segmented according to the number of physician-reported, CKD-related comorbidities (anemia, SHPT and/or hyperkalemia) experienced and patient-reported QoL was assessed using EuroQol-5D-3L (EQ-5D).

Results: Results from 1758 CKD patients showed that as CKD worsened, patients were more likely to experience multiple comorbid conditions (Figure 1). An increase in multimorbidity at Stage 3-ND and Stage 4-ND was associated with a decrease in patient-reported QoL. For Stage 4-ND patients, a significant reduction was observed in the mean EQ-5D score for patients with 3 conditions compared with those who have 0 conditions (Figure 1). Although a similar trend was not observed amongst the Dialysis population, the QoL scores were lower overall than those patients at an earlier stage (Figure 1).

Conclusions: Multimorbidity increases as CKD progresses. Increased multimorbidity is associated with a poorer quality of life for CKD patients. Slowing disease progression could help prevent the onset of anemia, SHPT and/or hyperkalemia leading to maintenance of better QoL for longer.

Figure 1: Proportion of patients with 0, 1, 2 or 3 comorbidities commonly associated with CKD and related EQ-5D utility scores



SA-PO456

Association between Peer Mentoring and Quality of Life among Patients with CKD Hafiz Z. Mahmood, Awais Ammar, Emily J. Wasserman, Tara Liaghat, Umar Farooq, Nasrollah Ghahramani. *Penn State College of Medicine, Hershey, PA.*

Background: Health related quality of life (HRQOL) has been increasingly recognized as an important medical outcome in patients with chronic kidney disease (CKD). Peer mentoring (PM) has been proposed as an effective model for active patient engagement and subsequent improvement in HRQOL. This study evaluates the preliminary effects of face-to-face peer mentoring on HRQOL among patients with chronic kidney disease.

Methods: Sixty-one patients with CKD were assigned to trained peer mentors with whom they had weekly phone contact and at least monthly face-to-face contact for a six month period. All participants completed a baseline Short Form Kidney Disease Quality of Life (KDQOL) instrument, developed as a self-report, health-related QOL tool designed specifically for patients with CKD. Currently, 25 patients have also completed the 12-month assessment. The Wilcoxon Signed Rank Test was used to evaluate paired differences in patient outcome measures for patients receiving face-to-face mentorship between the baseline and 12-month assessments (Change = Difference of 12-month assessment minus baseline assessment). All reported p-values are two-sided with a significance level of 0.05.

Results: There was a significant difference in the 'Symptoms/Problems' subscale (p=0.003; Median Change =6.25, IQR = 20.83, N=25) and the 'Effects of Kidney Disease' subscale (p=0.01; Median Change=12.50, IQR=25.00, N=25) of the KDQOL between the baseline and 12-month assessments. No significant differences were noted in the Burden of Kidney Disease (p=0.73, N=25), Physical Component Summary (p=0.89, N=15) and Mental Component Summary (p=0.30, N=15).

Conclusions: Face-to-face peer mentoring is associated with improved symptoms and problems subscale, as well as the effects of kidney disease subscale of the KDQOL instrument.

Depression, Anxiety, and Stress – Before and After Dialysis Initiation: A Pilot Study Cicero I. Bezerra, Bruno C. Silva, Rosilene M. Elias. *Universidade de Sao Paulo, Sao Paulo, Brazil*.

Background: Chronic kidney disease (CKD) affects psychological and emotional aspects that are particularly critical while choosing the renal replacement therapy (RRT) modality. Anxiety, depression and stress are common yet frequently overlooked among these patients. We have examined the behavior of these emotional components pre- and post-RRT, and hypothesized that there will be an improvement of symptoms after starting dialysis, regardless of chosen modality.

Methods: This is a prospective observational study in which patients were approached in two moments: while attending the structured Pre-Dialysis Education Program, and after starting RRT (within the first 3 months). Scales of anxiety, depression and stress (Hospital Anxiety and Depression Scale and Perceived Stress Scale, respectively) were applied. Demographic and clinical characteristics were also assessed.

Results: Out of 67 patients, 16 have already started RRT by April 2017 (50% men, age 56 ± 15 years, 58% Caucasian, 42% diabetic). Scores of depression, anxiety and stress reduced significantly from pre to post RRT initiation (Table 1), with no difference between patients who chose peritoneal dialysis or hemodialysis. Before RRT, anxiety scores correlated significantly with depression (r=0.75) and stress scores (r=0.79); after RRT initiation, anxiety scores correlated significantly with depression (r=0.59) and stress scores (r=0.62).

Conclusions: Although decision-making on RRT is a process associated with high scores of depression, anxiety and stress, these symptoms are attenuated at the end of this process, with patients already on dialysis. This finding identifies the importance of targeting psychological symptoms on RRT modality choosing process, and highlights that an improvement might occur after RRT initiation.

Table 1 - Anxiety, Depression and Stress scores before and after RRT initiation

	Before starting RRT	After starting RRT	p
Anxiety scores	6.1 ± 3.3	1.9 ± 1.8	<0.0001
Depression scores	7.8 ± 4.0	4.2 ± 2.8	<0.0001
Stress scores	29.4 ± 7.5	11.1 ± 6.4	<0.0001

Enhanced Evaluation of Human Renal Biopsies Using Multicolor Flow Cytometry and Cytokine Analysis: A Focus on Transplanted Kidneys Kimberly A. Muczynski, Nicolae Leca, Susan K. Anderson. *Medicine-Nephrology, University of Washington, Seattle, WA.*

Background: Virtually all renal disease is due to an immune response. Examination of renal biopsies with light, immunofluorescence and electron microscopy provide limited information about immune mechanisms causing kidney injury and disease activity. In adddition, information is often insufficient to direct therapy with specific agents, which becomes a frustration with new immune modulating agents being developed.

Methods: To enhance the information available from a biopsy we developed a technique for reducing a fraction of a renal biopsy to single cells for multicolor flow cytometry and for capture and quantitation of secreted cytokines present within the biopsy. As proof of concept, after evaluation of over 400 biopsies, we use our technique to suggest new criteria for evaluating rejection and renal inflammation that are clinically useful for directing therapy.

Results: A ratio of CD8+ to CD4+ lymphocytes of greater than 1.2 within the biopsy of transplanted kidneys is associated with rejection, even before it is apparent by microscopy. Elevated numbers of CD45 leukocytes and higher levels of IL-6, IL-8 and IL-10 within the kidney indicate more severe injury. Antibody binding to renal microvascular endothelial cells can be measured and corresponds to antibody-mediated forms of allograft rejection. Eculizumab binding to endothelial cells suggests complement activation, which may be independent of bound antibody. A comparison of intrarenal leukocyte subsets and their activation states to those of peripheral blood from the same donor at the time of biopsy identify significant differences supporting the need to develop techniques which interrogate the immune system within the kidney.

Conclusions: Our use of cytometry to assess intrarenal leukocyte subsets, microvascular endothelial cell properties and secreted cytokines from a fragment of a standard renal biopsy provide useful information about the immune processes in the kidney. After evaluation of over 400 biopsies we find results reliable indicators of disease activity. This information is not available from peripheral blood. While we have focused on biopsies from transplanted kidneys (due to their availability), our techniques are equally applicable to native kidneys. Cytometry can enhance renal biopsy evaluation in a clinically significant manner.

Outcomes of Kidney Transplant Recipients with G3 Glomerulitis Fahad Aziz,[2] Sandesh Parajuli,[5] Weixiong Zhong,[4] Didier A. Mandelbrot,[3] Arjang Djamali.[1] *[1]School of Medicine and Public Health, Madison, WI; [2]University of Wisconsin, Madison, WI; [3]U of Wisconsin Hospital, Madison, WI; [4]University of Wisconsin Madison, Madison, WI; [5]UW Health, Middleton, WI.*

Background: Glomerulitis is one of the pathological features of AMR. However, the natural history of kidney allografts with g3 lesions (glomerulitis in >75% of glomeruli) is poorly defined.

Methods: We sought to determine the concomitant immunopathological findings and outcomes in a case series of kidney transplant recipients with g3 lesions.

Results: Thirty seven consecutive kidney transplant recipients with g3 lesions in diagnostic biopsies performed 6.2 ± 6.7 years after transplant were included. At the time of biopsy, mean age was 45.5 years and all patients were on triple therapy with CNI, MPA, and prednisone. The majority were Caucasian (80%), male (60%), and had transplant glomerulopathy (68%). Kidney function and immunopathological findings (mean values) at the time of biopsy are displayed in table 1. Treatment after the biopsy included pulse steroids/IVIG (70%), Rituximab (50%), and plasma exchange (10%). Patients were followed up for a mean of 1.6±1.1 years. The incidence of graft loss and death was 11 (30%) and 3 (10%), respectively. Univariate regression analyses including demographic, functional, and immunohistological variables determined that t score (HR = 2.7, 95%CI: 1.3 to 5.8), ct score (HR = 2.1, 95%Cl: 1.009 to 4.7), Scr (HR = 1.6, 95%CI: 1.1 to 2.2), and live donor status (HR = 0.18, 95%Cl: 0.3 to 0.9) were significantly associated with graft loss. Multivariate stepwise Cox regression analyses only retained Scr (HR = 1.8, 95%Cl: 1.2 to 2.7) and live donor status (HR = 0.14, 95%Cl: 0.02 to 0.8). Notably, C4d staining and DSA were not retained as significant predictors.

Conclusions: In this largest case series of patients with g3 lesions, 30% of the grafts were lost with in 2 years. Scr and live donor status were the most important variables associated with graft loss. Future studies are needed to determine preventive and treatment stratagies to improve outcomes in patients with g3 lesions.

Table 1. Kidney function and immunopathological characteristics of 37 patients with G3 lesions

SA-PO460

Eosinophil-Rich Inflammation in Allograft Renal Biopsies: An Analysis of Clinical Significance and Correlation with Rejection Payaswini Vasanth, Carla L. Ellis. *Emory University, Atlanta, GA.*

Background: In this study we investigate the significance of interstitial eosinophilic inflammation in renal allograft and its association with rejection, response to treatment, risk of subsequent rejections, and allograft outcome.

Methods: We studied 26 kidney transplant pts between 2012-17 with AKI who underwent biopsies. The biopsies showed clusters of interstitial eosinophils histologically, with or without evidence of ACR, AMR, or both. Allograft function at the time of the biopsy was assessed by SCr and by its change from baseline. After initial treatment, pts were categorized as, - Complete Responders (CR): SCr returned to baseline - Partial Responders (PR): SCr decreased to a level that was greater than 50% of SCr at the time of biopsy, but never returned to baseline. - Non Responders (NR): SCr remained at or above SCr at the time of biopsy.

Results: 22 out of the 26 biopsies with eosinophils had rejection [Borderline 10(45%), 1A 1 (5%),1B 5(23%), 2A 1(5%), 2B 2(9%), AMR+ACR 3(14%)]. Allograft response to treatment of underlying and incidents of subsequent rejection is shown in Table 1. 13 of 22 pts with eosinophilia and rejection had subsequent rejections. 7 (4 NR, 3 PR) pts progressed to needing RRT, of which 4 lost allograft within 2 yrs. 22%(5) of pts with eosinophilic rejection had h/o BK viremia, 22%(5) had h/o CMV viremia, of which 75% were NR. 50%(11) of the pts who had eosinophilic rejection had history of recurrent UTIs. One pt with HIV had severe rejection with plasma cells and allograft loss within a year of transplantation. 61% (16) pts were on drugs that are shown to be associated with AIN especially PPIs. Only 3%(1) pts had peripheral eosinophilia.

Conclusions: Of the 26 pts with eosinophilic inflammation in their allograft biopsy we note a higher incidence of ongoing rejection and risk of developing subsequent rejection and allograft loss. Pts with history of infection (UTIs, BK, CMV) had higher incidence of underlying rejection with eosinophilic infiltrates.

Table 1: Allograft response to treatment of underlying and incidents of subsequent rejection

	With Rejection		Subsequent Rejection	
	# of Pts	% of total pts	# of Pts	% of total pts
CR	6	27%	3	21%
PR	8	36%	5	43%
NR	8	36%	5	36%
Total Pts:	22		13

Angiotensin-2 Expression Is Increased in Macrophages during Acute Cellular Rejection of Human Allografts Ping L. Zhang. *Anatomic Pathology, Beaumont Laboratory, Beaumont Health System, Royal Oak, MI.*

Background: The renin-angiotensin system (RAS) is well known to involve in hemodynamic changes in the kidney, but recent in vivo studies imply immunologic effects of RAS to cause damages in kidneys, partially through stimulating Interleukin-1 production by macrophages. We previously demonstrated that macrophages are one of dominantly cellular components in prominent acute cellular rejection (ACR). This study was to investigate whether there was an expression of angiotensin-2 (Ang2), the effector molecule in RAS, in macrophages involving ACR.

Methods: The study included 3 groups. The group 1, as the negative controls, was composed of 15 normal parenchyma sections away from renal cell carcinoma in nephrectomy specimens. The group 2, as the study group, consisted of 20 human allograft explant cases with ongoing ACR. As Ang2 is a small 8-peptid molecule being difficult for targeted staining, we selected 20 sarcoidosis cases (composed of aggregated and fused macrophages into giant cells), mostly known to have elevated serum angiotensin-converting enzymes, as the positive controls (4 in kidneys, and others in tonsil, liver and hilar lymph nodes). All paraffin embedded sections were stained for Ang2 by immunohistochemical staining method and cytoplasmic staining of Ang2 was graded 0 to 3+ (0 - no staining, 1+ - weak fine granular staining, 2+ - moderate granular staining and 3+ - strong granular staining).

Results: All negative controls (group 1) stained negatively for Ang2, as no or minimal inflammatory cells were present. All sarcoid granulomatous cells (macrophages and giant cells) in positive controls demonstrated moderate to prominent (2+ to 3+) positive staining for Ang2 in the cytoplasm. In macrophages involved in ACR of group 2, there was diffuse granular expression of Ang2 in macrophages with intensity ranging from 1+ to 3+. In the group 2, lymphocytes with scant cytoplasm appeared to stain weakly for Ang2 as well.

Conclusions: Using sarcoid granulomas as positive controls for Ang2 expression, the data indicate that Ang2 expression can be highly present in the activated macrophages involving in ACR of human allografts, implying Ang2 as a potential therapeutic target against ACR. In addition, the results from human specimens also support a notion that the RAS may affect some immunologic activities in the kidneys, based on previously in vitro and in vivo experiments.

SA-PO462

Peritubular Capillary Loss in the First Month after Kidney Transplantation Is More Pronounced in Patients with Rejection Compared to Delayed Graft Function Anke Keijbeck,[1] Floortje Steegh,[1] Marielle Gelens,[2] Maarten H. Christiaans,[2] Carine Peutz-Kootstra.[1] [1]*Pathology, MUMC, Maastricht, Netherlands;* [2]*Internal Medicine, MUMC, Maastricht, Netherlands.*

Background: Loss of peritubular capillaries (PTC) in patients with chronic transplant dysfunction is associated with worse outcome. We have shown previously that PTC loss occurs in the first three months after transplantation and precedes renal function decline (Steegh *et al.* JASN 2011). PTC density in the first weeks after transplantation has not yet been studied.

Methods: A cohort of 205 patients, who had a kidney transplantation between August 2003 and December 2009 at the Maastricht University Medical Centre and of whom representative protocol biopsies were taken at transplantation, and 3 and 12 months posttransplant, was analysed. In 102 of these patients an indication biopsy was taken in the first month after transplantation because of delayed graft function (DGF) or rise of creatinine. PTC numbers were studied as described earlier (Steegh *et al.* JASN 2011).

Results: Recipients who underwent an indication biopsy more often received a DCD graft. Consequently the ischemia times were higher than in the recipients who did not have an indication biopsy. Furthermore, patients with an indication biopsy developed more IF/TA 1 year after transplantation (p=0.04). In patients with indication biopsies, a significant loss of PTC density occurs already in the first month after transplantation (Figure 1 panel A) (p<0.01). This PTC loss is more pronounced in patients suffering from rejection than patients with DGF (Figure 1 panel B). However, in the rejection group there is a stabilisation of the PTC loss between 1 and three months, while in the DGF group there is further loss of PTCs (p<0.01).

Conclusions: We found that PTC loss occurs in the first weeks after transplantation. The pattern of PTC loss in the first 3 months after transplantation differs between patients with rejection and DGF. Prevention of microvascular damage during and early after transplantation may be crucial to prevent chronic transplant dysfunction.

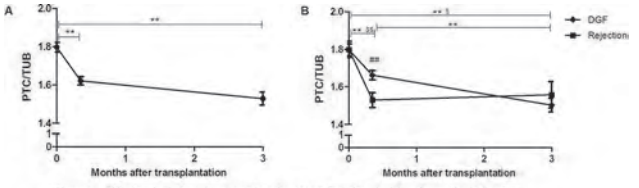

Figure 1. PTC density in first three months after transplantation. A) All patients with indication biopsy. B) Per indication; DGF and rejection.
Results shown as mean ± SEM.
A) ** p<0.01

SA-PO463

Molecular Diagnosis of Rejection in Formalin Fixed Paraffin Embedded Kidney Transplant Biopsies Is Feasible but Extensively Compromises the RNA Konrad S. Famulski, Jeff Reeve, Philip F. Halloran. *University of Alberta, Edmonton, AB, AB, Canada.*

Background: While molecular assessment of transplant biopsies is usually performed on biopsies immediately frozen or stabilized in RNA*later*™, there would be advantages to analyze the FFPE biopsies already prepared for routine histology. We undertook a systematic characterization of microarray gene expression performance with degraded RNA from FFPE compared to intact RNA from RNA*later*™ specimens from the same kidney transplant biopsies.

Methods: We compared selected paired 70 FFPE and RNA*later*™ samples from 67 patients representing T cell-mediated rejection (n=11), antibody-mediated rejection (n=16) and no rejection in the Molecular Microscope system. The RNA performance was evaluated by quality matrices, rejection-associated transcripts (RATs) obtained from each method and diagnostic classifiers were developed.

Results: The FFPE samples yielded less RNA, and showed massive deterioration in RNA quality compared to RNA*later*™, causing false positive and false negative hybridization with the microarray probe sets (Figure 1A, B). Most RNA*later*™-RATs were not detectable in FFPE specimens and vice versa, and their association strength (p-value) with rejection was stronger than FFPE-RATs. RNA*later*™-RATs and FFPE-RATs distributed rejection phenotypes in Principal Component Analysis similarly, only when tested in their originating material (Figure 1C, D). FFPE classifier of rejection performed in FFPE samples with lower accuracy (71%) compared to RNA*later*™ classifier in RNAlater samples (80%).

Conclusions: Molecular system for assessing FFPE samples is possible when RNA*later*™ material is not available, but with disadvantages of smaller RNA yields (potential sampling error) and increase in diagnostic errors. Rejection associated transcript sets or classifiers developed with RNA*later*™ samples cannot be used for FFPE samples: they must be developed in FFPE samples.

SA-PO464

Mapping Potential Errors in Histology by Comparison with Molecular Phenotyping in 1208 Kidney Transplant Biopsies Philip F. Halloran, Jeff Reeve. *University of Alberta, Edmonton, AB, Canada. Group/Team: MMDx-Kidney study group.*

Background: Histologic interpretation of biopsies is empirical because there has been no external standard for comparison. For kidney transplants, the emergence of a centralized molecular diagnostic system for kidney transplant biopsies, the Molecular Microscope™ system (MMDx) (Nature Reviews Nephrology 12:534, 2016) provides an external standard for assessing the accuracy of histologic diagnoses.

Methods: In 1208 prospective indication biopsies, we compared diagnoses of rejection (Banff criteria) assigned by local standard-of-care histology in 13 experienced international centers to the MMDx assessments by microarrays (Clinicaltrials.gov NCT01299168).

Results: MMDx used archetype scores derived from 84 classifier equations to assign diagnoses of antibody-mediated rejection (ABMR) (subclassified early-stage, fully-developed and late-stage) and T cell-mediated rejection (TCMR) (J. Reeve et al. *JCI Insight* 2017 (In Press). Disagreement with histology was 39%: 16% in biopsies with no histologic rejection, but 72% in biopsies with histologic rejection. Discrepancies were particularly common in TCMR, early-stage ABMR, and mixed rejection. Analyzing 161 selected discrepancies in detail (figure 1) revealed 3 classes of discrepancies: errors by pathologists applying complex Banff rules (N=59/161); previously flagged errors in Banff rules e.g. isolated v lesions (N=42/161); or inherent limitations (non-specificity) of histology lesions (N=60/161). For example, tubulitis occurs in many renal inflammatory diseases, including ABMR, and is not exclusive to TCMR.

Conclusions: There is a high rate of errors in standard–of-care histology assessments in experienced centers, particularly in rejection-related conditions. Potential solutions include simplifying and correcting rules; using probabilistic regression equations (AJT 16: 1183, 2016); and incorporating molecular assessments. P F Halloran holds shares in Transcriptome Sciences Inc., a company with an interest in molecular diagnostics. The other authors have declared no conflict of interest exists.

SA-PO465

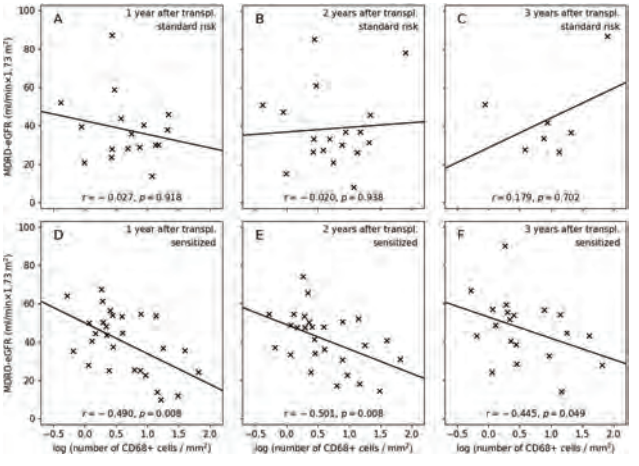
The Predictive Value of the Tissue Expression of CD68 in the Occurrence of Antibody Mediated Rejection, Graft Dysfunction, and Loss in Both Standard-Risk and Sensitized Kidney Transplant Recipients Luis E. Becker, Anne-Sophie Nick, Martin G. Zeier, Christian Morath. *Nephrology, University of Heidelberg, Heidelberg, Germany*.

Background: Tissue analysis of intragraft immunological processes remains an essential, but often underestimated tool as an early prognostic determinant of humoral changes and graft loss in kidney transplantation. This is particularly true for the growing population of sensitized recipients with an increased risk of immunological graft loss.

Methods: We retrospectively studied all eligible 213 allograft biopsies from 104 standard-risk and sensitized patients transplanted between 2006 and 2012, obtained in the first year after transplantation. We compared the effect of macrophage infiltration on long-term-allograft function and death-censored graft loss in both risk populations, analyzing the impact on the development of acute and chronic changes.

Results: Organ recipients from deceased donors had a higher CD68-positive cell infiltration one month after transplantation compared to living donor ones. Strong CD68 positivity in the first month after transplantation was associated with the occurrence of delayed graft function in sensitized patients. High number of CD68 positive cells one month after transplantation was a valid predictor of death censored graft loss in standard-risk patients. In sensitized patients, the number of tissue infiltrating CD68-positive cells in biopsies obtained between day 90 and 360 of transplantation was inversely correlated with the kidney function 1, 2 and 3 years after transplantation. Moreover, each CD68-positive cell increased the risk in 1.024 for the further development of antibody mediated rejection in this collective.

Conclusions: Macrophage tissue infiltration represents a potential additional tool for the analysis of kidney transplant biopsies and may predict worse outcomes especially in sensitized patients, irrespective of the histological diagnosis.



SA-PO466

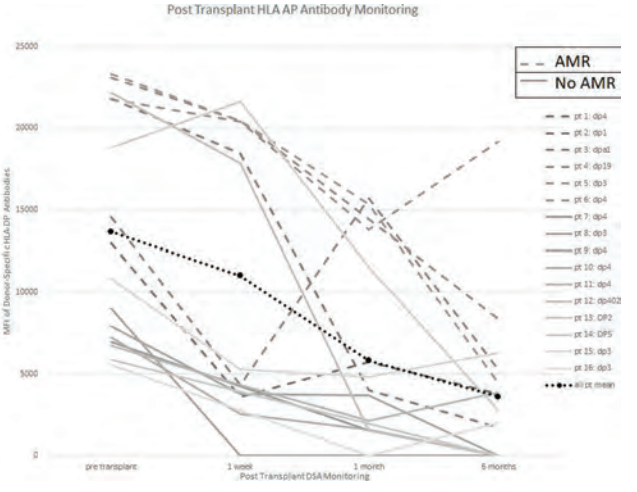
Kidney Transplantation across Strong Donor-Specific HLA-DP Antibodies Patrick Ahearn,[1] Allison B. Webber,[1] Kelly J. Cunniffe,[2] David Gae,[2] Matthew M. Tavakol,[3] Garrett Roll,[3] Gilberto Da Gente,[2] Ryutaro Hirose,[3] John Roberts,[3] Rajalingam Raja.[2] [1]*Nephrology, UCSF, San Francisco, CA;* [2]*Immunogenetics Laboratory, UCSF, San Francisco, CA;* [3]*Surgery, UCSF, San Francisco, CA.*

Background: Patients (pts) awaiting kidney transplant (ktx) with pre-formed donor specific anti-HLA antibodies (DSA) have been subjected to aggressive desensitization or long wait times for a compatible donor. Anti-DP DSA may represent a unique situation amenable to ktx without desensitization. Since 2014, we have done 16 ktx with isolated pre-formed anti-DP DSA with Mean Fluorescence Intensity (MFI) >5000 without desensitization.

Methods: We performed a chart review to assess the incidence of antibody mediated rejection (AMR) and graft survival at 6 months post ktx in this pt population.

Results: 16 pts with DP DSA >5,000 MFI and cPRA ranging from 75-100% underwent ktx. All pts have completed 6 month follow up. Virtual crossmatch was used in all pts; 8 had a positive B cell flow crossmatch. All pts received 2 g/kg IVIG in the immediate post- ktx period. There was a significant decrease in DP DSA MFI (figure). During six month follow up period, 14 pts had allograft biopsy. Six pts were diagnosed with AMR. There was no graft loss. Mean eGFR (MDRD equation) at 6 months was (63.9 ml/min). eGFR for the 10 patients without AMR was 71.5 ml/min versus 43.1 ml/min in those patients with AMR (P=0.02). There was no difference between those with AMR vs no AMR wrt sex (P=0.12), race (P=0.28), cPRA (P= 0.65), or positive flow x match (P=1). Pts with AMR were younger (P=0.03) and displayed a trend toward higher pre-ktx DP DSA MFI compared to those without AMR (16897 vs 11719, P= 0.16).

Conclusions: We have been successfully transplanting pts with high levels of DP DSA (even with positive FXM) without aggressive desensitization. At 6 months, 10 out of 16 patients with anti DP DSA MFI >5000 experienced no AMR and there was no graft loss. Further investigation is needed to identify definitive risk factors for AMR in ktx with anti-DP DSA. Higher MFI pre-ktx may be a risk factor for AMR in this population and should be further investigated.



SA-PO467

An Integrative Approach of Assessing Peritubular Capillaritis Extent and Score in Microvascular Inflammation Is Superior in Predicting Transplant Glomerulopathy and Graft Loss Zeljko Kikic,[1] Farsad A. Eskandary,[1] Gregor Bond,[2] Georg Bohmig,[1] Nicolas Kozakowski.[1] [1]*Medical University Vienna, Vienna, Austria;* [2]*None, Vienna, Austria.*

Background: Banff Classification accepts two histomorphological features as surrogates of HLA Antibody-Antigen interaction on renal endothelium: C4d staining and microvascular inflammation scores (MVI sum score:ptc+g≥2) which are strong predictors of transplant glomerulopathy (TG) and subsequent graft loss. However, increasing evidence questions the ability of the ptc score to solely mirror all diagnostic and prognostic aspects of ptc morphology. More recently we observed a highly significant relationship of diffuse extent of ptc (inflammation of >50% the renal cortex) with graft loss and significantly higher DSA levels suggesting potential inclusion of diffuse ptc as an additional surrogate of antibody-antigen interaction.

Methods: We included 616 patients (Tx 1999-2006) with adequate material for interpretation of MVI and C4d staining in first indication biopsies. Alternatively we assessed MVI with an integrated view of ptc morphology including both results of ptc score and ptc extent: additionally to MVI scores, cases with a ptc score of 1 but diffuse extent of ptc (ptc $1_{diffuse}$, n=25) and no glomerulitis were added as a surrogate of antigen-antibody interaction. Outcomes measured were prediction of any TG in all indication biopsies (n=1619) and death-censored graft loss until 01.01.2017.

Results: Linear C4d in PTCs and MVI scores ≥2 were observed in 11% and 19% of the specimens. TG (cg score>0) in one or more biopsies was found in 13% of patients. The incorporation of ptc $1_{diffuse}$ in addition to the MVI score≥2 significantly increased the

receiver operating characteristic curve for TG [AUC: 0.605 (95%CI 0.53-0.68), p=0.003] compared to the Banff MVI score ≥2 [AUC: 0.571 (95%CI 0.49-0.64), p=0.046] or C4d + [AUC: 0.540 (95%CI 0.47-0.61), p=0.26]. After adjusting for multiple confounders, including C4d or cellular rejection, ptc $1_{diffuse}$ remained independently related to TG [OR 2.13 (CI: 1.22-3.72), p=0.008]. Ptc $1_{diffuse}$ and MVI score ≥2 subjects had similar graft survival (44%) compared to patients with ptc 1_{focal} or without MVI with best overall survival (70% and 68%) after a mean follow-up of 9 years.

Conclusions: An integrated view of ptc morphology including diffuse ptc in assessing MVI is superior for TG and subsequent graft loss risk prediction

SA-PO468

Differential Outcomes in Patients with De Novo Donor-Specific Antibodies (DSA) Compared to Patients with Preformed DSAs Maria Ajaimy,[1] Adriana Colovai,[1] Nicole A. Hayde,[3] Enver Akalin.[2] *[1]Montefiore Medical Center, Bronx, NY; [2]Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, NY; [3]None, Bronx, NY.*

Background: We aimed to investigate the prevalence and dynamic changes of preformed and de novo DSAs after kidney transplantation and its association with clinical outcomes

Methods: This is a prospective study including 664 non-HLA-identical patients who received a kidney transplant between January 2009 and December 2014. Protocol testing for DSA via LABScreen single antigen beads was done before and at 1, 3, 12 months, and then annually. Patients with preformed DSAs received a transplant with anti-thymocyte globulin and IVIG induction treatment if CDC cross-match was negative and MFI value was < 5,000 for HLA-A, B, DR and < 10,000 for HLA-C, DQ and DP.

Results: 108 (16%) patients had preformed DSA before transplantation. During a median 3.8 (2.4-5.3) years of follow-up, de novo DSA developed in 95 patients (17%) at a mean of 20.3±13.3 months after transplantation. Those patients were compared to 461 patients without any DSA. There was no difference between incidences of acute antibody(AMR) or T cell mediated rejection(ACR), chronic rejection, transplant glomerulopathy(TG), serum creatinine levels, graft and patient survival when preformed DSA patients compared to no DSA patients. While there was no significant difference in patient survival, de novo DSA group had lower graft survival (64.1% vs. 92.7%), higher AMR (17.3% vs. 1.6%), ACR (14.1 vs. 4.3%) and TG/CAMR (16.3% vs. 3.3%). Of the 108 patients with preformed DSA, 67 patients lost DSA and 41 showed persistent DSA. Persistent DSA patients had more class II antibodies (56% vs. 36%) and higher MFI values (4608+/-4150 vs. 2325+/-1283). For de novo DSA patients, 49% had persistent DSA, 40% lost their DSA and 11% had their DSA MFI decreased by more than 50%. The mean sum MFI of de novo DSA in the persistent group (9562.8±9409.1) was higher than the patients who lost their DSAs (4063.9±3487) or DSA MFI decreased by more than 50% (8768.7±4854.5).

Conclusions: 17% of our transplant recipients develop de novo DSA after kidney transplantation and associated with significantly higher acute and chronic rejection and lower allograft survival. Low leveL pre-tx DSA does not increase the risk of graft loss in patients who receive thymoglobulin/IVIG induction therapy

SA-PO469

The Natural History of De Novo Donor Specific Antibody (dn DSA): Results from Systemic Monitoring of DSA at ECMC Shirley S. Chang,[1] Cindy S. Yip,[1] Sunil Patel,[2] Aijaz A. Gundroo,[1] Mareena S. Zachariah.[1] *[1]Internal Medicine, SUNY Buffalo, Buffalo, NY; [2]Surgery, SUNY Buffalo, Buffalo, NY.*

Background: Dn DSA development has shown to adversely affect long-term allograft survival, but it's natural history is not well studied.

Methods: Systemic screening DSA post-transplant at ECMC prospectively was performed from Jan 2012 to Sept 2016 on kidney (K) transplant (tx) recipients at 1 month (m), 2 m, 3 m, 6 m, & yearly interval, more frequently if DSA+. Management of dn DSA+ includes Tx K Bx if MFI>3000, and treatment depends on the bx findings. ACR is treated with steroid bolus, acute AMR with steroid bolus±Thymo & Plasmapheresis/IVIG, and those without rejection were treated with IVIG until MFI<1500 (negative).

Results: 49 recipients developed DSA, & 330 did not. Of those with dn DSA, 27% developed HLA I DSA (median onset 40 days post-tx), 88% HLA II DSA (median onset 180 days, p<0.05), 12% had HLA I & II DSA. Causes of dn DSA were due to infection [N=12 (8 had BKN, 1 BK viremia, 1 BK viremia & CMV viremia, 1 recurrent UTI, 1 Hep C], rejection [N=11 (3 with prior ACR, 3 prior AMR, 1 prior ACR+AMR; 4 with current ACR, 1 with current AMR], elevated cPRA/prior Tx [N=9 (4 due to cPRA>80%, 5 with prior K Tx with elevated cPRA), nonadherence (N=8), unknown etiology (N=7), and long CIT >39 hours with DGF (N=2). Patient with dn DSA were grouped into **Transient DSA** (N=19, with 10 had minimal intervention, & 9 had intervention such as PE+IVIG or Rituximab or IVIG alone), **Persistent DSA** (N=30, 7 had MFI<3000, 8 had MFI between 3000-6000, and 15 had MFI>6000). Of those dn DSA who had K Bx (N=48), 36% developed concomitant rejections at initial dn DSA presence; 3 with borderline, 4 Banff 1A, 3 Banff 1B, 3 Banff 2B, and 3 with acute AMR rejections. None of the recipients with transient DSA lost their graft. There was one graft failure in the persistent dn DSA with MFI<3000, 3 graft failure in the MFI 3000-6000 range, & 5 graft failures including 2 patient death in the MFI>6000 group.

Conclusions: 12.9 % K Tx recipients develop dn DSA, with HLA I occurs earlier than HLA II. Causes for dn DSA include infection (25%), rejection (22 %, with 12% occurs after prior rejection episodes, & 10% with active rejection concomitantly), highly sensitization (18%), nonadherence (16%), unknown cause (14%), & prolonged CIT/DGF (4%). Recipients with persistent DSA especially Class II and higher MFI levels are risk factors for graft failure.

De Novo Donor Specific Antibody (dnDSA) and Biopsy Proven Acute Rejection (BPAR) Are Associated with Higher Intrapatient Variability (IPV) in Tacrolimus Trough Levels Following Renal Transplant Petra M. Goldsmith. *Royal Liverpool Hospital, Lymm, United Kingdom. Group/ Team: UK Transplant Audit Collaborative.*

Background: High IPV in Tacrolimus trough levels has been associated with poorer kidney transplant outcomes, including the occurrence of BPAR. However, there is a paucity of information in the published literature about any association between high IPV and the development of dnDSA.

Methods: We performed a single centre retrospective cohort study with the hypothesis that patients identified as having BPAR or dnDSA at any timepoint would have a greater mean IPV than those who did not. Patients transplanted in our centre between 2009-2014 and receiving standard preparation Tacrolimus based immunosuppression were included. Patients receiving other primary immunosuppression, who were in receipt of organs other than kidneys and who did not have a functioning transplant at 2 years were excluded. One hundred and seventy one patients were identified with IPV data collected at 2 predetermined time points: 6-12 months post-transplant (T1) and the most recent 12 months (T2).

Results: IPV values were compared using Mann Whitney U tests between patients developing a) BPAR and b) dnDSA with those who did not, at both T1 and T2. The results are shown in table 1. There is a clear association between BPAR and high IPV at T1 (p=0.01) which reverses at T2 but fails to reach statistical significance. For dnDSA, we observe a higher IPV for both T1 and T2 although in both cases it is not statistically significant.

Conclusions: As most episodes of BPAR occur early post-transplant, it is possible that the observed reversal in IPV at T2 reflects more precise monitoring and control of Tacrolimus exposure in these patients following rejection. In respect of the observation of higher IPV at both T1 and T2 for dnDSA, the small sample size who developed antibodies may have contributed to the failure to reach significance and it is anticipated that this analysis will be expanded to a multicentre cohort in the future.

Table 1: Mann Whitney U Test to compare BPAR and DnDSA

	Mean Rank T1	T1 P Value	Mean Rank T2	T2 P Value
BPAR (N=24) No BPAR (N=147)	108.3 82.4	0.01	71 88.5	0.05
DnDSA (N=16) No dnDSA (N=155)	84.6 99.3	0.13	84.8 97.2	0.17

SA-PO471

Anti-HLA Antibody-Mediated Rejection in ABO-Incompatible (ABOI) Living Donor Kidney Transplant (KT) Patients Hyuk yong Kwon, Jin M. Kong. *Nephrology, BHS-Hanseo hospital, Busan, Republic of Korea.*

Background: Antibody-mediated rejection(AMR) in ABOi KT patients can either be due to donor-specific antiHLA antibody(DSA) or anti-blood group antibody(anti-ABO). The relative frequency and possible differential clinical features of these two types of AMR in ABOi KT patients has not been investigated.

Methods: Among 91 ABOi KT patients between 2007 and 2016 in our center, 11(12.1%) patients developed clinical acute AMR. Since there is no histologic distinction between DSA- and anti-ABO-induced AMR, we assumed the causative antibody in each case based on anti-ABO level and DSA, measured in serum collected at the time of AMR. DSA was determined by luminex single antigen beads assay.

Results: Of these 11 cases of AMR, 5 were attributable to anti-ABO since anti-ABO titer was 16 or higher and DSA was undetectable at the time of rejection. Three cases were attributable to DSA since DSA was detectable and anti-ABO was low (≤ 8) during rejection. Another 2 cases with low (2) anti-ABO titer and undetectable DSA were assumed to be DSA-induced, since this low level of anti-ABO is unlikely to cause rejection and DSA can be undetectable in DSA-induced AMR by adsorption of Ab on graft, as frequently seen in ABO-compatible patient. One case with anti-ABO 8 and no detectable DSA was regarded as undetermined. The onset of AMR was within 2 weeks in all cases and comparable between two types of AMR. Initial anti-ABO titer was also not statistically different, median(range) 256(64-4096) in ABO-AMR and 64(16-256) in DSA-AMR. All the 5 patients with ABO-AMR had negative PRA before KT, whereas 4 of 5 patients with DSA-AMR had positive PRA before KT, and one DSA-AMR patient had persistent DSA before KT and at the time of AMR. All the AMR were recovered by treatment and no graft was lost to rejection.

Conclusions: We conclude that a significant proportion of AMR in ABOi KT are caused by DSA, and clinical features and possible differential therapeutic approach of these 2 types of AMR needs to be explored by further studies.

SA-PO472

Altered Kynurinine 3-Monooxidase May Mediate Rejection and Tubular Cell Injury in Pig Kidney Transplants Youli Wang,[1] Xuexiu Fang,[1] Daniel T. Kleven,[1] Chak-Sum Ho,[2] N. Stanley Nahman,[3,4] Todd D. Merchen.[3] *[1]Augusta University, Evans, Colombia; [2]Gift of Life Michigan, Ann Arbor, MI; [3]Medical College of Georgia at Augusta University, Augusta, GA; [4]Norwood VAMC, Augusta, GA.*

Background: The indoleamine 2,3-dioxygenase (IDO) transprotein prevents rejection (RJX) in rodent solid organ transplantation, including kidney transplant (KTx). Thus, the increase in IDO activity in RJX seen in our pig KTx model (JASN 27:723A) and in KTx patients (KI 77:60) is paradoxical. Kynurinine (KYN) 3-monooxidase (KMO) is a downstream enzyme of IDO generating 3-OH-KYN which is both pro-tolerant and cytoprotective. On this basis, we theorized that RJX would blunt KMO activity from rejecting pig kidneys, and in particular, silence tubular epithelial cell (TEC) KMO expression.

Methods: Pigs underwent allogeneic (Allo) (n=9) or auto renal transplants (Auto) (n=10 and as a control for ischemia), as we described (Trans Immunol, in press). For Allo, pairs of mismatched pigs were operated simultaneously with L kidneys exchanged. All Autos were also the L kidney. All pigs then had right nephrectomy (control tissue = RNx) prior to closure, and left Nx at sacrifice after 72 hrs. No immunosuppression was used. In all kidneys, RJX was assessed using Banff criteria; IDO and KMO gene expressions quantitated with qPCR; tissue IDO activity measured by HPLC, and tissue KMO localized and quantitated with immunohistochemistry (IHC).

Results: Postop creatinine was higher in Allo vs Auto (8.12±1.50 vs 2.83±0.60 mg/dL respectively, P=0.006). Auto had mild tubular injury, and no changes in IDO mRNA or activity vs RNx (n=16). Allo showed acute rejection (Banff 1 to 3), with a 6 fold (X) increase in allograft IDO mRNA, and 19.5X increase in tissue IDO activity vs Auto. KMO showed a 2X reduction in Auto, and 5X decrease in Allo RJX kidneys. By IHC KMO activity was constituent in Auto and RNx TEC, but silent in TEC from rejecting Allo.

Conclusions: KMO gene activity and TEC expression are blunted in KTx rejection. KMO may be an important downstream mediator of IDO activity and function in a protolerant and cytoprotective capacity. This may help explain the paradoxical increase in IDO activity seen in KTx rejection.

SA-PO473

Association of HLA-DR and DQ Mismatches and Acute Rejection in Living Donor Kidney Transplant Recipients Daniel Onete,[3] Qingyong Xu,[1] Rita Suri,[2] Lakshman Gunaratnam.[1] *[1]London Health Sciences Centre, Oakville, ON, Canada; [2]Université de Montréal, Montreal, QC, Canada; [3]Physiology and Pharmacology, Western University of Canada, London, ON, Canada.*

Background: Previous studies show that HLA incompatibility is associated with greater risk of graft failure in deceased-donor kidney transplant patients. However, whether HLA-mismatches are important in low-risk recipients of living donor kidneys in the era of modern immunosuppression is unclear. Given that de novo, donor specific antibodies against Class II HLA (DQ or DR) are associated with poor long-term outcomes in deceased donor transplant recipients, we hypothesized that having 3-4 (vs. 0-2) HLA DQ/DR mismatches would be associated with acute rejection in low-risk, living donor kidney transplant recipients.

Methods: We conducted a retrospective cohort study of all cross-match negative, transplant-naive, living donor kidney transplant recipients at our center from 2006-2016. Electronic charts were reviewed for demographics, comorbidities, HLA genotype and outcomes. HLA genotyping was performed using molecular typing. The primary outcome was acute rejection within 1-year post-transplant, and was defined as either: definitive biopsy-proven T-cell mediated rejection (TCMR) (Banff criteria), or as borderline TCMR on biopsy that was treated with pulse steroids and/or anti-thymocyte globulin. The secondary outcome was serum creatinine at 1 year post-transplant. Outcomes were compared between patients with 0-2 vs. 3-4 HLA-DR/DQ mismatches.

Results: Of the 178 recipients transplanted with living donor kidneys from 2006-2016, 6 were excluded due to incomplete follow-up data. In total, 124 (72%) and 48 (28%) received 0–2 and 3–4 HLA-DR/DQ mismatched kidneys, respectively. We observed 27 definitive rejections and 25 treated borderline rejections within 1-year post-transplant. Patients with 3–4 HLA-DQ/DR mismatched kidneys had a statistically significant greater risk of acute rejection (odds ratio = 3.43 [95% CI 1.69-6.94]; p=0.0008). This association persisted when we limited the primary outcome to definitive rejection (odds ratio = 3.39 [95% CI 1.45-7.89]; p=0.0053). There was no significant difference between groups in the mean 1-year serum creatinine (122.4 ± 5.889 vs. 117.0 ± 4.035; p=0.59).

Conclusions: In this single center study, we found that greater HLA-DR and DQ mismatches were associated with increased risk of acute rejection at 1-year after living donor kidney transplant.

Highly Sensitized Patients at Miami Transplant Institute: An Update Camilo Cortesi,[2] Mai Sedki,[2] Giselle Guerra,[3] Gabriel Contreras,[1] Adela D. Mattiazzi.[2] *[1]University of Miami, Miami, FL; [2]University of Miami/Jackson Memorial Hospital, Miami, FL; [3]University of Miami/Miller School of Medicine, Miami, FL.*

Background: Highly sensitized (HS) patients are defined as transplant candidates sensitized against human leukocyte antigen (HLA) antibodies with a panel reactive antibody (PRA) greater than 80%. This has been a major obstacle to kidney transplantation (KT). Major causes are blood transfusions, pregnancy and prior transplants. HS patients have an increased risk of rejection, worse graft survival, and less annual transplant rates. There are different strategies available for desensitization including intravenous immunoglobulin (IVIG), plasmapheresis (PE), and Rituximab (R). We provide an update of our experience comparing patients undergoing desensitization.

Methods: This is a retrospective analysis of 50 HS KT recipients categorized into 2 groups based on induction immunosuppression received at transplantation. The control group (CG), 12 HS KTs, received standard induction. The Rituximab group (RG), 38 HS KTs, received standard induction as well as R ± IVIg ± PE based on the immunological risk stratification model. The primary outcomes were defined as rejection rate, allograft failure, and death. Secondary outcomes assessed graft function via serum creatinine at various times post-transplant.

Results: The number of HLA mismatches was not statistically different between the 2 groups. In the CG, 75% had prior transplants compared to 53% in the RG. Mean waiting time for KT was 7.6 years and 5.4 years for the CG and RG, respectively (p=0.007). The cumulative proportion of patients who remained free of death or allograft failure was significantly higher in the RG (87%) compared to the CG (60%)(p=0.039). The probability of rejection was similar in both groups (p=0.36). The mean serum creatinine at 1 year was 1.35 ± 0.54 and 1.36 ± 0.64 mg/dL for the CG and RG, respectively.

Conclusions: Desensitization strategies are fundamental for the management of the HS population. Our study confirms that the addition of R continues to improve allograft survival and decrease death rates.

Magnitude of Pre-Biopsy Decline in Renal Function and Its Association with Allograft Rejection Santhi Voora, Patrick Ahearn, Matthew M. Tavakol, Kirsten L. Johansen, Elaine Ku. *UCSF, San Francisco, CA.*

Background: Acute rejection is a significant cause of morbidity, and transplant biopsy remains the gold standard for the diagnosis of rejection. Guidelines published by KDIGO recommend biopsy for "persistent, unexplained increase in serum creatinine." To our knowledge there have been few studies defining the magnitude of decline in renal function that should trigger a biopsy to rule out rejection.

Methods: We performed a retrospective analysis of patients at a single center who underwent diagnostic transplant biopsy (excluding surveillance biopsies) between 2006-2016 at least three months post-transplant. We evaluated for association between pre-biopsy decline in renal function (mean of renal function measured between 6 months prior to biopsy and day of biopsy) and pathologic findings of rejection using logistic regression models (adjusted for age, race, sex, diabetes, donor type and transplant year). Absolute rise in serum creatinine and percent change in estimated glomerular filtration rate (eGFR) by CKD-EPI equation were examined as predictors of the outcome of rejection (cellular or antibody-mediated).

Results: 1,224 biopsies were included for analysis. Mean age was 46.3 years. 58.3% were men, and 18% were black. Overall, 53.5% of biopsies demonstrated evidence of rejection. Declines in eGFR of ≥20% were associated with higher odds of rejection in both unadjusted and adjusted analyses compared to a <5% decline in eGFR [Table]. Rises in absolute serum creatinine by ≥0.3 mg/dL also corresponded with a higher risk of rejection compared to rises in creatinine by <0.3 mg/dL.

Conclusions: In this single-center study, decline in eGFR ≥20% or rise in serum creatinine by ≥0.3 mg/dL were associated with higher risk of rejection. Changes in renal function of this magnitude may warrant prompt arrangement of biopsy given the high risk of rejection.

Funding: NIDDK Support, Other NIH Support - NHILB

Ultrasound and CT Guided Kidney Transplant Biopsies: Evaluating Complications Camilo Cortesi,[4] Karla G. Carias martinez,[1] Mai Sedki,[4] Giselle Guerra,[5] David Roth,[3] Adela D. Mattiazzi.[2] *[1]Jackson Health System, Miami, FL; [2]None, Miami, FL; [3]University of Miami Miller School of Medicine, Miami, FL; [4]University of Miami/Jackson Memorial Hospital, Miami, FL; [5]University of Miami/Miller School of Medicine, Miami, FL.*

Background: Kidney transplant (KT) rejection is one of the main indications for KT biopsy (KTb). The ultrasound (US)-guided approach is the preferred method however the computed tomography (CT)-guided approach offers an excellent alternative when the yield is low. We sought to evaluate the incidence of complications in both techniques.

Methods: We identified 646 KTb performed to rule out rejection, 32 of those were CT-guided and the rest US-guided. Retrospective chart review was performed. Complications were divided into moderate and severe where moderate complications included: hematoma, hydronephrosis, arteriovenous fistula, hemoglobin drop >2 g/dL, and need for blood transfusions; severe included the former events associated with a kidney dysfunction, Page kidney or the need for nephrectomy. Descriptive analysis was used for the CT-KTb and a logistic regression was conducted for the US-KTb.

Results: The logistic regression was statistically significant, indicating that the predictors as a set did reliably predict complication occurrence (chi square=51.044, p<0.05, df=34). Prediction success overall was 91.2%. The Wald criterion demonstrated that blood pressure control, BUN, and use of anticoagulants prior to biopsy had a statistically significant impact in predicting complications (p=0.015, p=0.001, p=0.027, respectively). Patients on anticoagulants prior to biopsy were 4 times as likely to have complications (odds ratio 4.167). In CT-KTb only one patient had complications. This patient had uncontrolled blood pressure, BMI > 35, platelet count of 93K/uL and INR was 1.21 at the time of biopsy.

Conclusions: Our data shows that uncontrolled blood pressure, defined as >160/90, uremia, and anticoagulant use were the main predictors of negative outcomes. The presence of these risk factors, particularly in combination, could be of great value in weighing the necessity of a procedure. Additionally, CT-KTb was shown to be a safe alternative for obtaining renal tissue. We highlight the need to achieve adequate control of blood pressure prior to KTb.

Evaluation of C1q status and Titre of Donor Specific Antibodies as Predictors of Allograft Survival Osama Attia,[2,1] Emma White,[3] Delordson Kallon,[3] Arun Gupta,[3] Neil Ashman,[1] Muhammad M. Yaqoob.[4,1] *[1]renal unit, Royal London hospital, London, United Kingdom; [2]Renal Unit, Zagazig university hospital, Zagazig, Egypt; [3]Royal London Hospital, London, United Kingdom; [4]William Harvey Research Institute, London, United Kingdom.*

Background: Donor-specific antibodies (DSA) either developed as de-novo or formed before renal transplantation are independent predictors of allograft loss. However, it is unknown if DSA and DSA C1q status post transplantation can independently predict allograft loss. Serologically emergence of de-novo or rising titres of preformed DSA is used as surrogate markers of impending graft dysfunction and rejection. However sensitivity and specificity of this approach is not robust enough to escalate immunosuppression. However recent evidence suggests that complement binding DSA may identify clinically relevant anti-allograft antibodies

Methods: 600 patients received either a deceased or live donor kidney transplant between January 2008 and June 2015 after negative CDC cross match. All patients received standard immunosuppression as per departmental protocol. 42 patients with either persistent or de-novo DSA between 3-28 months post transplantation were studied retrospectively. C1q fixing DSA were studied using single Ag luminex technique with MFI more than 5000 was detected as positive.

Results: 19 patients were positive for C1q status. 60% graft developed rejection and 43% of the grafts were lost in the entire cohort predominantly within the two years of positivity. C1q positive status compared to negative did not differentiate between rate and type of rejection (68% vs 52% p=1.14). Rejection within three months of C1q positivity were significantly higher (63% vs 33% p=0.034). However, significantly greater grafts were lost with C1q positivity compared to C1q negative (63% vs 35% p < 0.05) despite receiving similar antirejection therapy.

Conclusions: We conclude that C1q binding DSA post transplantation is associated with rejection if tested within three months of biopsy for graft dysfunction. More importantly It is also associated with poor graft survival. C1q status may help clinician in the identification of patients who may be at high of losing graft following rejection and help in optimization of immusuppression therapy.

Genome-Wide Association Meta-Analysis for Acute Rejection of Kidney Transplants Ajay K. Israni,[3,11] Pamala A. Jacobson,[11] Weihua Guan,[11] Casey R. Dorr,[4,11] Martin H. De Borst,[7] Caragh P. Stapleton,[5] Paul J. Phelan,[15] Peter J. Conlon,[1] Kelly A. Birdwell,[13] Stephan J. Bakker,[7] Gianpiero Cavalleri,[5] William S. Oetting,[11] David P. Schladt,[4] Jessica Van setten,[6] Pui-Yan Kwok,[2] Michael Eikmans,[14] Harold Snieder,[7] Baolin Wu,[11] Laia Bassaganyas,[9] Jianxin Yang,[14] Peter J. Van der most,[10] Folkert W. Asselbergs,[8] Brendan Keating.[12] *[1]Beaumont Hospital, Dublin 9, Co Dublin, Ireland; [2]UCSF, San Francisco, CA; [3]Hennepin County Medical Center, Minneapolis, MN; [4]Minneapolis Medical Research Foundation, Minneapolis, MN; [5]RCSI, Dublin, Italy; [6]UMC Utrecht, Utrecht, Netherlands; [7]University Medical Center Groningen, Roden, Netherlands; [8]University Medical Center Utrecht, Utrecht, Netherlands; [9]University of California, San Francisco, San Francisco, CA; [10]University of Groningen, Groningen, Netherlands; [11]University of Minnesota, Minneapolis, MN; [12]University of Pennsylvania, Philadelphia, PA; [13]Vanderbilt University, Nashville, TN; [14]Leiden University, Leiden, Netherlands; [15]NHS Lothien, Edinburgh, United Kingdom. Group/Team: Kidney Group of iGeneTRAiN.*

Background: Acute rejection (AR) is associated with worse kidney allograft survival.
Methods: We performed a genome-wide association study (GWAS) meta-analysis of AR in recipients and donors after kidney transplantation using the Affymetrix exome plus chip. AR was defined by treating physician at anytime post-transplant. Genotype imputation was carried out based on the 1000 Genomes project and Genomes of The Netherlands reference datasets. The analysis was adjusted for age, sex, living versus deceased donors, and population stratification using principal components.

Results: The interim meta-analysis of 5 GWAS cohorts participating in iGeneTRAiN included 4,437 Caucasian kidney transplant recipients with 999 (23%) AR events (Table 1). Twenty-five recipient single-nucleotide polymorphisms (SNPs) reached GWAS significance ($p \leq 1E-7$) for their association with AR. The top four recipient SNPs with strongest AR association include two located in introns of *MANSC1* rs12578158 (p =1.53E-9) and rs12580693 (p = 1.75E-9). Another is located 7.5 kb upstream of *UGT2B10* rs294768 (p = 1.24E-8). The fourth SNP is located in the 3'UTR of *NUB1* rs544144806 (p = 4.81E-8). Furthermore, 14 of the 25 top recipient SNPs are located in or near *UGT2B10*, including rs2942857, which is an mRNA splice acceptor. The donor analysis identified 66 SNPs reaching GWAS significance for their association with AR. The top two of these SNPs are rs8180830 (p = 2.90E-9) and rs77439859 (p = 3.69E-9) which are 79 kb and 58 kb upstream, respectively, of *HERPUD2*. Another donor SNP associated with AR is rs79865478 (p = 4.62E-8), located in an intron of *SOX5*.

Conclusions: We identified several novel susceptibility loci associated with AR, which can be validated by independent cohorts.

Bortezomib in Late Antibody-Mediated Kidney Transplant Rejection – A Double-Blind Randomized Placebo-Controlled Trial (BORTEJECT Study) Farsad A. Eskandary,[1] Heinz Regele,[2] Gregor Bond,[1] Nicolas Kozakowski,[2] Markus Wahrmann,[1] Luis G. Hidalgo,[5] Helmuth Haslacher,[4] Christopher Kaltenecker,[1] Bernadette Aretin,[6] Rainer Oberbauer,[1] Jeff Reeve,[3] Philip F. Halloran,[3] Georg Bohmig.[1] *[1]Nephrology and Dialysis, Medical University Vienna, Vienna, Austria; [2]Clinical Pathology, Medical University Vienna, Vienna, Austria; [3]Alberta Transplant Applied Genomics Centre, University of Alberta, Edmonton, AB, Canada; [4]Laboratory Medicine, Medical University Vienna, Vienna, Austria; [5]Laboratory Medicine and Pathology, University of Alberta, Edmonton, AB, Canada; [6]Pharmacy, AKH-Wien, Vienna, Austria.*

Background: Antibody-mediated rejection (ABMR) is a leading cause of long-term kidney transplant loss. Optimal treatment of late ABMR is unclear, and our current knowledge is mostly based on uncontrolled studies.

Methods: In this randomized, double-blind, placebo-controlled, single-center phase 2 trial (NCT01873157), we investigated whether two cycles of the proteasome inhibitor bortezomib (each cycle: 1.3 mg/m2 on days 1, 4, 8 and 11) are able to halt the progression of late ABMR, using eGFR slope (Over 0, 3, 6, 12, 18 and 24 months) as primary endpoint (44 patients; 1:1 randomization). Secondary outcomes were mGFR at 24 months, donor-specific antibody (DSA) course and morphological/molecular results of 24-month follow-up biopsies.

Results: Upon systematic cross-sectional HLA antibody screening of 741 recipients [inclusion criteria: age >18a, eGFR >20 ml/min/1.73 m2 at ≥180 days post-transplantation] we identified 111 recipients with DSA. Forty-four DSA+ recipients with morphological evidence of ABMR were included in the trial. Twenty-one patients were allocated to receive bortezomib, and 23 placebo. Despite a trend in reduction of DSA levels, bortezomib neither affected eGFR decline (bortezomib vs. placebo: -4.6 ± 2.7 vs. -4.8 ± 2.5 ml/min/1.73 m2/year), nor median mGFR at 24 months [33mL (IQR: 28-40) vs. 43mL (26-51), p=0.2]. There were also no differences regarding two-year overall graft survival (81% vs. 96%, p=0.1) and morphological (ABMR category, g+ptc score, IFTA score, C4d) and molecular results (Molecular-ABMR score, MMDx) of 24-month follow-up biopsies. Bortezomib treatment was associated with a higher rate of GI adverse events (diarrhea: 67% vs. 22%, p=0.005) and thrombo- and leukocytopenia.

Conclusions: The BORTEJECT trial demonstrates that proteasome inhibition does not ameliorate the two-year course of late ABMR. Our results underscore the need for randomized trials to dissect the efficiency and safety of new treatment strategies in this context.

Rituximab in Antibody Mediated Rejection: Delayed Benefit for Graft Survival? Sandesh Parajuli,[3] Didier A. Mandelbrot,[2] Brenda L. Muth,[4] Maha A. Mohamed,[6] Robert R. Redfield,[4] Weixiong Zhong,[5] Brad C. Astor,[4] Arjang Djamali.[1] *[1]School of Medicine and Public Health, Madison, WI; [2]U of Wisconsin Hospital, Madison, WI; [3]UW Health, Middleton, WI; [4]University of Wisconsin, Madison, WI; [5]University of Wisconsin Madison, Madison, WI; [6]University of Wisconsin School of Medicine and Public Health, Madison, WI.*

Background: There is limited information on the role of monitoring biopsies and treatment strategies in late antibody mediated rejection (ABMR) after kidney transplantation.

Methods: Seventy-eight patients diagnosed with late ABMR were treated with standard of care (SOC) steroids/IVIG (n=38) ± rituximab (n=40). All patients underwent a follow-up biopsy and DSA monitoring within 3-12 weeks. Patients were followed for 15.9 ± 9.6 months.

Results: Both treatment strategies were associated with a significant decline in DSA, microcirculation inflammation (ptc+g), and C4d Banff scores. In univariate regression analyses, rituximab, eGFR, Banff i, t, v, and chronicity (ci+ct+cv+cg) scores on the first biopsy, and eGFR and Banff v score on the follow-up biopsy were associated with graft loss. Mulltivariate analyses retained only rituximab (HR 0.23, 95% CI 0.06 to 0.84, p=0.03) and eGFR at follow-up biopsy (0.84, 95% CI 0.76 to 0.92, p<0.001) as significant predictors of graft loss. Kaplan-Meier analyses demonstrated that the benefit associated with rituximab was apparent after one year (15% vs. 32% graft loss, p=0.01) (Figure 1).

Conclusions: In conclusion, treatment of late ABMR with steroids/IVIG + rituximab was effective in reducing DSA, microcirculation inflammation, and graft loss. Follow-up biopsies could be considered in the management of acute rejection to monitor the effect of therapy.

Figure 1. Rituximab was associated with improved graft survival

Hospitalization Trends for CMV Disease in Kidney Transplant Recipients in the United States, 2004–2014 Neetika Garg,[7] Nilay Kumar,[7] Sandesh Parajuli,[4] Tripti Singh,[1] Fahad Aziz,[5] Maha A. Mohamed,[6] Brenda L. Muth,[5] Arjang Djamali,[2] Didier A. Mandelbrot.[3] *[1]None, Madison, WI; [2]School of Medicine and Public Health, Madison, WI; [3]U of Wisconsin Hospital, Madison, WI; [4]UW Health, Middleton, WI; [5]University of Wisconsin, Madison, WI; [6]University of Wisconsin School of Medicine and Public Health, Madison, WI; [7]University of Wisconsin, Madison, Madison, WI.*

Background: CMV infection is a frequent complication of kidney transplantation, especially with increasing use of more aggressive immunosuppressive regimens. How the burden of inpatient hospitalization related to this diagnosis has changed over time in the United States is not known.

Methods: We used the National Inpatient Sample 2004 – 2014 to identify hospitalizations with primary or secondary diagnosis of CMV disease (ICD-9 code: 078.5) in the setting of known history of kidney transplantation. Survey analysis techniques were used to generate national estimates. Data regarding prevalent kidney transplant recipient population was obtained from OPTN/SRTR. Linear and logistic regressions were used to test trends in hospitalization rate, acute kidney injury (AKI), dialysis-requiring AKI, length of stay (LOS) and cost.

Results: 2,126 hospitalizations over the 11-year study period were representative of 10,215 hospitalizations for CMV disease nationally. Mean age was 52 years; 44.3% were women. Rate of hospitalization remained stable during the study period (6.3 to 5.3 per thousand prevalent recipient population, p-trend=0.75). However, a trend towards increasing in-hospital mortality (1.8% to 2.9%, p-trend=0.07) along with significant increases in rates of AKI, dialysis-requiring AKI, LOS and cost were noted (Table 1). This was accompanied by an increase in comorbidity burden as measured by Mean Charlson Comorbidity Index (0.80 to 2.02, p<0.001) during the study period.

Conclusions: Our study findings may reflect a shift towards outpatient management of CMV disease with hospitalization only for the sickest patients in the United States. Patient outcomes were worse and resource utilization (duration and cost of hospitalization) was higher for those admitted in more recent years.

Table 1

	2004	2005	2006	2007	2008	2009	2010	2011	2012	2013	2014	p-trend

SA-PO482

Long-Term Outcomes of Valganciclovir versus Valacyclovir for Cytomegalovirus Prophylaxis in Renal Transplantation: A Parallel Group, Open-Label Randomized Controlled Trial Tomas Reischig,[1] Martin Kacer,[1] Petra Hruba,[2] Daniel Lysak,[1] Pavel Jindra,[1] Ondrej Hes,[1] Mirko Bouda.[1] *[1]Charles Univ. Medical School and Teaching Hospital, Pilsen, Czech Republic; [2]Institute for Clinical and Experimental Medicine, Prague, Czech Republic.*

Background: Both valganciclovir and high-dose valacyclovir are recommended for cytomegalovirus (CMV) prophylaxis after renal transplantation. Less early acute rejection was observed with valganciclovir, however long-term comparison is lacking.

Methods: In a randomized, open-label, single-center trial, renal transplant recipients (recipient or donor CMV seropositive) were randomly allocated (1:1) to 3-month prophylaxis with valganciclovir (900mg daily) or valacyclovir (2g four times daily). The

primary outcome was moderate to severe interstitial fibrosis and tubular atrophy (IFTA) assessed by protocol biopsy at 3 years. Analysis was by intention-to-treat.

Results: A total of 119 patients were assigned to valganciclovir (n=60) or valacyclovir prophylaxis (n=59). At 3 years, the incidence of CMV DNAemia (36% vs 42%, P=0.272) and CMV disease (9% vs 2%, P=0.199) were comparable in both groups. Among the 101 patients with a protocol biopsy specimen available, 11 (22%) of the 51 patients in the valganciclovir group and 17 (34%) of the 50 patients in the valacyclovir group had moderate to severe IFTA. The risk of moderate to severe IFTA was significantly lower with valganciclovir after adjusting for baseline recipient and donor characteristics (adjusted odds ratio [aOR], 0.22; 95% confidence interval [CI], 0.07–0.70; P=0.011). A trend toward less acute rejection (24% vs 32%, adjusted hazard ratio [aHR], 0.53; 95% CI, 0.25-1.10; P=0.087) and more polyoma BK virus viremia (42% vs 26%; aHR, 1.91; 95% CI, 0.95–3.82; P=0.069) at 3 years was observed in the valganciclovir group. 4-year patient and graft survival was not significantly different between groups.

Conclusions: Valganciclovir prophylaxis compared to high-dose valacyclovir is associated with reduced risk of moderate to severe IFTA in late protocol biopsies in renal transplant recipients. (Trial registered at Australian New Zealand Clinical Trials Registry: ACTRN1260000016033)

Use of Body Surface Area Corrected GFR results in Inappropriate Valganciclovir Dosing in Kidney Transplant Recipients Rohan S. Paul, Chethan M. Puttarajappa, Sundaram Hariharan. *University of Pittsburgh Medical Center, Starzl Transplant Institute, Pittsburgh, PA.*

Background: Clinicians generally use the MDRD or CKD-EPI equations to gauge renal function, which normalize GFR to a body surface area (BSA) of 1.73 m^2. We hypothesized that since absolute GFR is rarely measured and used, prophylactic valganciclovir is being dosed inappropriately in certain renal transplant recipients which may predispose to leukopenia and/or CMV infection.

Methods: This cross-sectional study included 225 renal transplant recipients from UPMC who were transplanted from January 1, 2013 to December 31, 2015. MDRD reported GFR was converted to absolute GFR. Patients were categorized into BSA tertiles (low BSA < 1.73 m^2; middle BSA: 1.73-2.09 m^2; high BSA > 2.09 m^2). The appropriateness of valganciclovir dose among these groups at three months post-transplantation was determined and compared using Chi-squared test. The point prevalence of leukopenia (WBC < 3500 × $10^3/mm^3$) among the dosing categories was analyzed using One-way ANOVA. The incidence of PCR confirmed CMV infection was compared using Chi-squared test.

Results: The study population consisted of 138 (61%) males and 87 (39%) females. Analysis of valganciclovir dosing across the BSA tertiles found no significant difference based on normalized GFR (P = 0.811), but a significant difference based on absolute GFR, with a trend towards overdosing with low BSA and underdosing with high BSA (P < 0.001). There was no difference in the point prevalence of leukopenia across the dosing categories (P = 0.819). There was no difference in the incidence of CMV infection within 100 days post-transplantion as there were zero infections in this period. There was a signficant difference in the incidence of CMV infection 100-400 days post-transplantation with a higher rate seen with higher BSA (P = 0.0468).

Conclusions: We conclude that normalized GFR leads to inappopriate valganciclovir dosing in a large subset of kidney transplant recipients. This did not translate into a higher point prevalence of leukopenia in those receiving supratherapeutic doses. However there was a higher incidence CMV infection in the 100-400 days post-transplantation in patients with a higher BSA. The observed valganciclovir underdosing in this BSA group is suspected to be at play. We therefore propose that absolute GFR be routinely used for valganciclovir dosing in kidney transplant recipients.

SA-PO484

Significantly Less CMV- and BKV-Events with Everolimus-Based versus Tacrolimus-MPA Regimen in De Novo Renal Transplant Recipients: 12 Months Data on Infections from the Athena Study Ingeborg A. Hauser,[2] Claudia Sommerer,[11] Barbara M. Suwelack,[4] Duska Dragun,[10] Peter Schenker,[5] Oliver Witzke,[8] Christian Hugo,[12] Nassim Kamar,[3] Pierre Merville,[7] Martina Junge,[6] Friedrich Thaiss,[9] Björn Nashan.[1] *[1]Bundesärztekammer, Hamburg, Germany; [2]University Clinic Frankfurt (UKF), Frankfurt Main, Germany; [3]Toulouse University Hospital, Toulouse, France; [4]Muenster, Germany; [5]Ruhr-University Bochum, Bochum, Germany; [6]Novartis Pharma GmbH Germany, Nuremberg, Germany; [7]PELLEGRIN HOSPITAL, Bordeaux, France; [8]University Duisburg-Essen, Essen, Germany; [9]University Hospital, Hamburg, Germany; [10]University Hospital Charite, Campus Virchow, Berlin, Germany; [11]University Hospital of Heidelberg, HEIDELBERG, Germany; [12]University of Dresden, Dresden, Germany, Dresden, Germany. Group/Team: Athena Study Group.*

Background: The ATHENA trial was designed to compare everolimus [EVR] in combination with tacrolimus [TAC] or cyclosporine A [CyA] vs. a standard of mycophenolic acid [MPA] and TAC in de novo kidney transplant [KTx] recipients.

Methods: In this 12 months [M], prospective, open-label, randomized study with 15 German and 12 French sites, 612 patients [pts] were randomized 1:1:1 at time of Tx to either EVR (3-8ng/ml M1-M12) +TAC (4-8ng/ml M1-M3; 3-5ng/ml M3-M12), or EVR (3-8ng/ml M1-M12) + CyA (75-125ng/ml M1-M3; 50-100ng/ml M3-M12) or to control TAC regimen (4-8ng/ml M1-M3; 3-5ng/ml M3-M12) with MPA. All pts continued on steroids. Herein we report M12 outcomes on infections and CMV events from ITT with 208 EVR+TAC pts, 199 EVR+CyA pts and 205 TAC+MPA pts.

Results: From randomization to M12 total incidences of infections were 73% in EVR+TAC and 72% in EVR+CyA treated pts vs 82% in TAC+MPA pts. Whilst incidences of bacterial infections were similar between the three treatment groups (44% EVR+TAC, 43% EVR+CyA, 42% TAC+MPA) major differences were seen for viral infections with incidences of 41% in TAC+MPA vs only 26% in EVR+TAC and 12% in EVR+CyA groups. Incidence of BKV events was 23% in TAC+MPA vs 17% in EVR+TAC vs 9% in EVR+CyA pts (p<0.01). CMV events occurred two thirds less in EVR treated pts compared to TAC+MPA control group with an incidence of 21% in TAC+MPA vs 6% for EVR+TAC and 3% for EVR+CyA treatment pts (p<0.001).

Conclusions: ATHENA as largest European KTx study confirmed comparable efficacy and safety together with less viral infections for EVR-based treatment groups compared to TAC+MPA group. A significant, protective effect of EVR-based regimens vs CMV/BKV events was robustly confirmed.

Peptide Vaccination against Cytomegalovirus (CMV) Induces Cellular Immune Responses in CMV Seronegative ESRD Patients Claudia Sommerer,[2] Anita Schmitt,[3] Paul Schnitzler,[1] Martin G. Zeier,[2] Michael Schmitt.[3] *[1]Virology, University Hospital Heidelberg, Heidelberg, Germany; [2]Nephrology, University Hospital Heidelberg, Heidelberg, Germany; [3]Internal Medicine V, University Hospital Heidelberg, Heidelberg, Germany.*

Background: Cytomegalovirus (CMV) reactivation occurs particularly in patients after solid organ transplantation (SOT) from seropositive donors. CMV reactivation is associated with a high risk of disease and mortality. The nonamer peptide NLVPMVATV derived from CMV phosphoprotein 65(CMVpp65) is highly immunogenic. Here we report on a clinical phase I peptide vaccination trial with this peptide in a water-in-oil emulsion (Montanide™) plus administration of or imiquimod (Aldara™) as adjuvant.

Methods: Four vaccines were administered subcutaneously at a biweekly interval to ten CMV seronegative endstage renal disease patients waiting for kidney transplantation. The clinical course, CMVpp65 antigenemia and CMV replication were monitored. CMV-specific CD8+ T cells were characterized by multi-color flow cytometry and Enzyme Linked Immuno Spot Assay (ELISPOT) and correlated it to clinical parameters.

Results: Peptide vaccination was well tolerated and no drug-related serious adverse events were detected except from local skin reactions. In four patients, specific CD8+ T cell responses against CMV could be elicited by prophylactic vaccinations. In responders an increase of CMV-tetramer positive CD8+ T cells and interferon gamma secretion was detected. Interestingly a shift from CCR7+CD45+ naïve T cells towards CCR7-CD45RA+ effector T cells could be observed suggesting an effective immune response against the virus.

Conclusions: In ten CMV seronegative endstage renal disease patients on the waiting-list for kidney transplantation we demonstrated that administration of CMVpp65 peptide vaccination was safe, well tolerated and clinically encouraging. Imiquimod can serve as an adjuvant with a similar efficacy.

SA-PO486

Intensive BK Virus Screening Protocol – A Single Center Experience Anshul Bhalla, Nitender Goyal, Ronald D. Perrone. *Tufts Medical Center, BOSTON, MA.*

Background: Polyoma virus associated nephropathy (PyVAN) caused by BK virus (BKV) occurs in 1-10% of kidney transplant recipients (KTR). Due to lack of effective treatment, screening for BKV replication is the most important tool to improve outcomes. Proposed screening strategies are based on consensus guidelines but protocols vary across centers. Increased frequency of BKV monitoring can allow for early detection and guide management. We report 1 year outcomes in a single center with an intensive BKV screening protocol.

Methods: We performed a retrospective analysis of KTR between January 2014 and March 2016. BKV screening protocol included monthly plasma BKV DNA quantitative PCR for the first 12 months. BK Viremia >3-log copies/mL was considered positive. Since management was based on confirmation of the positive value, only patients (PTS) with 2 or more positive results within a 4-week period were considered to have presumptive PyVAN (PP). Information regarding incidence, treatment and outcomes of PyVAN, rejection episodes and graft and patient survival was collected.

Results: Among 77 KTR, 70 underwent screening. Median age was 51 years (range 24-75), 61% male, 66% white and 40% had a deceased-donor transplant. 15% underwent desensitization with IVIG and 93% received Thymoglobulin for Induction. Maintenance immunosuppression (IS) regimen included Tacrolimus in 93%, Mycophenolate in 84% and Steroids in 37% PTS. Delayed graft function, defined as the need for dialysis in first week, was noted in 20%. 6 PTS (9%) had biopsy proven cellular rejection in the first 12 months. PP was noted in 19 patients (27%) during the screening period. Median time from transplant to detection of BK viremia was 81 days (range 37-265). Almost all PTS (18/19, 95%) were managed with reduction of IS (most commonly, calcineurin inhibitor followed by anti-proliferative agent and steroids). IVIG was used in 3/19 patients (16%). 8 PTS (42%) underwent allograft biopsy of which 3 had BK nephropathy. 14 out of 19 PTS (74%) had resolution of BK viremia during follow up period. Graft and PTS survival was 100% at 12 months.

Conclusions: Intensive BKV screening in the 1st year post kidney transplant allows for early intervention to guide IS management with excellent graft outcomes. This strategy reduces risk of over-treatment or risk of acute rejection. Larger trials are needed to determine the optimum frequency of BKV monitoring.

SA-PO487

Targeted Sequencing of BKPyV in Urothelial Carcinomas in Transplant Recipients Evan A. Farkash, Edward S. Harake. *University of Michigan, Ann Arbor, MI.*

Background: Some urothelial carcinomas arising in transplant recipients show strong, universal expression of BKPyV Large T antigen (LTA). BKPyV is closely related to known oncoviruses SV40 and MCPyV; we hypothesize that BKPyV acts as oncovirus in immunosuppressed transplant reciepients. Determining the genomic structure of BKPyV in urothelial tumors may provide clues to the mechanism of oncogenesis.

Methods: We designed 26 sets of fully nested 5' and 3' primers using the BKPyV DIK strain and validated on a DIK isolate. DNA was extracted from paraffin blocks of 2 urothelial carcinomas with diffuse LTA expression (QIAMP FFPE). The BKPyV genome was amplified by 2x overlapping nested PCRs and Sanger sequenced. Sequences were aligned and compared to 312 full length BKPyV sequences from the NCBI database, as well as 1 tumor previously sequenced by a different method (Megalign, Figtree).

Results: Tumor 1 (fatal) arising 9.7 years after transplant in 59 year old male harbors a clade Ib1 virus (84.8% sequenced). Tumor 2 (nonfatal) arising 8.9 years after transplant in a 68 year old female harbors a clade IV virus (31.2% sequenced). Tumor 3 (previous work) contains a clade 1a virus. Clade I has a worldwide distribution, and clade IV is enriched in Asian and Japanese regions.

Conclusions: A targeted amplification strategy was partially successful at sequencing BKPyV from urothelial carcinoma tumors from FFPE tissue. Identification of viruses from clades Ia, Ib1 and IV provides evidence that potential oncogenecity from BKPyV in transplant recipients is not restricted to a single clade. No viral integration sites or flanking DNA were identified, and a linker DNA technique is likely needed to map potential integration sites.

SA-PO488

Shotgun Cellfree DNA Sequencing to Evaluate Renal Allograft Damage in Recipients with BKVN Darshana Dadhania,[2] Philip Burnham,[1] John R. Lee,[2] Catherine Snopkowski,[3] Carol Y. Li,[2] Hua Yang,[2] Thangamani Muthukumar,[2] Manikkam Suthanthiran,[2] Iwijn De Vlaminck.[1] *[1]Cornell University, Ithaca, NY; [2]Weill Cornell Medical College, New York, NY; [3]Weill Medical College of Cornell University, New York, NY.*

Background: BKV replication is frequent and is associated with graft loss in 20-50% of cases. Existing non-invasive assays to detect BKV replication fail to correlate with the extent of renal allograft damage. Advances in the measurement of cellfree (cf) DNA in allograft recipients may be useful to identify allograft damage associated with BKVN.

Methods: In 16 recpients with stored urine supernatants, we studied cf DNA of BK virus DNA & donor DNA fractions. Analysis was performed in sex-mismatched individuals with normal protocol biopsy (n=4) & biopsy proven BKVN diagnosis (n=12). We performed shotgun metagenomic sequencing on an Illumina NextSeq (2 x 75 bp) using a single-stranded library preparation. In patients who received organs from the opposite sex, a comparison of the depth of sequencing coverage of the sex chromosomes was used to determine the cf donor DNA fraction and associated with graft injury.

Results: Urine cellfree BKV DNA correlated with urine cell pellet BKV VP1 copies (Fig 1) and Figure 2 demonstrates the correlation between serum creatinine at the time of biopsy and cf donor DNA fraction. Female recipients (n=4) receiving a male donor kidney had significantly lower cf DNA fraction compared to male recipients (n=12) receiving female kidney (Fig 3a). Among the male recipients, those with BKVN diagnosis had significantly higher urine cf donor DNA fraction compared to those with normal protocol biopsy and stable graft function (Fig 3b).

Conclusions: Our data on sex mismatched allograft recipients demonstrates that urinary cf DNA measurement in recipients offers a noninvasive measure of the burden of viral disease & allograft damage. Additional studies are needed to apply this technology to study the dynamic changes in cf donor DNA fraction with increasing/decreasing allograft damage & changes in renal function.

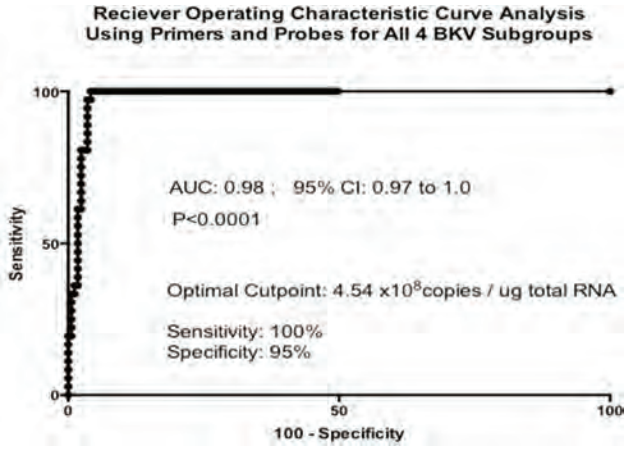
A Universal Real Time Quantitative Multiplex PCR Assay for the Non-Invasive Diagnosis of BK Polyomavirus Associated Nephropathy Darshana Dadhania,[1] Catherine Snopkowski,[2] Carol Y. Li,[1] Liana S. Perry,[1] Hua Yang,[1] John R. Lee,[1] Thangamani Muthukumar,[1] Manikkam Suthanthiran.[1] *[1]Weill Cornell Medical College, New York, NY; [2]Weill Medical College of Cornell University, New York, NY.*

Background: BK Polyomavirus associated nephropathy (BKVN) is an important cause of kidney allograft failure. Early detection & reduction of immunosuppression is the best strategy for mitigating BKVN associated graft dysfunction. Use of sensitivity DNA PCR and neighbor-joining method, a phylogenetic tree of BKV has been developed & population specific prevalence of BK has been emphasized. Existing BKV PCR assays fail to account for BKV subtypes, we designed & developed a multiplex quantitative PCR assay for detection of clinically significant subtypes.

Methods: We designed 3 sense & 3 antisense primers and 3 TaqMan probes, which in combination, amplified 7 BKV subtypes- BKV Dunlop, Ia, IC, III, 1v, V, and VI. Total RNA was isolated from 205 biopsy matched urine specimens reverse transcribed to cDNA and real-time quantitative multiplex PCR assays were established. All biopsies were stained for SV40: 36 were SV40 positive & classified as BKVN biopsies; remaining 169 were SV40 negative & classified as acute rejection (n=56); Normal (n=53); acute tubular injury (n=50); Other (n=10). Receiver-operating- characteristic curve analysis was used to calculate area under the curve (ROC-AUC), sensitivity and specificity for distinguishing BKVN biopsies from all other biopsy diagnoses.

Results: Analysis involving ROC curve demonstrated that BKVN diagnosis can be predicted with a sensitivity of 100% & a specificity of 95% with the use 4.54×10^8 copies of BKV mRNA per microgram of RNA as the cutpoint (ROC-AUC=0.98, 95% CI, 0.97 to 1.0, P<0.0001). (Figure 1)

Conclusions: We have designed and developed real time quantitative multiplex PCR assays for the detection of major subtypes of BKV and demonstrate its utility for the noninvasive diagnosis of BKVN. In view of population specific prevalence of BKV subtypes, the newly developed assay should have universal appeal.



SA-PO490

Predictive Value of the Combination of Peripheral Blood Lymphocyte Count and Urinary Cytology in the Diagnosis of Polyomavirus BK Nephropathy Kosuke Masutani,[2] Akihiro Tsuchimoto,[2] Yuta Matsukuma,[2] Yasuhiro Okabe,[3] Kazuhiko Tsuruya,[4] Takanari Kitazono.[1] *[1]Department of Medicine and Clinical Science, Fukuoka, Japan; [2]Kyushu University, Fukuoka, Japan; [3]Kyushu University Hospital, Fukuoka, Japan; [4]None, Fukuoka, Japan.*

Background: Screening of Polyomavirus BK (BKV) infection is recommended for kidney transplant (KT) patients. Graft biopsy is the gold standard for the diagnosis of BKV nephropathy (BKVN), and polymerase chain reaction for viral DNA is the most specific screening technique. However, the identification of non-invasive, and cost-effective marker is still important and can improve monitoring. Thus we investigated the predictive value of the peripheral blood lymphocyte (PBL) count and urinary cytology for the diagnosis of BKVN.

Methods: From July 2008 through May 2014, 492 adult patients received KT at Kyushu University Hospital. We investigated the PBL count and cytology results at graft biopsy in the patients with BKVN (BKVN group, n=21), acute T-cell mediated rejection (TCMR group, n=79), and no evidence of rejection (NoAR group, n=149). We performed univariate and multivariate logistic regression and receiver operating characteristics analyses to compare the test performance of PBL count alone, cytology alone, and their combination in the diagnosis of BKVN.

Results: PBL count (mean ± SD) at graft biopsy was significantly lower in BKVN group than those in TCMR and NoAR groups (959 ± 290, 1433 ± 673, and 1531 ± 549 /μL, respectively, p<0.01). PBL count increased after the treatment of BKVN (at diagnosis, after 1, 2, and 3 months were 959 ± 290, 1123 ± 377, 1238 ± 419, and 1292 ± 491, respectively, p<0.05). On univariate logistic regression analysis, the area under the curve for prediction of BKVN was significantly higher in the combined model than those in PBL alone and cytology alone (0.930, 0.797 and 0.875, respectively, p<0.01). The improvement of predictive performance in the combined model remained significant after adjustment for the classical risk factors of BKVN (0.972, 0.844, and 0.928, respectively, p<0.01).

Conclusions: Decreased PBL count was found in the patients with BKVN. Although PBL count alone showed moderate accuracy, the predictive performance of the combination of PBL count and urinary cytology is significantly enhanced in the diagnosis of BKVN.

SA-PO491

Urinary Exosomal Viral miRNA as a Marker of BK Virus Nephropathy after Kidney Transplantation Sang-Ho Lee,[3] Yu ho Lee,[3] Seo Jung-Woo,[3] Jin sug Kim,[4] Yang gyun Kim,[1] Kyung-hwan Jeong,[5] Ju young Moon,[8] Chun-Gyoo Ihm,[6] Tae won Lee,[2] Byung ha Chung.[7] *[1]Division of Nephrology Department of internal medicine Kyung Hee University College of Medicine, Seoul, Republic of Korea; [2]Kyung Hee Universitiy School of Medicine, Seoul, Republic of Korea; [3]Kyung Hee University Hospital at Gangdong, Seoul, Korea, Seoul, Republic of Korea; [4]Kyung Hee University Medical Center, Seoul, Republic of Korea; [5]Kyung Hee University, School of Medicine, Seoul, Republic of Korea; [6]None, Seoul, Republic of Korea; [7]Seoul St. Mary's Hospital, Seoul, Republic of Korea; [8]University of Southern California, Los Angeles, AL.*

Background: Recently, bkv-miR-B1-5p, one of the miRNAs encoded by BK virus, was reported to be elevated in the blood among the patients with BK virus nephropathy (BKVN). Urinary exosome was suggested to be a possible source of biomarker for kidney diseases, but it was unknown whether it could contain viral miRNA as well as human miRNAs.

Methods: In a cross sectional, observational study, we evaluated the prevalence of biopsy proven BKVN among 458 graft biopsies from 385 kidney transplant recipients at five transplantation centers from August 2013 to July 2015. For patients with BKVN (n=13) and 67 age, sex-matched renal transplant recipients, we measured BK viral miRNA B1-5p, 3p and human miRNA-16 in urinary exosomal fraction and compared the diagnostic value with viral DNA in plasma and urine.

Results: Pathology proven BKVN was diagnosed in 13 patients (2.8%). The prevalence of BKVN was significantly higher in patients who underwent indication biopsy than in patients who underwent protocol biopsy (4.8% vs. 0.5%). High levels of bkv-miR-B1-5p and bkv-miR-B1-3p were shown in all patients with BKVN. Plasma viral DNA assay (cut-off value of $1x10^4$ copies/mL) showed false negative in 3 cases and urinary viral DNA assay (cut-off value of $1x10^7$ copies/mL) showed false negative in 1 case among these 13 patients. When compared to 67 propensity score matching patients with other pathologic classification, the receiver operator characteristics (ROC) curve analysis for bkv-miR-B1-5p and bkv-miR-B1-5p/miR-16 showed excellent values of area under curve (AUC) for the diagnosis of BKVN.

Conclusions: This study suggests that urinary exosomal bkv-miR-B1-5p and bkv-miR-B1-5p/miR-16 also could be surrogate markers for the diagnosis of BKVN.

SA-PO492

Clinical Outcomes of Patients with BK Viremia in ABO-Incompatible Kidney Transplantation and Comparison with ABO-Compatible Kidney Transplantation Jung a Yoon, Chung Hee Baek, Su-Kil Park, Hyosang Kim. *Nephrology, Asan Medical Center, University of Ulsan College of Medicine, SEOUL, Republic of Korea.*

Background: ABO-incompatible kidney transplantation (ABOiKT) recipients may have an increased risk of BK virus allograft nephropathy (BKVAN), a major cause of renal dysfunction and allograft loss. We investigated BK viremia and BKVAN in ABOiKT recipients compared to those receiving ABO compatible kidney transplantation (ABOcKT).

Methods: This study analyzed a total of 1111 kidney transplant recipients between January 2012 and December 2015 (n= 217 ABOiKT and n= 894 ABOcKT) at Asan Medical Center. High viremia was defined as serum BK viral load with peak ≥ 10,000 copies/mL more than once after transplantation and low viremia was defined as serum BK viral load with peak < 10,000 copies/mL. BKVAN was confirmed by biopsy.

Results: The incidence of high viremia was 12.0% (n= 26/217) in ABOiKT and 8.4% (n= 75/894) in ABOcKT (p= 0.067). BKVAN was diagnosed in 4.6% (n= 10/217) ABOiKT recipients and 1.6% (n = 14/894) ABOcKT recipients (p= 0.015). In ABOiKT, graft survival was not significantly different among the groups according to degree of BK viral loads (p= 0.092), but graft functions of patients with high viremia were worse than that of patients with aviremia, especially at 6 months and 12 months (p= 0.020 and p=0.006, respectively). Among patients with high viremia, 38.5% (10/26) patients in ABOiKT were diagnosed BKVAN compared with only 18.7% (14/75) patients in ABOcKT (p= 0.041). BKV was first detected within 6 months after transplantation in both groups (p=0.304). In patients with high viremia, graft functions of ABOiKT patients were worse than that of ABOcKT patients at 6 months after transplantation. There was no significant difference in the incidence of graft failure, but graft failure was caused by BKVAN in ABOiKT with high viremia and by acute rejection in ABOcKT with high viremia. However, there was no significant difference in graft survival between ABOiKT and ABOcKT.

Conclusions: ABOiKT recipients have a greater risk for BK viremia and BK allograft nephropathy compared to ABOcKT. In ABOiKT, high BK viremia was associated with worse graft function although it did not affect graft survival.

SA-PO493

Variable Presentation and Histologic Findings in JC Nephropathy Brian K. Lee,[3] Kuang-Yu Jen,[2] Zoltan G. Laszik.[1] *[1]Pathology, University of California San Francisco, San Francisco, CA; [2]Pathology, University of California, Davis, Sacramento, CA; [3]Nephrology, University of California San Francisco, San Francisco, CA.*

Background: Polyomaviruses commonly infect healthy individuals and remain latent. However, immunosuppression (IMMS) can result in reactivation. With renal tropism BK virus is the most common cause of virus associated nephropathy (VAN) in kidney allografts while JC VAN is a rare complication with only a handful of JC VAN cases reported previously.

Methods: From 01/2007 to 12/2014, 3 cases of JC VAN in renal transplant patients were detected at our institution. Here, we report on the variable presentation and histologic findings for JC VAN in these patients. Two patients had an acute rise in serum creatinine which prompted allograft biopsy (bx), while the other underwent a surveillance bx. The time at bx ranged from 6 to 75 months post-transplant. Only one case displayed viral cytopathic changes, but two showed inflammation and tubulitis. All exhibited polyoma VAN with positive SV40 stains. However, plasma BK viral loads were undetectable, which prompted further testing for JC virus. All subsequently showed JC viremia. Recent acute cellular rejection was seen in two cases, which resulted in intensified IMMS.

Results:

Conclusions: JC VAN can present sub-clinically with low/transient viral replication. Presence of viral cytopathic changes is variable, making histologic diagnosis challenging. Previous reports suggest that the onset of JC VAN lagged behind that of BK virus. One of our cases presented early at 6 months post-transplant, arguing that a higher index of suspicion even in those with stable graft function undergoing protocol bx is crucial in capturing this condition. Routine SV40 stains may help catch some cases. Reduction in IMMS remains the mainstay of treatment. Caution with treating accompanying

inflammation as rejection activity should be exercised, as intensified IMMS likely contributes to JC VAN.

Cases	1	2	3
Age	62	62	46

Incidence of Hepatitis B Virus Reactivation after Kidney Transplantation with Low-Dose Rituximab Administration Kosuke Masutani,[2] Kazuya Omoto,[4] Masayoshi Okumi,[4] Yasuhiro Okabe,[3] Tomokazu Shimizu,[4] Kazuhiko Tsuruya,[2] Takanari Kitazono,[1] Hideki Ishida,[4] Kazunari Tanabe.[4] *[1]Department of Medicine and Clinical Science, Fukuoka, Japan; [2]Kyushu University, Fukuoka, Japan; [3]Kyushu University Hospital, Fukuoka, Japan; [4]Tokyo Women's Medical University, Tokyo, Japan. Group/Team: Japan Academic Consortium of Kidney Transplantation (JACK) Investigators.*

Background: In patients with hematological malignancy who are intended to receive rituximab, hepatitis B virus (HBV) serology screening and viral reactivation monitoring are recommended. However, the effect of single-dose rituximab on HBV reactivation in kidney transplant (KT) patients with previous HBV infection is still unclear.

Methods: In this retrospective cohort study of 1,294 KT patients, we identified 76 who were negative for preoperative hepatitis B surface antigen and HBV DNA, and positive for hepatitis B core antibody. A rituximab dose of 200 mg/body was administered to 48 patients; 46 of whom did not receive prophylaxis (rituximab + group). Twenty-eight patients received neither rituximab nor prophylaxis (rituximab – group). We monitored HBV DNA by polymerase chain reaction every 1–3 months, and HBV reactivation was defined as detectable HBV DNA.

Results: HBV reactivation was found in one patient in the rituximab + group (2.2%) and one in the rituximab – group (3.6%) at 6 weeks and 5.5 years post-KT, respectively, but it was spontaneously cleared. Both patients were positive for hepatitis B surface antibody (anti-HBs) preoperatively. HBV reactivation was not found in six patients lacking anti-HBs preoperatively.

Conclusions: Low-dose rituximab administration in KT patients without prophylaxis is associated with a low incidence of HBV reactivation. However, the sequential monitoring is necessary for many years to detect viral reactivation and prevent de novo hepatitis.

SA-PO495

Comparison of Renal Safety and Efficacy of Tenofovir and Entecavir Treatment in Chronic Hepatitis B Patients with Kidney Transplantation Seonghoon Kim, Hyosang Kim, Soo Ya Bae. *Asan Medical Center, University of Ulsan College of Medicine, SEOUL, Republic of Korea.*

Background: Nucleotide reverse transcriptase inhibitor is used for the treatment of chronic hepatitis B (CHB). Preemptive antiviral therapy can improve the survival of HBsAg-positive renal allograft recipients. But there are concerns about the potential risk of nephrotoxicity with long-term use. This study aims to assess the nephrotoxicity and efficacy of tenofovir and entecavir in kidney transplant recipients.

Methods: We performed a single center based, retrospective study of 55 patients with CHB treated with tenofovir (n=34) and entecavir (n=21) after kidney transplantation. Patients with a decrease <20% in eGFR were recorded, calculated using the Modification of Diet in Renal Disease. Treatment efficacy was assessed by HBV DNA levels and virological breakthrough.

Results: Tenofovir was associated with a decrease in eGFR at 1 year from treatment (unadjusted odds ratio, 10.313; 95% CI, 1.111-95.762; p=0.026; patients with decreased GFR, 5/21 vs. 1/34). Mean eGFR at 1 year was 55.6 ml/min/1.73m^2 and 64.0 ml/min/1.73m^2 at tenofovir and entecavir group. Delta eGFR at 1 year was -2.82 ml/min/1.73m^2 in entecavir group and 0.10 ml/min/1.73m^2 in tenofovir group. There was no significant change in eGFR between the entecavir group and the tenofovir group after a mean of 45 months (Mean eGFR, 56.5 ml/min/1.73m^2 vs. 62.7 ml/min/1.73m^2). There was no difference in rate of virological breakthrough between two groups at the end of treatment (patients with virological breakthrough, 5/21 vs. 6/34; p=0.731). By multivariate analysis, the significant factor associated with a decrease in eGFR at 1 year from treatment were tenofovir (adjusted odds ratio, 18.477; 95% CI, 1.123-275.953; p=0.034).

Conclusions: Patients who received KT and treated with tenofovir were likely to have decline in renal function than patients who treated with entecavir at 1 year from treatment. Tenofovir was independently associated with decrease in eGFR at 1 year from treatment. There was no significant difference in an efficacy between tenofovir and entecavir group at the end of treatment.

SA-PO496

MAGELLAN-2: Glecaprevir/Pibrentasvir for 12 Weeks in Renal Transplant Patients With Chronic Hepatitis C Virus Genotypes 1–6 Nancy Reau,[4] Paul Kwo,[5] Susan Rhee,[1] Martin Prieto,[2] Edward Gane,[7] Parvez Mantry,[6] Abhishek Gulati,[1] Preethi Krishnan,[1] Emily Dumas,[1] Nancy Shulman,[1] Xavier Forns.[3] *[1]AbbVie Inc., North Chicago, IL; [2]Hospital Universitario y Politécnico La Fe and CIBERehd, Valencia, Spain; [3]Liver Unit, Hospital Clinic, CIBEREHD, IDIBAPS, Barcelona, Spain; [4]Rush University Medical Center, Chicago, IL; [5]Stanford University School of Medicine, Stanford, CA; [6]The Liver Institute at Methodist Dallas, Dallas, TX; [7]University of Auckland, Auckland, New Zealand.*

Background: Chronic HCV infection is associated with poor long-term patient and allograft survival following renal transplant. Treatment is challenging and limited data exist on the use of IFN-free direct-acting antiviral (DAA) therapies in these patients. This study evaluated the safety and efficacy of glecaprevir/pibrentasvir (G/P) in renal transplant patients with chronic HCV infection.

Methods: MAGELLAN-2 was a Phase 3, single-arm, open-label trial. Renal transplant patients infected with chronic HCV genotypes (GT) 1–6, who were treatment-naïve or -experienced (IFN- or SOF-based) and non-cirrhotic, received 12 weeks of G/P 300/120 mg once daily. Safety data and the percentage of patients achieving sustained virologic response (HCV RNA <LLOQ) at post-treatment Week 12 (SVR12) were assessed.

Results: Overall, 20 patients were enrolled: the majority were male (55%), white (55%), and treatment-naïve (80%); 30% had HCV GT1a, 55% had GT1b, 10% had GT3, and 5% had GT4 infection; 90% had F0–F1 and 10% had F3 fibrosis. Most patients had a baseline eGFR <60 mL/min/1.73 m^2 (55%), and baseline immunosuppressants (IS) were cyclosporine (20%), tacrolimus (55%), or other (25%); adjustments in IS dosing were minor. SVR12 was 100%. AEs were mostly mild; fatigue, nausea, and upper respiratory tract infection were most common (20% each). One patient had decreased creatinine clearance (<30 mL/min) during treatment 2 days after the last G/P dose, which was not related to the DAA. There were no DAA-related serious AEs and no graft rejections.

Conclusions: G/P for 12 weeks is highly efficacious for renal transplant patients infected with chronic HCV GT1–6, with a 100% SVR12 rate. G/P was well tolerated, with no discontinuations.

SA-PO497

Effectiveness of Direct-Acting Antiviral Regimens in the Treatment of Hepatitis C Virus (HCV) in Kidney Transplant Recipients Karolyn S. Horn,[1] Maya Campara,[2] Michelle T. Martin,[2] Ignatius Y. Tang.[1] *[1]University of Illinois Hospital and Health Sciences System, Chicago, IL; [2]University of Illinois Hospital and Health Sciences System / University of Illinois at Chicago College of Pharmacy, Chicago, IL.*

Background: The AASLD Hepatitis C virus (HCV) guidance document does not offer recommendations for the treatment of kidney transplant recipients. Real-world data are needed to evaluate the effectiveness of direct-acting antivirals (DAAs) in this underrepresented population.

Methods: Authors performed a retrospective chart review of kidney transplant recipients (KTRs) who were treated for HCV at an urban medical center from January 1, 2014 to December 1, 2016. This reports[M1] our single-center, retrospective analysis of the efficacy and safety of DAA-based regimens in kidney (K), kidney-liver (KL), and kidney-pancreas (KP) transplant patients.

Results: 28 KTRs were treated for HCV; 54% were K, 32% KL, and 14% KP. Patients had a mean age of 60 (±7) years, 50% were male, 71% were treatment naïve, 25% had cirrhosis, and all GT 1. Pre-treatment and end-of-treatment levels did not differ for serum creatinine (n=22 patients, 1.5mg/dL vs 1.7mg/dL, p=0.4); or urine microalbumin to creatinine ratio (n=15 patients, 337.3 vs 111, p=0.3). 18% had dose changes in immunosuppression (IMS) levels during and after HCV treatment, but the mean daily tacrolimus levels did not differ from baseline and 12 weeks after treatment completion (4.6 mg vs 4.8 mg, respectively, p>0.05). The overall SVR rate was 86%. SVR did not differ by regimen; 50% with sofosbuvir+ribavirin, 90.9% with sofosbuvir+simeprevir, 90% with ledipasvir/sofosbuvir, 75% ledipasvir/sofosbuvir + ribavirin, and 100% with elbasvir/grazoprevir achieved SVR (p=0.55). SVR did not differ by type of transplant (92.9% K vs 80% KL vs 75% KP, p = 0.54). SVR also did not differ by genotype, gender, ethnicity, BMI, baby-boomer status, cirrhosis, treatment history, adherence, or diabetes (p>0.05). SVR did differ by primary IMS agent, SVR rates were 100% for mycophenolate mofetil (n=1), 91.7% for tacrolimus (n=24), 100% for sirolimus (n=1), and 85.7% for cyclosporine (n=2) (p=0.005).

Conclusions: DAA regimens were highly effective in treating HCV in KTRs. Renal allograft function was stable throughout and 12 weeks after DAA therapy. Comparison

across groups was limited due to small numbers. IMS levels should be monitored closely during HCV treatment as many patients required dose adjustments.

SA-PO498

Impact of Early Ureteric Stent Removal on Urinary Tract Infection and Ureteric Complication after Kidney Transplantation – A Single Centre Experience Stephanie Chong,[3] Viyaasan Mahalingasivam,[2] Sajeda Youssouf,[1] Mark Blunden.[3] *[1]Barts Health NHS Trust, London, United Kingdom; [2]Mid Essex Hospitals NHS Trust, Harrow, United Kingdom; [3]Royal London Hospital, London, United Kingdom.*

Background: Recurrent urinary tract infection (UTI) is a common cause of renal allograft dysfunction as well as a burden on patient quality of life and the health economy.

Methods: We performed a retrospective study of consecutive deceased donor transplants undertaken at our centre between January 2012 and June 2016 to determine the effectiveness of strategies which had been established to reduce rates of UTI in our patient cohort. These included changing pre-operative antibiotic prophylaxis from co-amoxiclav to meropenem in January 2014, whilst a cohort of patients underwent the intra-operative tying of ureteric stents to indwelling urinary catheters, in order to allow for early concurrent removal on day 5. The remaining patients continued to undergo standard cystoscopic stent removal after six weeks. Our aim was to determine the difference these changes made to the incidence of UTI in the first three months after transplantation. 555 adult deceased donor transplants were studied of which 23 were excluded due to early explantation. 115 underwent early stent removal whilst 418 underwent later cystoscopic removal.

Results: There was no difference in the number of patients with at least one UTI between with groups (37.0% with early stent removal, 38.3% with later stent removal, p=0.83) or with more than two UTIs (15.6% vs 14.8%, p=0.83). There was no difference in the average number of UTIs per patient (1.02 vs 1.05, p=0.43). There was also no difference in the incidence of extended-spectrum beta-lactamases (ESBL) (6.09% vs 7.42%, p=0.58) or hospital admission (10.5% vs. 6.09%, p=0.15). There was no difference in the rate of ureteric complication (6.9% vs 5.7%, p=0.85). There was however, an increase in the rate of UTI per patient after the antibiotic protocol was switched from co-amoxiclav to meropenem (0.68 to 1.33, p<0.05). The rate of ESBL was similar (5.49% vs 8.36%, p=0.20) in both groups.

Conclusions: Early ureteric stent removal does not appear to reduce the incidence or frequency of UTI and there was no significant difference in ureteric complication rates in our patient cohort. These findings suggest that early stent removal is a potentially viable and cost effective surgical strategy in renal transplantation but further prospective randomised controlled trials are needed for validation.

SA-PO499

Gut Microbiota Disturbances and Post-Transplant Diarrhea in Kidney Allograft Recipients John R. Lee,[2] Matthew Magruder,[2] Lisa T. Zhang,[2] Thangamani Muthukumar,[2] Darshana Dadhania,[2] Lars Westblade,[2] Michael Satlin,[2] Lilan Ling,[1] Eric Pamer,[1] Manikkam Suthanthiran.[2] *[1]Memorial Sloan Kettering Cancer Center, New York, NY; [2]Weill Cornell Medicine, New York, NY.*

Background: Diarrhea is a common complication in kidney transplant recipients, but its etiology is unknown. In a prior gut microbiota profiling study, we reported lower abundance of commensal bacterial taxa (*Ruminococcus, Dorea, Corpococcus,* and *Bacteroides*) in kidney transplant recipients with post-transplant diarrhea.

Methods: Herein, we perform a validation study using an independent cohort of 71 kidney transplant recipients. We collected 199 serial fecal specimens from this population in the first 3 months of transplantation and profiled their microbiota using 16S rRNA deep sequencing of the V4-V5 hypervariable region. 24 subjects developed post-transplant diarrhea and 47 did not. We compared 28 diarrheal fecal specimens from the Diarrhea Group to 111 fecal specimens from the No Diarrhea Group.

Results: Microbial diversity was significantly lower in the diarrheal fecal specimens from the Diarrhea Group than in the fecal specimens from the No Diarrhea Group (P < 0.001, Wilcoxon rank sum) (Fig A) and non-metric dimensional scaling using Bray-Curtis dissimilarity separated the two groups (Fig B). Thirteen genera including the 4 reported in the prior study were significantly lower in the diarrheal fecal specimens from the Diarrhea Group than in the fecal specimens from the No Diarrhea Group (q value<0.15, Benjamini-Hochberg correction) (Fig C). PCR array for common diarrhea-associated pathogens (Biofire GI Film Array) was negative in 26 of 28 diarrhea fecal specimens.

Conclusions: We have identified decreased commensal bacterial taxa in the kidney transplant recipients with post-transplant diarrhea, which supports future studies using prebiotics and/or probiotics to prevent and/or treat this common complication.

Funding: Other NIH Support - NIAID K23 AI 124464

SA-PO500

Gut Microbiota Disturbances and Urinary Tract Infections in Kidney Transplant Recipients John R. Lee,[2] Matthew Magruder,[2] Lisa T. Zhang,[2] Darshana Dadhania,[2] Thangamani Muthukumar,[2] Lilan Ling,[1] Eric Pamer,[1] Manikkam Suthanthiran.[2] *[1]Memorial Sloan Kettering Cancer Center, New York, NY; [2]Weill Cornell Medicine, New York, NY.*

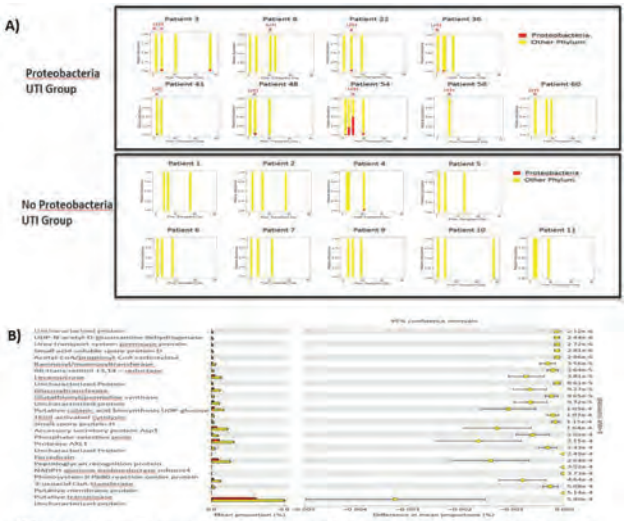
Background: Disturbances in the gut microbiota has been linked to infectious complications beyond *C. difficile.* In a pilot gut microbial profiling study, we found a link between the abundance of pathogenic gut microbiota and urinary tract infections (UTI) in kidney transplant recipients.

Methods: Herein, we perform a validation study using an independent cohort of 71 kidney transplant recipients. We collected 199 serial fecal specimens from this population in the first 3 months of transplantation and profiled their gut microbiota using 16S rRNA deep sequencing of the V4-V5 hypervariable region. Among the 71 subjects, 13 developed Proteobacteria UTIs and 58 subjects did not. We compared the gut microbial profiles in the 11 fecal specimens collected at the time of Proteobacteria UTI (Proteobacteria UTI Group) to the gut microbial profiles of 135 fecal specimens collected at the same time urine cultures were negative for Proteobacteria UTI (No Proteobacteria UTI Group).

Results: The fecal abundance of Proteobacteria, the phylum that contains gram negative pathogens like *Escherichia,* was significantly higher in the 11 fecal specimens from the Proteobacteria UTI Group than in the 135 fecal specimens from the No Proteobacteria UTI Group (1.3% vs. 0.2%, P=0.03, Wilcoxon rank sum) (Fig A). Predicted bacterial genes based on the 16S rRNA data (using PICRUSt) revealed lower metabolism related genes in the fecal specimens in the Proteobacteria UTI Group than in those in the No Proteobacteria UTI Group (Fig B).

Conclusions: Our identification of a gut microbiota-urinary tract infection relationship in kidney transplant recipients suggest that correction of gut dysbiosis may help prevent and/or treat UTIs, especially recurrent and multi-drug resistant UTIs.

Funding: Other NIH Support - K23 AI 124464



A) Each set of bar graphs represent a subject. On the x axis is the post-transplant day and on the y axis is the relative abundance of different phyla with Proteobacteria in red and other phyla in yellow. The top 9 graphs are representative patients from the Proteobacteria UTI Group and the bottom 9 are representative patients from the No Proteobacteria UTI Group. Abundance of Proteobacteria is associated with the timing of UTI. **B)** The top 27 genes that were significantly different between the fecal specimens from the Proteobacteria UTI Group and the fecal specimens from the No Proteobacteria Group are shown. On the left are the relative mean abundances of the different genes by group and on the right are the differences in mean proportions between the two groups. Q value is represented on the far right.

Cell-Free DNA Sequencing of Urine Supernatants: A Novel Approach to Characterize the Urine Microbiome, Bacterial Growth Dynamics, and Antibiotic Resistomes in Kidney Transplantation John R. Lee,[1] Philip Burnham,[2] Darshana Dadhania,[1] Thangamani Muthukumar,[1] Manikkam Suthanthiran,[1] Iwijn De Vlaminck.[2] *[1]Weill Cornell Medicine-, New York, NY; [2]Cornell University, New York, NY.*

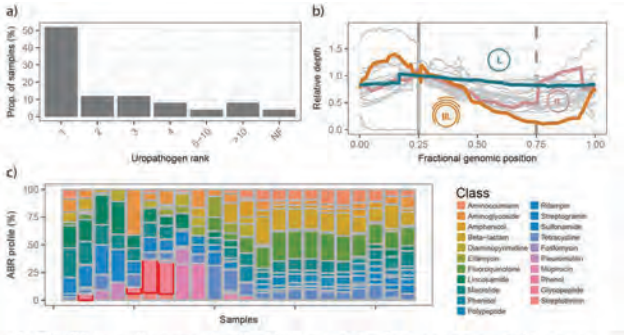
Background: Cell-free DNA sequencing can provide an all-inclusive method to profile the microbiome, bacterial growth dynamics, and antibiotic resistant patterns. Herein, we utilize cell-free DNA sequencing of urine supernatants to test its utility in a cohort of kidney transplant recipients with and without urinary tract infections (UTI).

Methods: We collected serial urine supernatants from kidney transplant recipients with UTI (N=25 urine samples from 18 subjects) and without UTI (N= 20 samples from 7 subjects). We performed single-stranded library preparation and shotgun sequencing on all of the 45 urine supernatants (Illumina Next Seq, 75 bp by 75 bp). Microbial identification was performed using the Grammy pipeline.

Results: In 24 of the 25 UTI samples, cfDNA identified the pathogen confirmed by bacterial culture (Fig. A) but also identified other pathogens in the same sample that were not detected by conventional urine culture. Uneven coverage over the origin of replication has been shown to reflect bacterial growth rates (Korem et al., Science 2015). We therefore utilized this novel principal and detected active growth rates in the pathogens causing UTIs (Fig. B). The antibiotic resistome profiles derived from cfDNA, shown in Fig. C, demonstrate the additional layer of information captured by cfDNA sequencing.

Conclusions: In this first-in-kind study, we report urinary cfDNA sequencing as an all-inclusive method to detect co-infections, bacterial growth rates, and antibiotic resistomes, which may be particularly useful in measuring the response to treatment in recurrent UTI in kidney transplantation.

Funding: Other NIH Support - K23 AI 124464



A) The 25 uropathogens identified by bacterial culture are presented by rank found in the cfDNA, indicating co-pathogens identified in the urine not detected by bacterial culture. B) Relative coverage of cfDNA (y-axis) based on fractional genomic position (x-axis) with origin region (25% fractional genomic position) and terminus region (75% fractional genomic position) with pathogen I) low growth, II) medium growth, and III) high growth. C) antibiotic resistant genes by relative abundance for each of the 25 cfDNA profiles associated with UTIs.

SA-PO502

Prevalence and Clinical Outcomes in Kidney Transplant Patients with Viral and Fungal Opportunistic Infections and Malignancies Michelle L. Lubetzky,[2] Nicole A. Hayde,[5] Layla Kamal,[3] Maria Ajaimy,[3] Puneet Bedi,[1] Enver Akalin.[4] *[1]Brookdale University Hospital Medical Center, Brooklyn, NY; [2]Transplantation, Montefiore Medical Center, New York, NY; [3]Montefiore Medical Center, Bronx, NY; [4]Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, NY; [5]None, Bronx, NY.*

Background: Opportunistic infections (OI) and malignancy after kidney transplant (KTX) are associated with increased morbidity and mortality. We aimed to assess clinical outcomes in patients with these complications.

Methods: We performed a single-center retrospective review of KTX patients from January 2009 until December 2014. Patients with opportunistic viral infections (BK virus or cytomegalovirus (CMV)), fungal infections, or malignancies were reviewed and compared to patients without these complications.

Results: During a median follow-up of 3.8 years (2.4-5.3), out of a total 677 patients, 222 developed OI or malignancy (32.8%); 19.2% had BK viremia, 1.5% BK nephropathy, 9.5% CMV viremia, 2.1% invasive CMV infection, 2.5% fungal infection, and 5.6% had malignancies. There was no difference between the groups in terms of age, race, gender, induction type, or etiology of kidney disease (Table). One year and most recent serum creatinine levels were significantly higher in the OI/Malignancy group ($p<0.01$). There were significantly higher rates of acute rejection in the OI/Malignancy group ($p<0.01$). There was significantly more graft loss (22.5%) in the OI/malignancy group compared to only 4.2% in the non OI group ($p<0.01$). Additionally patient survival was lower in the OI/malignancy group ($p=0.05$). Graft loss in the OI/malignancy group was more likely to be due to chronic rejection (58% vs. 31.6% $p=0.06$); in most cases rejection occurred in the setting of reduced immunosuppression.

Conclusions: Opportunistic infections and malignancies develop in 33% of kidney transplant recipients, and are associated with lower graft and patient survival and increased risk of acute rejection.

Characteristic	Opportunistic infections/malignancy (N=222) %	Opportunistic infections/malignancy (n=455) %	P Value
Recipient Age	53.6±13.5	53.2±13.2	0.73
Recipient Gender (Male)	63.9%	57.1%	0.10
Race (African-American)	42.6%	39.6 %	0.11
Etiology of Kidney disease (Diabetes Mellitus)	24.23%	26.2%	0.24
Transplant Type (Deceased-donor)	78.4%	76.2%	0.56
Induction (Thymoglobulin)	59.2%	55.5%	0.42
Acute Rejection	21.2%	5.9%	<0.01
1 year creatinine mg/dl	1.85+/-1.3	1.44+/-0.7	<0.01
Most recent creatinine mg/dl	1.6+/-0.75	1.5+/-1.1	<0.01
Graft Survival	77.5%	95.8%	<0.01

SA-PO503

A Randomized Controlled Trial Comparing Belatacept to Tacrolimus in De Novo Kidney Transplantation Gretchen N. De Graav, Carla Baan, Marian Clahsen - van Groningen, Jan H. Von der thüsen, Monique Cadogan, Jacqueline Van De Wetering, Joost van Rosmalen, Willem Weimar, Dennis A. Hesselink. *Erasmus MC, Rotterdam, Netherlands.*

Background: Belatacept (bela) allows for calcineurin-inhibitor-free immunosuppressive therapy after kidney transplantation but is associated with a higher acute rejection risk than ciclosporin. We compared clinical outcomes in a randomized-controlled trial comparing bela to tacrolimus (tac) in *de novo* kidney transplantation.

Methods: Forty kidney transplant recipients were 1:1 randomized to a bela- or tac-based immunosuppressive regimen combined with basiliximab, mycophenolate, and prednisolone. One-year graft- and biopsy-proven acute rejection (BPAR)-free survival were assessed, as well as the development of *de novo* donor-specific anti-HLA antibodies (DSA), the incidence of adverse events (AEs) and eGFR (in mL/min/1.73m^2).

Results: Three graft losses occurred on days 12, 59, and 161 after transplantation, resulting in a 1-year death-censored graft survival of 85% in the belatacept group *vs.* 100% in the tacrolimus group ($p=0.08$). All were the result of glucocorticoid-resistant

rejection. The incidence of BPAR was higher in the bela-treated than in the tac-treated patients, n=11 (55%) *vs.* n=2 (10%), p=0.006, respectively, and rejections were of a more severe grade. In the first year, 2 patients, of which 1 rejected, developed DSA, both in the bela group. Total AEs were similar between groups; means of 10.3 and 11.9 per patient in the bela- and tac-groups, respectively, p=0.41. Post-transplant diabetes mellitus occurred more often in the tacrolimus group; n=7 *vs.* n=1 in the belatacept group, p=0.04. eGFR, excluding graft losses, was not different between bela-treated and tac-treated patients on month 12: 54 (28–89) and 50 (33–84) mL/min, respectively; p=0.57. However, graft-loss censored eGFR in bela-treated rejectors (n=8) was 36 (28-76) mL/min at month 12, which was lower than the eGFR of 58 (37-84) mL/min in the bela-treated non-rejectors, p=0.001.

Conclusions: Bela-based immunosuppressive therapy results in a higher rejection rate and severity compared to standard, tac-based therapy, and shows similar graft function 1 year after transplantation.

SA-PO504

Single-Dose (SD) Pharmacokinetics (PK), Pharmacodynamics (PD), and Safety of Belatacept (Bela) in Adolescent Kidney Transplant Recipients (KTRs) Asha Moudgil,[3] Vikas R. Dharnidharka,[1] Daniel Feig,[4] Barry L. Warshaw,[5] Vidya Perera,[2] Bindu Murthy,[2] Martin Polinsky,[2] Robert B. Ettenger.[6] *[1]Washington University, St Louis, MO; [2]Bristol-Myers Squibb, Princeton, NJ; [3]Children's National Medical Center, Washington, DC; [4]University of Alabama, Birmingham, AL; [5]Emory University & Children's Healthcare of Atlanta, Atlanta, GA; [6]University of California, Los Angeles, CA.*

Background: Bela blocks CD86-CD28 co-stimulation between antigen presenting cells and T-cells. It is approved for rejection prophylaxis in KTR >18 yrs old. A phase I trial of adolescent KTR assessed SD bela PK and its PD effect, measured by % CD86 receptor occupancy (%CD86RO).

Methods: 9 EBV-positive KTR aged 13–17 yrs (mean 15.1 yrs) on CNI-based immunosuppression for >6 months post-KT received one IV bela infusion (7.5 mg/kg, 30 min). Blood was collected for PK serially over Days 1–57 and for %CD86RO on Days 1, 29, and 57. Adverse events (AEs) were recorded to Day 57 and serious AEs (SAEs) to Month 6.

Results: All 9 completed the study. Mean half-life ($t_{1/2}$), volume of distribution (V_{ss}), and systemic clearance (CL) in adolescent KTR were comparable to values from healthy adult volunteers (HV) and adult KTR (Table), indicating consistency across adolescent and adult populations. Mean %CD86RO increased with increasing bela concentration, indicating a direct PK/PD relationship (Figure). Three had 7 AEs, with 4 SAEs; all SAEs were considered unrelated to bela.

Conclusions: In adolescent KTR, the range of PK values was similar to those seen in HV and adult KTR. The PK/PD relationship between %CD86RO and bela concentration was similar to that seen in adults, providing a basis for dose selection in future adolescent studies. SD bela was well tolerated in the 9 adolescent KTR.

SA-PO505

Induction Immunosuppressive Therapy with One versus Two Basiliximab Dosage in Kidney Transplant Patients with Low Immunological Risk: Preliminary Report Diana A. Aguirre Campos, Luis A. Mariscal, Jesus Arellano. *Hospital General Dr. Miguel Silva, Morelia, Mexico.*

Background: The two basiliximab dosage is supported by phase III studies which established the optimal prescription with two 20 mg intravenous dose on day 0 and 4 of renal transplant. More recent studies have shown that one single doses(20mg) achieve adequate T cell suppression with similar clinical outcomes. There is no information about this topic on Mexican population The objective of the study is to compare one single 20mg dosage of basiliximab versus standard two dosage in patients with low immunological risk.

Methods: Single center, prospective, randomized 2:1 study that included kidney transplant patients between August 2012 and February 2016 with low immunological risk. Low immunological risk was defined as live donor with antibody reactive panel I and II less than 5%. Patients were randomized to receive one (1D) versus two basiliximab dosage (2D). Renal biopsies were indicated or by protocol at 6 months and one year after renal transplantation. Statistical analysis was performed using chi-squared test and Mann-Withney U test; the rejection-free survival curve was performed by Kaplan-Meier method. A preliminary report is presented

Results: At this moment 33 patients have been included, 23 men (69.7%), with a median age of 25 [21-34] years old and follow-up of 498 [304-722] days. There were 20 patients in the 1D group versus 13 patients on 2D group. No differences were found between demographic and clinical baseline data in both groups; the basal function of the graft was similar in both groups (creatinine 1.12 [0.8-1.3] vs 1.1 [0.9-1.2] mg/dL and GFR 85 [67-98] vs 89 [64-98] mL / min, p=NS, 1D vs 2D group, respectively), with no difference in delayed graft function, slow graft function or maintenance calcineurin inhibitor. The graft function at the end of follow-up was similar in both groups (creatinine 1.3 [1.1-1.5] vs 1.1 [0.9-1.4] mg/dL and GFR 77 [63-86] vs 79[54-102] mL/min, p=NS, 1D and 2D group respectively). Rejection-free survival was similar in both groups (Log rank=NS)

Conclusions: This preliminary report suggests that there is no difference in rejection-free survival and graft function at the end of follow-up with the 20 mg dose of basiliximab compared to 40 mg in patients with renal transplantation and low immunological risk. Should confirm this results with a large number of patients

SA-PO506

Induction Therapy with Low Dose Thymoglobulin versus Standard Therapy with Basiliximab: A Comparative Study of Safety and Effectiveness in Marginal Donor Kidney Transplant Recipients Giorgia Comai, Olga Baraldi, Vania Cuna, Matteo Ravaioli, Maria Cappuccilli, Gaetano La Manna. *University of Bologna, Bologna, Italy.*

Background: In renal transplant the most commonly administered induction immunosupprive therapy is based on Basiliximab, a chimeric non depleting anti-IL2-receptor monoclonal antibody, or Thymoglobulin, a polyclonal depleting agent. The use of Thymoglobulin in the recipients of marginal kidney transplants is an attractive opportunity, since besides the known anti-rejection effect, it has a protective potential against ischemia/reperfusion injury and the subsequent delayed graft function (DGF), thus allowing the reduction of maintenance therapy.

Methods: We retrospectively analyzed 71 patients who received a kidney transplant from marginal donors in the period 2013-2015 to assess the safety (incidence of infections, new onset diabetes after transplantation-NODAT, cardiovascular events) and efficacy (rejection rate, graft survival, DGF, graft function) of two different induction regimens during the 2-year follow-up period: Basiliximab (n=39) vs Thymoglobuline (n=32) at a very low dose (with a cumulative dose of 2 mg/kg).

Results: The two groups were similar for donor and recipient age, but there were different frequencies of double renal transplants: 4/39 (10.3%) in Basiliximab group and 18/32 (56.2%) in Thymoglobulin group (p<0.01). Likewise, ischemia interval and Karpinski score were higher in the Thymoglobulin group (p<0.05). The safety of the two induction regimens was comparable, as no significant differences were found in the incidence of infections, NODAT and cardiovascular events. Concerning the parameters used to evaluate efficacy, rejection rate, graft survival and DGF did not differ significantly between the groups, while serum creatinine (sCreat) and proteinuria were higher in Basiliximab group that in Thymoglobulin group (sCreat: 1.8 ± 0.3 vs 1.6 ± 0.4 mg/dL; p=0.019; urine protein levels: 37 ± 21 vs 17 ± 18 mg /dL; p<0.01).

Conclusions: Induction therapy with low dose thymoglobulin has been shown to have a comparable efficacy with Basiliximab, also showing an excellent safety profile. This finding appears to be promising, also in view of unfavourable characteristics of the transplanted patients included in the Thymoglobulin group, namely double kidney transplant, longer cold ischemia time and higher Karpinski score.

SA-PO507

Basiliximab versus Thymoglobulin Induction for Pancreas Transplant: A Retrospective Comparative Study of Graft and Patient Outcomes Yvonne El Kassis, Ziad S. Zaky, Emilio D. Poggio. *Cleveland Clinic, Cleveland, OH.*

Background: Induction therapy is common practice following pancreas transplant (PTx). According to the International Pancreas Transplant Registry, ≥90% of PTx recipients treated with induction receive depleting agents (Thymoglobulin aka ATG)

whereas <10% get IL2-receptor blockade (Basiliximab). Our center has historically used ATG induction but has more recently favored Basiliximab for simultaneous pancreas kidney transplants (SPK). We sought to retrospectively compare the graft and patient outcomes of SPK and pancreas transplant alone (PTA) recipients treated with either ATG or Basiliximab induction.

Methods: We reviewed all 242 cases of PTx at out institution between 2003 and 2014. Patients who received a pancreas after kidney (51) and those who did not receive induction (15) were excluded. From the remaining 176 patients, 105 received ATG induction at 4.5 mg/kg and 71 got Basiliximab 20mg on POD 0 and 4. Outcomes included 1 and 3-year graft survival, patients' survival, incidence of rejection episodes, time to first rejection episode, viral infections (CMV, BK, and EBV viremias), and malignancies.

Results: Mean duration of follow up was 81.6 ± 3.8 months (m) for the ATG group and 63.6 ± 3.4 for Basiliximab (p<0.01). All patients in the Basiliximab group had received an SPK whereas 44% of those who received ATG induction had a PTA (p<0.01). Maintenance immunosuppression was similar in both groups. Graft survival at 1 and 3 years were 96 and 88% for Basiliximab and 90 and 81% for the ATG group (p 0.05). Patients' mean survival was not different between both groups (121 ± 6 m for Basiliximab and 142 ± 5 for ATG, p=0.7). There was no statistically significant difference in the incidence of rejection, infections, or malignancies (Table 1).

Conclusions: Basiliximab appears to be a reasonable alternative for induction following SPK, and does not seem to be associated with a higher incidence of rejection, graft failure, or viral infections.

	Thymoglobulin	Basiliximab	p value
Rejection	25 (24%)	19 (27%)	0.65
Time to first rejection episode (months)	23.4 ± 7.6	13.2 ± 3.9	0.24
Infections (%)	33 (31%)	28 (39%)	0.27
CMV viremia (%)	17 (16%)	15 (21%)	0.40
BK viremia (%)	13 (12%)	12 (17%)	0.39
EBV viremia (%)	10 (10%)	6 (8%)	0.8
Malignancy (%)	9 (9%)	7 (10%)	0.77

SA-PO508

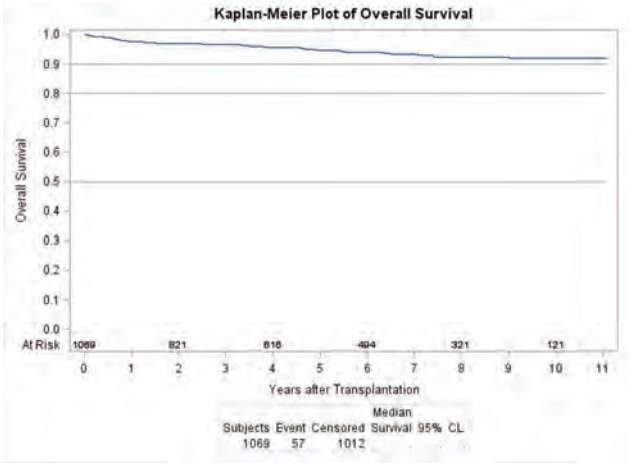
Low Dose Rituximab and Thymoglobulin Induction in a Steroid Free Protocol Involving Protocol Biopsies Improves Patient and Graft Survival at 11 Years after Kidney Transplantation Vivek Pathak. *Nephrology, Kovai Medical Center and Hospitals, Coimbatore, India.*

Background: The purpose of this study is to document long term patient and graft survival in a steroid free regime with a different induction protocol.

Methods: 1069 patients, who underwent renal transplantation at our institute in eleven years since July 2005 till Jan 2017 were studied. Thymoglobulin was used for induction at a dose of 1.5mg/kgm 3 doses in the first 5 days. Rituximab 200 mg was given to those patients who were considered to be at high risk for rejection and approximately 60 to 65% of the cohort received it. Maintenance immunosuppression was Tacrolimus and Mycophenolate mofetil. Prednisolone was rapidly discontinued by fifth post operative day. All patients underwent protocol biopsies at 3 months, 1 year, 5 years and 10 years indicated biopsies were done whenever required.

Results: The Patient and graft survival rates at 11 years were 92% and 85.4 % respectively. Biopsy proven acute rejection free graft survival was 78.1% at 11 years including subclinical rejections. The cumulative incidence of graft loss was 8.07%. The incidence of death was 5.3%. This is an improvement over the data published by Rizarri et al(CJASN 2012) where patient and graft survival rates were 70% and 61% repsectively at 10 years. The OPTN data in AJT December 2016 showed all cause graft failure >35% at 10 years whereas our all cause graft failure is 14.6% at 11 years. 79.07% patients were prednisolone free at 11 years.

Conclusions: The reasons for the improved patient and graft survival in our study in comparison to published literature could have been the addition of low dose pre-operative Rituximab, steroid withdrawal and aggressive cardiovascular screening resulting in low post transplant mortality due to ischemic heart disease, decreased incidence of BK virus induced graft loss, reduced death due to malignancy and reduction in fatal infections.



SA-PO509

Reassessing Thymoglobulin Induction in Kidney Transplantation (RETHINK): An Analysis of the Scientific Registry of Transplant Recipients (SRTR) Isa Ashoor,[1] Robbie A. Beyl,[2] Vikas R. Dharnidharka.[3] *[1]Pediatrics, LSU Health Sciences Center, New Orleans, LA; [2]Pennington Biomedical Research Center, Baton Rouge, LA; [3]Washington University School of Medicine, St Louis, MO.*

Background: Recent single center studies suggest lower dose Thymoglobulin (TMG) for induction in kidney transplant (KT) provides effective rejection prophylaxis comparable to higher dose TMG with less infectious morbidity. We sought to determine whether less TMG exposure is effective in a large national cohort of KT recipients.

Methods: All first time KT only recipients in SRTR on MMF and tacrolimus based immunosuppression who received TMG induction were analyzed. Recipients of expanded criteria donor kidneys or with delayed graft function were excluded. TMG exposure days were analyzed. Primary outcome was graft failure due to acute rejection or infection by 12 mo post KT. Logistic regression was used to identify covariates affecting primary outcome.

Results: 27,808 KT recipients met inclusion criteria (56% male, 52% Whites, 39% Living donor source). Most were adults (92% >21 years old) and transplanted in past 10 years since 2007 (70%). Recipients received a median of 4 days of TMG with 45% receiving 3 days or less. Low (≤3 days) and high (>3 days) TMG exposures differed in gender, transplant year, peak PRA, and HLA mismatch (**Table**). The primary outcome of graft failure due to acute rejection or infection within 12 mo post KT was seen in 197 recipients. Logistic regression identified worst odds of graft failure in relation to non-white race (OR 2.2), younger age ≤21 years (OR 3.7), and older transplant era prior to 2007 (OR 2) all with p-value <0.0001. Low TMG exposure was not detrimental to graft outcome and just missed significance for benefit (OR 0.76, p-value 0.06).

Conclusions: In this large cohort of first time KT recipients on contemporary immunosuppression with TMG induction, graft failure due to acute rejection or infection within 1 year was rare, and not influenced by TMG exposure days. Further studies are needed to confirm results using granular dosage information.

Everolimus [EVR]-Based versus Tacrolimus [TAC]-MPA Regimen in De Novo Kidney Transplant Recipients: 12 Months Safety and Efficacy Data from the Athena Study Duska Dragun,[10] Claudia Sommerer,[11] Ingeborg A. Hauser,[2] Barbara M. Suwelack,[3] Peter Schenker,[6] Oliver Witzke,[8] Christian Hugo,[12] Nassim Kamar,[7] Pierre Merville,[5] Martina Junge,[4] Björn Nashan,[1] Friedrich Thaiss.[9] *[1]Bundesärztekammer, Hamburg, Germany; [2]University Clinic Frankfurt (UKF), Frankfurt Main, Germany; [3]Muenster, Germany; [4]Novartis Pharma GmbH Germany, Nuremberg, Germany; [5]PELLEGRIN HOSPITAL, Bordeaux, France; [6]Ruhr-University Bochum, Bochum, Germany; [7]Toulouse University Hospital, Toulouse, France; [8]University Duisburg-Essen, Essen, Germany; [9]University Hospital, Hamburg, Germany; [10]University Hospital Charite, Campus Virchow, Berlin, Germany; [11]University Hospital of Heidelberg, HEIDELBERG, Germany; [12]University of Dresden, Dresden, Germany, Dresden, Germany. Group/ Team: Athena Study Group.*

Background: The ATHENA study was set up to compare EVR combined with TAC or cyclosporine A [CyA] vs. mycophenolic acid [MPA] combined with TAC in de novo kidney transplant [KTx] recipients.

Methods: In this 12 months [M] prospective, open-label, multi-center study 612 patients [pts] were randomized 1:1:1 at time of Tx to either EVR (3-8ng/ml M1-M12) + TAC(4-8ng/ml M1-M3; 3-5ng/ml M3-M12), or EVR (3-8ng/ml M1-M12) + CyA (75-125ng/ml M1-M3; 50-100ng/ml M3-M12) or TAC(4-8ng/ml M1-M3; 3-5ng/ml M3-M12) + MPA, all with steroids. Here we report M12 efficacy and safety (208 EVR +TAC, 199 EVR+CyA, 205 TAC+MPA pts).

Results: M12 Kaplan Meier estimates for treated BPAR were 6.7% in EVR+TAC, 17.6% in EVR+CyA and 3.9% in TAC+MPA group, with most events graded BANFF IA (1.9%; 9%; 1.5%), few (1.5%, 2% vs 0.5%) BANFF IIB/III. 5 pts in EVR+TAC, 5 in EVR+CyA and 6 in TAC+MPA died. Few graft losses occured: 10 pts (4.8%) in EVR+TAC, 13 (6.5%) in EVR+CyA, 6 (2.9%) in TAC+MPA arm, including 5 primary non-functioning grafts in each EVR-group and 1 in TAC+MPA arm. Safety profiles were comparable, incidences of AEs/infections leading to study drug discontinuation or dose adjustment/interruption were 56.7% in EVR+TAC, 55.5% in EVR+CyA vs 61.3% in TAC+MPA arm. Main reasons for changes were infections (7.1%EVR+TAC, 4.5%EVR+CyA, 23.5%TAC control) and lympho-/leucopenia (3.3%, 3.5%, 13.2%). No differences in AEs on wound complications were seen (sum-incidences: 41.9% EVR+TAC, 38.9% EVR+CyA, 43.2% TAC+MPA).

Conclusions: ATHENA as largest European KTx study confirmed good efficacy and event rates within international standards for all 3 groups with no unexpected safety events for this pts population. There were no differences in reported AEs wound healing and less leucopenia with EVR-based regimens.

SA-PO511

Randomized Controlled Trial Assessing the Impact of Conversion to Everolimus with Ultra-Low Tacrolimus Exposure on Graft Outcomes in Kidney Transplant Recipients David J. Taber,[3] Avudaiappan Chokkalingam,[2] Zemin Su,[3] Titte Srinivas.[1] *[1]Intermountain Medical Center, Murray, UT; [2]Mayo Clinic, Rochester, MN; [3]Medical University of South Carolina, Charleston, SC.*

Background: Despite low rate of acute rejection, the triple regimen of tacrolimus (FK), mycophenolate (MMF) and prednisone can increase the risk of late graft loss due to nephrotoxicity and opportunistic infections.

Methods: Single-center, randomized, controlled trial assessing the impact of a three month conversion to EVR with ultra-low FK exposure, compared to the regimen of full exposure FK with MMF (NCT 02096107). Adult, solitary kidney transplant recipients with a functioning graft at 3 months were eligible for inclusion. Goal trough levels in the intervention arm were 2-5 ng/mL for FK and 3-8 ng/mL for EVR, while FK was maintained at 5-12 ng/mL in the control arm.

Results: 60 patients were randomized (30 in each arm). Groups were well matched at baseline (3 months post-transplant), except there were fewer females in the intervention arm. FK levels were significantly lower in the EVR arm (Figure 1). At 12-months post-transplant, acute rejection rates (7% FK/MMF vs. 3% FK/EVR, p=0.554, Table 1) and graft function (mean eGFR FK/MMF 56±15 vs FK/EVR 59±14 mL/min/1.73 m^2, p=0.465; Figure 2) were similar between arms. The EVR/ultra-low FK arm had significantly lower rates of CMV infection, severe BK infection and improved BK viral clearance kinetics (Figure 3). All safety measures, including immunosuppression discontinuation, hospitalizations, and graft and patient loss were similar between arms (Table 1).

Conclusions: An immunosuppression conversion regimen of EVR with ultra-low exposure FK provides equally sufficient immunosuppression prophylaxis efficacy as compared to standard exposure FK and MMF, with the potential advantage of significantly lower rates of opportunistic viral infections, including BK and CMV.

Funding: Commercial Support - Novartis Pharmaceuticals

Table 1 – Clinical Outcomes by Study Arm

Outcome	Control FK/MMF	Intervention FK/EVR	p-value
Acute Rejection	7%	3%	0.554
BK Infection	13%	7%	0.389
Mild BK (<2,000 copies/mL)	0%	3%	0.313
Mod BK (2-10,000 copies/mL)	0%	3%	0.313
Severe BK (>10,000 copies/mL)	13%	0%	0.088
BK Nephropathy	7%	0%	0.150
CMV Infection	17%	0%	0.020
Other Infection	10%	13%	0.688

Median Intrapatient Tacrolimus Variability Is Comparable between Renal Transplant Centres: A Multicentre UK Retrospective Study Matthew J. Bottomley. *Oxford Kidney Unit, Churchill Hospital, Oxford, United Kingdom. Group/Team: UK Transplant Audit Collaborative.*

Background: Tacrolimus is an immunosuppressant with a narrow therapeutic window and regular serum trough level monitoring is necessary. Increased intrapatient variability (IPV) in these levels has been identified as a risk factor for graft rejection and loss after renal transplant. Previous reports have been from single centre studies with varying methodologies: thus it is unclear how comparable tacrolimus levels and hence IPV are between centres and studies.

Methods: A retrospective study was undertaken in five UK transplant centres using a unified methodology. Renal databases in all centres were interrogated to provide demographic details and laboratory results for all renal transplant recipients (RTR) between 1 January 2009 and 31 December 2014 who received tacrolimus therapy. RTR were excluded if they received dual-organ transplants or if death or graft loss occurred within two years of transplantation, or if their immunosuppression regimens included modified release tacrolimus. IPV was calculated from trough levels taken during the 6-12 month post-transplant period (T1) and the last 12 months of follow-up (T2).

Results: A total of 1070 eligible RTR across the five centres were included (Table 1). Despite variation in ethnic make-up and median age across centres, median tacrolimus IPV at both T1 and T2 was similar at around 14-16%. Across all centres male gender and non-Caucasian ethnicity were not associated with increased IPV. Increasing age did not correlate with IPV. There was no correlation between duration of transplant follow-up and T2 IPV.

Conclusions: In the first national retrospective study of this kind, we report that despite variation in population demographics between centres, median tacrolimus IPV is remarkably consistent. Increased IPV does not appear to be associated with age or ethnicity. This data will be pooled to enable formulation of a 'national standard' IPV, which will allow further study to assess whether RTR with an above median IPV have poorer transplant outcomes.

Table 1: Tacrolimus IPV in UK Transplant Centres

	Oxford (n=284)	King's London (n=134)	Liverpool (n=171)	Glasgow (n=168)	Manchester (n=313)
% Male	60.6%	76.1%	61.4%	63.8%	63.9%
Median (IQR) age at transplant	53 (42 - 61)	51 (40 - 59)	51 (39 - 60)	50 (39 - 56)	46 (37 - 57)
%Caucasian	80.6%	47.0%	88.9%	91.1%	71.9%
Median (IQR) T1 Tacrolimus IPV	15.4% (10.4 - 22.1)	14.8% (10.1 - 20.4)	16.4% (12.2 - 23.0)	15.6% (12.3 - 23.2)	15.9% (11.8 - 22.3)
Median (IQR) T2 Tacrolimus IPV	16.0% (10.3 - 24.0)	14.8% (9.8 - 23.9)	14.9% (8.9 - 21.1)	14.0% (9.4 - 19.5)	14.9% (10.6 - 23.7)

SA-PO513

Is There a Relationship Between HLA Mismatch and Intra-Patient Tacrolimus Variability in Kidney Transplant Patients? A Comparative Multi-Centre Retrospective Study Stavros Papachristos,[1] Bence Forgacs,[4] Anju john John velvet,[3] Okechukwu O. Okidi.[2] *[1]Transplantation Surgery, Central Manchester Foundation Trust, Manchester, United Kingdom; [2]Central Manchester NHS Foundation Trust UK, Manchester, United Kingdom; [3]Central Manchester University Hospitals NHS Foundation Trust, Manchester, United Kingdom; [4]Manchester Royal In irmasry, Manchester, United Kingdom. Group/Team: UK Tacrolimus Audit Collaborative.*

Background: Tacrolimus (Tac) is a critical component of immunosuppressive therapy after kidney transplantation (tx). It has been previously reported that high Tac Intrapatient Variability (IPV) (patient's trough level variability over time) is associated with higher rejection episodes and poor long term outcome after kidney tx. The relationship between HLA mismatch (MM) and Tac IPV has not been previously evaluated.

Methods: 1068 kidney transplant recipients in 5 UK centres between 2009-2014 and who were taking standard release Tac preparations were included in the study. IPV data was retrospectively collected from 2 time points – 6-12months post-transplant (T1) and the last 12 months of follow up (T2). Patients were divided into a high immunological risk HLA MM (HLA MM 4-6) and a low risk HLA MM group (HLA MM 0-3). Association between HLA MM and IPV was evaluated for each centre.

Results: Table 1 demonstrates the results of 1068 patients included from 5 UK centres. When comparing IPV≤20% and IPV>20%, there was no significant correlation with the high risk HLA MM group or the low risk HLA MM group (p>0.1 for all comparisons). The relation between HLA mismatch and Tacrolimus IPV did not reach significance in T1 and T2 periods in all centres.

Conclusions: This study represents the first and largest population based evaluation of relation between HLA mismatch and IPV. Our results demonstrate a clear evidence that HLA mismatch does not affect Tac IPV in either early or late post operative periods. This finding is consistent between 5 UK tx centres. Therefore, HLA mismatch should not be considered as a factor that affects Tac IPV for kidney transplant patients.

Table 1. Relation between HLA MM and Tac IPV for periods T1 and T2

		HLA MM 0-3 (Low Risk)		HLA MM 4-6 (High Risk)	
		IPV≤20%	IPV>20%	IPV≤20%	IPV>20%
Manchester (n=311)	T1	66.6%	33.3 %	67.5%	32.5 %
	T2	65.4 %	34.6 %	67.5 %	32.5 %
Glasgow (n=168)	T1	68 %	32 %	66.6%	33.3 %
	T2	76.6%	23.4%	77.7 %	22.3 %
Liverpool (n=171)	T1	65.5%	34.5%	67.3%	32.7 %
	T2	71.3%	28.7 %	67.3%	32.7%
Oxford (n=284)	T1	71.6 %	28.4 %	65.5%	34.4 %
	T2	63.4%	36.6%	75.5%	24.5%
King's College Hospital (n=134)	T1	70.8%	28.2%	68.4%	31.6%
	T2	65.6%	32.4%	65.8%	34.2%

SA-PO514

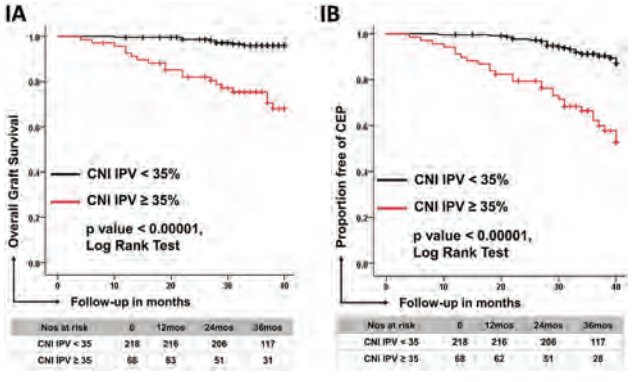
High Calcineurin Inhibitor (CNI) Intra Patient Variability (IPV) Is Associated with Early Renal Allograft Inflammation, Chronicity, and Loss Akhil Sharma,[3] Aravind Cherukuri,[1] Rajil B. Mehta,[1] Puneet Sood,[2] Sundaram Hariharan.[2] *[1]UNIVERSITY OF PITTSBURGH, Pittsburgh, PA; [2]University of Pittsburgh Medical Center, Pittsburgh, PA; [3]University of Pittsburgh Medical Center (UPMC), Pittsburgh, PA.*

Background: High CNI IPV has been associated with poor kidney allograft outcomes, albeit in small limited studies.

Methods: We evaluated effect of CNI IPV *(the degree of fluctuation of CNI levels in all patients over 2-12M post-transplant)* on early allograft inflammation, subsequent chronicity, graft loss (GL) and a composite end-point (CEP) of GL and impending GL (GLi defined as eGFR<30ml/min & 30% decline). 286 patients transplanted between 01/13-11/14 were enrolled with 2 Protocol Bx and any For-Cause Bx. The mean CNI values tested per patient was 37±15. The trough level < 6 ng/ml was considered as sub-therapeutic.

Results: CNI-IPV: The mean CNI-IPV was 28.5% and 1/4 of them had IPV≥35% (High IPV). High IPV was associated with more sub-therapeutic CNI levels (29% vs.11%, p<0.0001). Baseline demographic differences between those with high IPV and acceptable IPV were similar with a trend towards more non-Caucasian patients in the high IPV group. **Allograft Histology:** High IPV was associated with a higher incidence of subclinical & clinical acute rejection (AR) at 3mos (40.9% vs. 19.5%, p<0.0001), more persistent/recurrent AR at 1yr (18.2% vs 6.2%, p 0.002) and high-grade AR (≥Banff 1B, 27.5% vs 7.3%, p < 0.0001). Patients with *denovo* DSA & high IPV had more AR (24.6% vs. 9.1%, p=0.001). High IPV was associated with worse IFTA (p= 0.005) and IF+'i' (p < 0.0001) on 1yr protocol Bx. **Graft Outcomes**: High CNI-IPV was associated with increased GL (Fig1A) and GLi (Fig1B). Sub-analysis of patients with DGF and *denovo* DSA revealed that high IPV was associated with worse GLi. In a multivariate Cox Proportional Hazards Model, high CNI IPV was independently associated with GLi (HR 3.1, p=0.0005).

Conclusions: High CNI-IPV within 1 year post-transplant is associated with worse allograft outcomes including more severe acute rejection, allograft chronicity, GL, and GLi. Thus, this represents an early simple modifiable risk factor for allograft loss.



SA-PO515

Low Post-Transplant 1-Year Tacrolimus Level Is Associated with Poor Renal Allograft Survival in Kidney Transplant Patients Jung-hwa Ryu, Tai yeon Koo, Kyungok Min, Jaeseok Yang. *Seoul National University Hospital, Seoul, Republic of Korea.*

Background: Symphony study demonstrated that low-dose tacrolimus therapy with trough level between 3 to 7 ng/ml can achieve the best short-term renal allograft outcomes. However, it is still controversial that low tacrolimus exposure has good impact on long-term graft outcomes. Here, we investigated the association of tacrolimus trough-level at 1 year after kidney transplantation and graft survival rate.

Methods: This retrospective observation study included patients older than 18 year who underwent kidney transplantation under tacrolimus-based regimens in the Seoul university hospital between April 30, 1997 and June 8, 2016. Kaplan-Meier survival analysis and multivariate Cox regression analysis were performed according to tacrolimus trough-levels within 1 month and at 1 year after kidney transplantation.

Results: A total of 865 kidney transplant patients were included and 46 grafts failed during the study period. Tacrolimus levels < 7 ng/mL at 1 year after transplantation were associated with worse death-censored graft survival (Figure, P = 0.017). In multivariate analysis, tacrolimus < 7 ng/mL was an independent risk factor for poor graft survival (HR 0.469: 95% C.I. 0.235-0.936, P = 0.032). Furthermore, tacrolimus level < 7 ng/mL within 1 month was also associated with worse 10-year graft survival (P=0.007). However, there was no significant association between post-transplant 1-year tacrolimus levels and patient survival rate.

Conclusions: Keeping sufficient tacrolimus level (≥ 7 ng/mL) at 1 year after transplantation is beneficial for good long-term allograft survival.

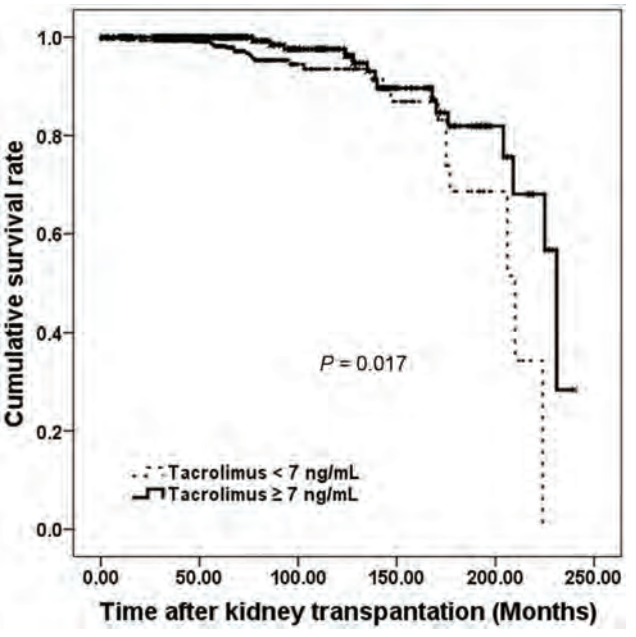


Figure. Renal allograft survival rates according to tacrolimus level of 7 ng/mL at 1 year after transplantation.

SA-PO516

Immunoadsorption and Rituximab Therapy Induces Sustained Reduction of Anti-Pneumococcal IgG in ABO Incompatible Kidney Transplantation Sian E. Faustini,[1,2] Andrew J. Bentall,[3,2] Nadezhda Wall,[1] Shazia Shabir,[2] Alex Richter,[1,2] Simon T. Ball.[2] *[1]University of Birmingham, Birmingham, United Kingdom; [2]University Hospitals Birmingham NHS Foundation Trust, Birmingham, United Kingdom; [3]Mayo Clinic, Rochester, MN.*

Background: Patients with chronic kidney disease (CKD) have a higher infectious burden than the general population. Immunosuppression in kidney transplantation increases infection risk further. In addition to conventional immunosuppression, ABO incompatible transplantation (ABOi) requires modulation of the recipient antibody (Ab) pool to reduce anti-donor blood group Ab, which may also reduce protective Ab.

Methods: This study measures specific-IgG against protein and polysaccharide vaccine antigens in 14 ABOi patients, who undergo immunoadsorption therapy and rituximab (IAR), and 37 patients who undergo ABO compatible (ABOc) transplant with conventional immunosuppression. Plasma samples were analysed for IgG directed against tetanus toxoid (TT) and 12 pneumococcal polysaccharides (PnPs), using a luminex bead based assay, at baseline and 12 months post-transplant for both cohorts and in addition, post-IA/rituximab for ABOi and 3 months post transplant for ABOc patients.

Results: At baseline, the ABOi and ABOc cohorts did not differ significantly in age or proportion of individuals with IgG titres above protective thresholds for TT (79 v 92%) or ≥ 8 Pneumococcal serotypes (50% v 65%). For ABOi, there was a significant reduction in anti-TT and 11/12 anti-PnPs titres from baseline to post-IAR (median reduction in titre of 17% and 27% respectively). For ABOc, there was significant reduction in anti-PnPs IgG titre for 8/12 serotypes tested at 3 months, but anti-TT IgG remained stable. At 12 months, the ABOc cohort had recovered anti-PnPs IgG titres to 10/12 Pneumococcal serotypes. In contrast, anti-PnPs IgG had only recovered for 2 serotypes in the ABOi group, despite anti-TT titres recovering to pre-transplant levels.

Conclusions: Both transplant cohorts had relatively low Pneumococcal, but good TT coverage pre-transplantation. Conditioning with IAR reduced specific IgG directed against non-blood group polysaccharide antigens such as PnPs. The ABOi cohort shower

a greater reduction in Pneumococcal IgG coverage than the ABOc group and this did not recover at 12 months. Our findings reveal the impact of IAR on protective antibodies and suggest an opportunity to revisit the timing of vaccination schedules.

SA-PO517

Weaning Immunosuppression in Patients with Failing Kidney Grafts: When and How? Hyunjin Ryu, Yong Chul Kim, Mi-yeon Yu, Yon Su Kim, Hajeong Lee. *Seoul National University Hospital, JongNo-Gu, Seoul, Republic of Korea.*

Background: Immunosuppressant (ISA) weaning protocol in failing allograft has not been established. Maintaining ISA would preserve residual renal function (RRF) and prevent graft intolerance syndrome (GIS) and sensitization, although it would increase risk of infection, malignancy and cardiovascular disease. However, there is no optimal ISA weaning protocol after GF.

Methods: We retrospectively reviewed graft failure (GF) cases after kidney transplantation (KT) in a single center. After excluding 424 patients with age under 19, death within 6 month after KT or 1 month after GF, and lost follow-up, a total of 131 GF patients were analyzed. Maintaining ISA was defined as either ≥10 mg of prednisolone (Pd) or combination treatment including Pd with calcineurin inhibitors or antimetabolites at 6 month after GF. ISA weaning was defined as either all ISA discontinuation or using < 10mg of Pd at 6 month after GF. Duration of low dose steroid usage after GF, which is < 10mg of Pd, were also reviewed. Outcomes were infection-related hospitalization, death, GIS, nephrectomy, and RRF represented as duration of diuretics usage.

Results: Among 131 cases, 34 (26%) were female and mean age at GF was 44.9±11.1 years. At the time of GF, 72 (55%) patients were maintaining ISA but 6 month after, only 22 (16.8%) patients were maintaining ISA. With low dose steroid usage, 60 (45.8%) and 33 (25.2%) patients maintained Pd at 6 and 12 months after GF. There were total 68 events of infection related hospitalization, 11 GIS, 20 graft nephrectomy (9 GIS, and 3 graft kidney cancers), and 17 deaths (8 Cardiovascular disease, 5 infection, 2 malignancy and 1 unknown) during median 216 months (range; 15-375 months) follow up. ISA maintaining significantly lowered patient survival rate (log rank P=0.027) than weaning. Moreover, it was an independent risk factor for mortality even after adjustment (odds ratio of 3.36, 95% CI 1.06-10.64, P=0.04). Infection related hospitalization, GIS and nephrectomy was not affected by ISA weaning protocol. However, low dose steroid maintaining at 6 and 12 months after GF, was protective in RRF preservation (P=0.002 and P<0.001, respectively).

Conclusions: In this study, we suggested that ISA should be maintained less than 6month after GF due to elevated mortality risk. However, lower dose steroid continuation up to 1 year after GF could be advantageous for preserving RRF.

SA-PO518

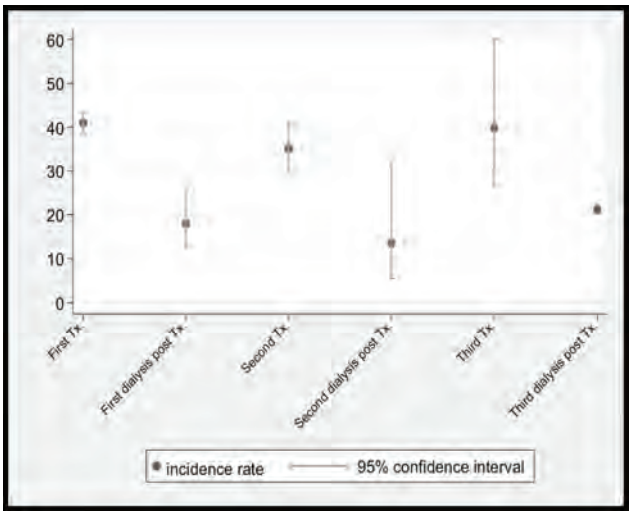
Non Melanoma Skin Cancer Risk Following Graft Failure in Renal Transplant Recipients in Ireland, 1994-2015: Does the Hazard Vary during Periods of Dialysis? Donal J. Sexton,[3,1] Patrick O'kelly,[4] Sandra Deady,[2] Peter J. Conlon.[1] *[1]Beaumont Hospital, Dublin 9, Co Dublin, Ireland; [2]National Cancer Registry, Ireland, Cork, Ireland; [3]The Irish Longitudinal Study on Ageing (TILDA), Trinity College Dublin., Dublin, Ireland; [4]Beaumont Hospital, Dublin, Ireland.*

Background: Non melanoma skin cancer (NMSC) is common after renal transplant. Whether the risk of skin cancer development varies as treatment for ESKD varies is not well described. We evaluated whether this risk is attenuated during periods of graft loss with a return to dialysis.

Methods: The National Kidney Transplant Service (NKTS) database was accessed for the years 1994-2015 and all recipients with available data were included in the analysis. This data was linked with the national Irish Cancer Registry (NCRI) to capture episodes of malignancy over follow up. In our analysis we considered end stage kidney disease (ESKD) treatment modality as a time varying covariate and calculated incidence rates, which may fluctuate between transplant and dialysis over follow up. Limitations include: difficulty in capturing the lag between exposure and diagnosis, which may vary by treatment period.

Results: 3,672 deceased and living donor adult kidney transplants were assessed comprising 2,310 (62.9%) male and 1,362 (37.1%) female recipients. Periods of treatment with functioning transplant had a higher incidence of skin cancer diagnosis [adjusted incidence rate ratio IRR 2.41 (1.72, 3.38), P<0.001]. Other risk factors for skin cancer included male sex, the number of transplants, and episodes of acute rejection. Tacrolimus was associated with a lower risk compared to cyclosporin however this may be due to a period effect, with longer follow up and ascertainment with ciclosporin.

Conclusions: The incidence of skin cancer was higher during periods defined by a functioning renal transplant and lower during subsequent periods of dialysis following graft failure. It is likely that periods defined by graft failure lead to lower overall immunosuppressive burden over follow up.



Non-Melanoma skin cancer incidence with ESKD treatment modality as a time-varying covariate.

SA-PO519

The Incidence and Predictors of Post-Transplant Lymphoproliferative Disease (PTLD) after Kidney Transplantation Anna Francis,[4] David W. Johnson,[2] Jonathan C. Craig,[3] Germaine Wong.[1] *[1]Auambie, NSW, Australia; [2]Princess Alexandra Hospital, Brisbane, QLD, Australia; [3]University of Sydney/Children's Hospital, Sydney, NSW, Australia; [4]University of Sydney, Sydney, NSW, Australia.*

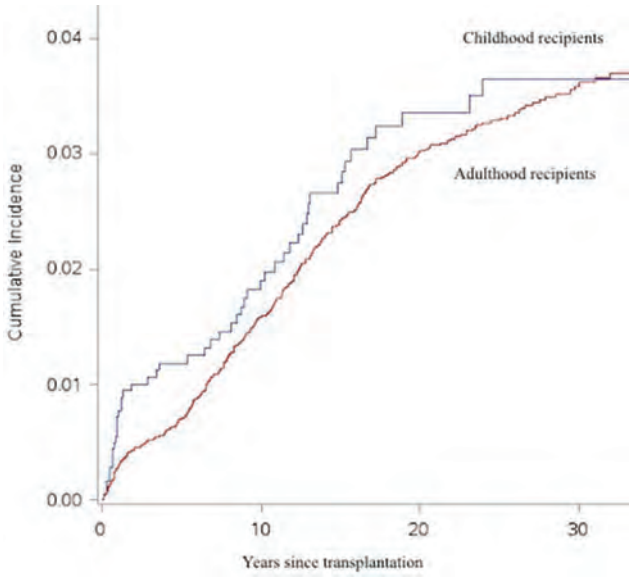
Background: PTLD is well described, but the long-term incidences and risk factors for PTLD for adult and paediatric renal transplant recipients remain unclear.

Methods: Using data from the Australian and New Zealand Dialysis and Transplant Registry (1963-2015), the cumulative incidence of PTLD in all kidney transplant recipients was calculated using a competing risk of death model and compared with age-matched population-based data using standardized incidence ratios (SIR). Risk factors for PTLD in the modern era of immunosuppression (from year 2000) were assessed using competing risk Cox regression.

Results: Among 23, 477 patients (92% adult, 60% male) followed for a median time of 8.5 years, 505 developed PTLD with 50/505 occurring in childhood (age at transplant under 20 years) recipients. The 25-year cumulative incidence of PTLD was 3.3% (95%CI 2.9-3.6%) for adult recipients and 3.6% (95%CI 2.7-4.8%) for child recipients (figure 1). Childhood transplant recipients had a 30-fold increased risk of developing lymphoma compared to the general population (SIR 29.5, 95%CI 21.9-38.8), higher than for adult transplant recipients (SIR 8.4, 95%CI 7.7-9.2). EBV negative recipient serology (adjusted hazard ratio [aHR] 2.85, 95%CI 1.69-4.81), year of transplantation (aHR 0.89 for each year after the year 2000, 95%CI 0.82-0.95) and having diabetes (aHR 2.53, 95%CI 1.37-4.67) were independently associated with PTLD, when adjusted for race, gender, age group and induction agent.

Conclusions: Lymphoproliferative disease in transplant recipients occurs at higher rates than in the general population, particularly in paediatric recipients. EBV-negative patients and those with diabetes are at increased risk of PTLD, however PTLD rates have been decreasing over the last 15 years.

Funding: Private Foundation Support



Cumulative incidence of PTLD post kidney transplantation

SA-PO520

Kidney Cancer after Renal Transplant: 9 Year Review Dennis Hu,[1] Suresh K. Rijhwani,[3,1] Harlan C. Rust,[3,1] Usama T. Hussein,[2,1] Sandeep Magoon,[4,1] Thomas R. McCune.[3,1] *[1]Eastern Virginia Medical School, Norfolk, VA; [2]Nephrology associates of tidewater, Virginia Beach, VA; [3]Renal Transplantation, Sentara Norfolk General Hospital, Norfolk, VA; [4]Nephrology, Nephrology Associates of Tidewater, Virginia Beach, VA.*

Background: Renal transplant patients are at increased risk of renal cell carcinoma (RCC). The overall incidence of RCC following renal transplantation from 1987-2010 is 5.68 times higher than in the general population. Possible explanations include immunosuppression leading to DNA repair interference, decreased host immune surveillance with resulting unchecked tumor development, and increased oncogenic viral infections. Due to the rapid growth and metastasis of RCC, renal ultrasounds (US) have been used as a screening tool; however, there is no guideline on the frequency of US after renal transplantation.

Methods: Retrospective chart review of 543 renal transplant recipients (age 21-75 at transplant) at Sentara Norfolk General Hospital from 1/1/07-10/31/16 was performed. All patients received similar immunosuppression regimens and serial routine post transplant renal ultrasounds. Patient characteristics including gender, race, age at transplant, underlying cause of ESRD, and US at 1, 3, 5, 7, and 9 years post-transplant were collected. If renal malignancy was found, tumor characteristics including timing of development, mass location, pathology, staging, and outcome was assessed. RCC incidence was calculated based on timing of US post-transplant.

Results: RCC incidence was 2.2% and found in 92% males and 8% females. RCC was found in patients aged 30-40 (16%), 40-50 (25%), 50-60 (16%), and 60-70 (41%) years old at transplant. Incidence on 0-1, 1-3, 3-5, 5-7, and 7-9 year ultrasounds post-transplant were 0.18%, 0.73%, 1.29%, 0%, and 0%, respectively. Median time of RCC diagnosis was 3 years post-transplant. Tumor characteristics were clear cell (33%), papillary (33%), oncocytoma (13%), tubulocystic (6%), and unclassified (13%). Staging was T1aNxMx (73%), T1bNxMx (20%), and T3aNxMx. (6.7%). 3 patients had different RCC in the same kidney. 1 patient had RCC 4.5 years after previous RCC. All patients had radical nephrectomies. Etiology of ESRD was HTN (33%), Diabetes (50%), and unspecified glomerulonephritis (16%).

Conclusions: US at 1,3,5 and 7 years post-transplant identified all RCCs and remained localized within the kidney. Men are at increased risk of RCC. PCKD is not associated with developing RCC. Multicentric development of RCC suggests that follow-up of remaining kidney after nephrectomy is required.

SA-PO521

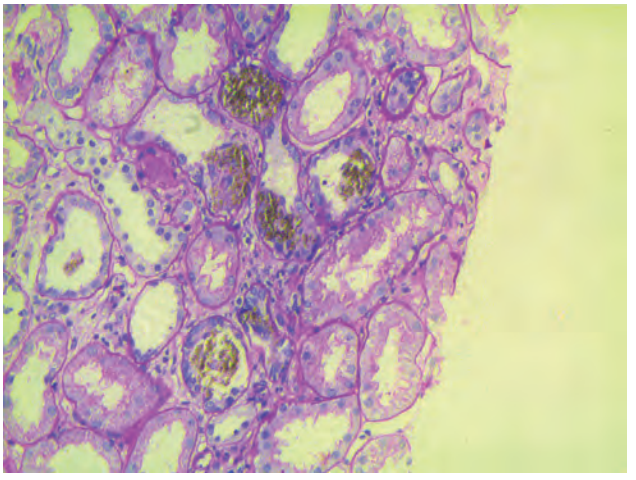
Recurrent 2,8 DHA Nephropathy Reversal in a Renal Allograft Recipient Vivek Pathak. *Nephrology, Kovai Medical Center and Hospital, Coimbatore, India.*

Background: APRT deficiency is a rare autosomal recessive inherited disorder of purine metabolism. In the absence of APRT, adenine is oxidized to 2,8 DHA and forms crystals resulting in nephrolithiasis and progressing to ESRD.This disease can cause recurrent renal allograft failure in post transplant patients. DHA stones are radiolucent and misdiagnosed as uric acid stones.

Methods: A 44 year old male was suffering from end stage kidney failure without any calculi. There was no family history of renal calculus disease. He underwent dialysis for 3 months and received kidney from his mother. He received triple immunosuppression. He had non-oliguric AKI post operatively and then renal function started worsening 4 weeks later A renal biopsy was done and it showed brown crystals favoring 2,8 DHA crystals. He was started on haemodialysis. Primary hyperoxaluria work up was negative. He was started on tab. Febuxostat 80mg a day due to suspicion of recurrent DHA nephropathy. A blood spot test showed very low level of APRT (courtesy Dr. Dawn Milliner, mayo Clinic) and a DNA analysis showed mutation of APRT gene. Patient gradually became better and creatinine came down from 7.8mg% to 2.7mg% in 4 months and is stable two-and-half years later.

Results:

Conclusions: This patient illustrates the importance of recurrent crystalline nephropathy in a post transplant patient. 2,8 DHA is an under-recognized cause of ESRD and can be prevented by correct diagnosis. This patient's diagnosis was not recognized pre-operatively. A repeat renal biopsy gave the first clue for the diagnosis. The diagnosis was confirmed by measurment of APRT activity in red blood cells and DNA analysis showed mutation consistent with APRT deficiency. This patient responded well perhaps due to early start of therapy with Febuxostat even before confirming the diagnosis. The disease must be considered in the differential diagnosis of crystalline nephropathy even in the absence of history of nephrolithiasis(Nasr et al NDT 2010).



SA-PO522

Association of Pre-Transplant Anti-LG3 Autoantibodies and Delayed Graft Function in Kidney Transplant Recipients Habib Mawad,[1] Julie Boucquemont,[3] Bethany J. Foster,[2] Heloise Cardinal.[1] *[1]Centre Hospitalier de l'Universite de Montreal, Montreal, QC, Canada; [2]McGill University Health Center, Montreal, QC, Canada; [3]Research Institute McGill Univ. Health Centre, Montreal, QC, Canada.*

Background: Pre-transplant antibodies to the LG3 fragment of perlecan (anti-LG3) are associated with an increased risk of delayed graft function (DGF) in kidney transplant recipients (KTR). Factors that increase susceptibility of the allograft to the deleterious effects of pre-transplant anti-LG3 antibodies have not been characterized. The aims of this study were to validate the association between pre-transplant anti-LG3 titers and DGF and to assess if this relationship is modified by longer ischemia or donor type.

Methods: We performed a retrospective cohort study in 2 Canadian adult kidney transplant centers. All consecutive KTR were recruited between June 1st, 2008 and July 20th, 2014. The primary outcome was DGF, defined as the need for dialysis within the first week after transplantation, failure of serum creatinine to decrease by more than 10% on the first 3 post-operative days, or serum creatinine >250 umol/L on post-operative day 5 in the presence of scintigraphic evidence of acute tubular necrosis. The main independent variable was pre-transplant anti-LG3 titers, measured with a locally-developed ELISA. Anti-LG3 >225 U/mL were considered positive. The interaction variables were ischemic time and donor type. Total ischemic time was dichotomized at the top quartile (15h). Donor type was classified as extended-criteria or deceased after cardiac-arrest vs. all other donor types.

Results: Among the 442 study subjects, 163 (37%) developed DGF. In multivariate analyses adjusted for donor type and ischemic time, positive anti-LG3 titers were associated with the occurrence of DGF (odds ratio (OR) 1.90, 95% confidence interval (CI) 1.18-3.07). The point estimates for the association between anti-LG3 and DGF were higher when total ischemic time was >15h (OR 2.51, 95% CI 0.89-7.78) vs. ≤15h (OR 1.80, 95% CI 1.07-3.00), but the interaction was not statistically significant. Similarly, the OR was higher for transplants from extended-criteria donors/donors after cardiac-arrest (OR 2.25, 95% CI 0.97-5.61) vs. other recipients (OR 1.60, 95% CI 0.90-2.78), but the interaction was not significant.

Conclusions: These results confirm that anti-LG3 are independently associated with DGF. Larger studies are needed to determine if ischemia and extended criteria donors/donors after cardiac arrest enhance the association between anti-LG3 and DGF.

SA-PO523

Frequent Histologic Recurrence of Lupus Nephritis after Kidney Transplantation M. Lourdes Gonzalez Suarez, Andrea G. Kattah, Fernando G. Cosio, Lynn D. Cornell, Mariam P. Alexander. *Mayo Clinic, Rochester, MN.*

Background: Recurrent lupus nephritis (RLN) has been described as uncommon after kidney transplantation (KTx), though reported incidences vary from 0 to 44%. RLN may be subclinical and therefore missed in some patients (pts) without protocol kidney biopsies (KBx). We aimed to assess the incidence and characteristics of histologic subclinical recurrence of lupus nephritis (SRLN) by protocol KBx.

Methods: A multicenter review of medical records of pts with lupus nephritis (LN) who underwent a KTx (January 1998-December 2012) was conducted. Baseline demographics, proteinuria, hematuria, LN class and KBx findings, graft and patient survival by Kaplan Meir were reviewed. A cohort of 60 pts with polycystic kidney disease (PKD) that had received a KTx in the same period was randomly selected as controls.

Results: We found 51 pts with LN who received a KTx in the participating centers. Population was predominantly female (66%); median age at time of KTx was 37±7. RLN, including SRLN and clinical RLN (CRLN) was seen in 29 pts (57%). Median time to any recurrence was 33.1 months. KBx was clinically indicated due to rising creatinine and/or BK viremia in 18 of 29 pts, and due to suspicion of RLN in 2 pts who had systemic flares. SRLN was found in 10 pts (34%). One of SRLN pts had concomitant acute rejection; 4 CRLN pts also had rejection. Among SRLN pts, hematuria was seen in 4 and mean proteinuria was 295 mg/24h (range 45-1433) vs. 9 of 18 CRLN pts had hematuria, and mean proteinuria was 1098 mg/24hr (range 100-4000) (p=0.1). Two CRLN pts had low complements (one had low C3 and C4, the other one only low C4); the rest of the CLRN pts and SRLN pts had normal complements. Graft loss occurred in 3 SRLN pts and 4 CRLN pts (30% vs. 22% accordingly). No difference was found in graft survival among SRLN, CRLN and PKD groups. Mean time to graft loss was 10.3±1.2 years in SRLN, and 7.6±0.7 years in CRLN (p=0.8). Patient survival was similar among SRLN, CRLN and PKD groups, with a median of 10 years (until time of follow up) (p=0.7).

Conclusions: RLN was found in more than half of our study population. There was clinical suspicion of recurrence in 2 cases. SRLN was found on 1/3 of protocol KBx. Our study showed that SRLN is common and can remain subclinical overtime, though did not impact graft loss or survival as compared to controls in this study population.

SA-PO524

Fate of Mesangial IgA Deposits in Donated Kidney after Transplantation Faiza N. Khan. *Sugar Land, TX.*

Background: IgA nephropathy is a primary cause of glomerulonephritis in the world with a recognized progression to ESRD and a known recurrence in transplanted kidney. However, the clinical significance of mesangial IgA deposits in healthy individuals and donor kidneys is unclear. Although, IgA deposits are often considered to be a precursor lesion to IgA nephropathy, the two entities likely have a distinct pathogenesis. Whereas IgA nephropathy results because of an aberrant IgA protein which activates the immune system causing mesangial damage, mesangial IgA deposits result from a high circulating load of normal IgA protein which deposit in mesangium due to filtration. Prior studies regarding mesangial IgA arise from eastern hemisphere where IgA nephropathy is common. We examined the frequency, clinical significance and histological fate of mesangial IgA deposits in our heterogenous population.

Methods: Donor baseline biopsies obtained at Houston Methodist Hospital during 2009-2016 were examined for IgA deposits noted with immunofluorescence. Subsequent biopsies of recipients of IgA positive deposits were examined for outcome of these deposits. Clinical data was obtained and two tailed T test was used to compare categorical variables.

Results: 958 baseline biopsies were examined. 94 biopsies had positive IgA deposits as the dominant or co-dominant immunoglobulin. An overall incidence rate of mesangial IgA deposits of 9.8% was noted with an incidence rate of 12.2% in deceased donor population and a rate of 6.3% in living donors. Of the 94 positive baseline biopsies, 43 recipients had adequate subsequent biopsies. During the first post-transplant year, 65% of the recipients showed complete resolution of IgA deposits and 12% with decreased IgA deposits. Mean time to resolution of IgA deposits in all re-biopsies was noted to be 295 days. Kaplan- Meier analysis (KM)of patient survival at 5 years showed 90% patient survival in IgA positive recipients vs 88% in recipients without IgA deposits. KM analaysis of graft survival at 5 years showed 88% graft survival in IgA positive donors vs 80% in donors without IgA deposits.

Conclusions: A higher incidence of mesangial IgA deposits were noted in deceased donors than living donors which may be secondary to systemic illnesses present in our deceased donors. Donor kidneys with IgA deposits have a higher incidence of delayed graft function but similar rate of patient and graft survival.

SA-PO525

Incidence and Treatment of Recurrent FSGS Following Kidney Transplantation in Patients with Pre-Emptive Plasmapheresis Meredith Harris, David K. Hooper. *Cincinnati Children's Hospital Medical Center, Cincinnati, OH.*

Background: Focal Segmental Glomerulosclerosis (FSGS) is a leading cause of end stage renal disease (ESRD) in children. Unfortunately, it reoccurs in up to half of patients following kidney transplantation. Pre-emptive therapeutic plasma exchange (TPE) has been suggested as a way to prevent recurrent FSGS, although few studies have evaluated its' efficacy. Once FSGS does recur, therapies such as rituximab and cyclosporine have been tried in combination with TPE to induce remission, but few studies report the efficacy of these therapies.

Methods: We performed retrospective chart review of 258 patients transplanted at CCHMC from May 2003 through November 2016 and identified patients with FSGS as the primary diagnosis. We then identified all patients who received at least one TPE treatment prior to kidney transplantation and evaluated the risk of FSGS recurrence. FSGS recurrence was compared between patients with 1 TPE treatment vs. ≥ 3 treatments. For patients with recurrent FSGS, we compared treatment in patients with early vs. late remission.

Results: 35/258 (14%) transplants had FSGS as the primary diagnosis, 20 of which received pre-emptive TPE. 11/20 (55%) patients with pre-emptive TPE experienced FSGS recurrence at a median of 3 days (range 1-90) post-transplant. 2/5 patients (40%) who received 1 pre-emptive TPE had recurrent disease compared 9/15 (60%) patients who received ≥ 3 TPE treatments (p =0.62). Of the 11 patients with FSGS recurrence, 10 (90%) achieved remission within a median of 9 months (range 1 – 24 mos). 8/11 patients received rituximab, 9/11 were switched from tacrolimus to cyclosporine, and all patients remained on TPE until remission was achieved. 5 patients experienced early remission (<3 months) whereas 6 had late (> 3 months) or no remission. Of 5 patients with early remission 100% switched to cyclosporine within 5 days of recurrent disease, compared to only 1/6 (17%) patients with late or no remission (p=0.015). 4/5 patients with early remission received rituximab compared to 4/6 patients with late remission (p=1).

Conclusions: Preemptive TPE does not prevent FSGS recurrence regardless of the number of treatments. Rapid switch to cyclosporine was associated with faster time to remission.

SA-PO526

Evolution of Post-Transplant Atypical Hemolytic Uremic Syndrome (aHUS) Silvana Maria C. Miranda,[1] Pedro Augusto M. Souza,[2] Gerson M. Pereira jr,[3] Carlos rafael A. Felipe,[3] Vanessa B. Souza,[1] Izabela L. Piana,[2] Andre S. Alvarenga,[3] Cláudia Ribeiro.[1] *[1]Hospital Santa Casa de Belo Horizonte, Belo Horizonte, Brazil; [2]None, Belo Horizonte, Brazil; [3]Santa Casa de Belo Horizonte, Belo Horizonte, Brazil.*

Background: The incidence of post-transplant thrombotic microangiopathy (PT-TMA) ranges from 1-5% and causes reduction of graft survival. Nevertheless, diagnosis of aHUS is difficult due to multiple potential triggers. Timely treatment of aHUS with eculizumab may improve prognosis.

Methods: Retrospective cohort review of 306 kidney transplant recipients (KTR) from September 2012 to September 2016 at a single brazilian center. PT-TMA was diagnosed by graft biopsy or thrombotic microangiopathic syndrome.

Results: The incidence of PT-TMA was 3.9% (n = 12). Of these, two were diagnosed with acute antibody-mediated rejection, one tacrolimus induced and nine with aHUS by excluding secundary causes. The etiology of renal disease was unknown in six patients of aHUS group. The other three cases were attributed to diabetic nephropathy, malignant arterial hypertension and membranous nephropathy. Fifty five percent of aHUS patients received prednisone, tacrolimus (TAC) and mycophenolate while the remaining received prednisone, tacrolimus and everolimus. Six had TAC trough levels greater than 10 ng/mL, two greater than 20 ng/ml and none had everolimus trough levels greater than 6 ng/mL. All nine patients received eculizumab, two of which received plasmapheresis with no response. Median time from transplant to aHUS diagnosis was 81 (35.5 – 134.5) days. Median time from diagnosis to eculizumab treatment was 17 (4.5 – 134) days and was not different between those whose grafts survived or not. After eculizumab creatinine improved in five patients, three remain on dialysis and one suffered sudden death after two doses. Two of those who improved renal function, died, one from gastrointestinal bleeding and one from sepsis of cutaneous infection. Death censored graft survival was 55.6% in six months versus 83.5% in those who did not have aHUS. No graft failed after 6 months in aHUS group.

Conclusions: aHUS occurred until 6 months PT-TMA and was related to tacrolimus trough levels above 10 ng/mL in 66% of patients. aHUS has a great impact in graft survival leading to very poor prognosis. Time from diagnosis to treatment with eculizumab did not correlate to better graft survival, but the small sample size should be considered when interpreting these results.

SA-PO527

Monoclonal IgG Deposits on Tubular Basement Membrane in Renal Allograft: Is This Significant for Chronic Allograft Injury? Anri Sawada,[3,5] Kunio Kawanishi,[4] Sekiko Taneda,[3] Masayoshi Okumi,[3] Kazuya Omoto,[3] Tomokazu Shimizu,[3] Hideki Ishida,[3] Kazuho Honda,[1] Shohei Fuchinoue,[3] Motoshi Hattori,[3] Kazunari Tanabe,[3] Junki Koike,[2] Yoji Nagashima,[3] Kosaku Nitta.[3] *[1]Showa University School of Medicine, Shinagawa-ku, Tokyo, Japan; [2]St.Marianna University, Kawasaki, Kanagawa, Japan; [3]Tokyo Women's Medical University, Shinjuku-ku, Japan; [4]University of California, San Diego, La Jolla, CA; [5]Nippion Medical School, Tokyo, Japan.*

Background: In renal allografts, tubular basement membrane immune deposit (TBMID) has often been observed. Such deposits are usually found in association with BK virus nephropathy and immune complex glomerulonephritis; however, their significance is not well-understood. In recent years, monoclonal immunoglobulin (Ig) G deposition in the glomeruli has been reported. However, monoclonal IgG TBMID has not been studied until now. Therefore, we conducted a retrospective clinicopathological study on monoclonal IgG TBMID.

Methods: In total, 7177 biopsy specimens obtained in our institution from 2007 to 2015 were studied. Conventional light and electron microscopic studies and indirect fluorescence immunostaining for Ig heavy and light chains and complements C1q and C3c were performed. Monoclonal IgG TBMID was diagnosed if an IgG subclass or light-chain restriction was present and all other antibodies were absent in TBMID.

Results: Ten patients showed monoclonal IgG TBMID. Of these, seven showed monoclonal IgG1κ TBMID and three showed monoclonal IgG2κ, IgG2λ, and IgG3κ TBMID, respectively. In all patients with monoclonal IgG1κ TBMID, abundant and large granular electron-dense deposits (EDD) were detected in the tubular basement membrane (TBM). EDD was absent in TBM in patients with monoclonal IgG2κ, IgG2λ, and IgG3κ TBMID. On the other hand, eight patients showed polyclonal IgG TBMID. Progression of interstitial fibrosis and tubular atrophy (IFTA) was significantly higher in patients with monoclonal IgG and IgG1κ TBMID compared with that in those with polyclonal IgG TBMID ($P < 0.05$). There were no significant differences in the other clinical parameters between monoclonal IgG and IgG1κ and polyclonal IgG TBMID.

Conclusions: This is the first study on patients with monoclonal IgG TBMID in renal allografts. We found that monoclonal IgG1κ TBMID was associated with EDD formation in TBM and the progression of IFTA.

SA-PO528

Allograft Crescent Predicts Graft Failure in Recurrent IgA Nephropathy Patients Sehoon Park, Hyunjeong Cho, Mi-yeon Yu, Yaerim Kim, Yon Su Kim, Hajeong Lee. *Seoul National University Hospital, SEOUL, Republic of Korea.*

Background: Recent studies demonstrated the predictive value of crescent in IgA nephropathy (IgAN) prognosis. However, it remains unclear whether allograft crescent is associated with worse graft prognosis in patients with recurrent IgAN.

Methods: We reviewed 376 IgAN patients who received kidney transplantation from 1979-2016 in a university hospital in Korea. Allograft biopsies were performed when patients had a significant proteinuria, hematuria, or a progressive deterioration of renal function. Clinical and pathologic characteristics at the time of biopsy were collected in recurrent IgAN cases. The degree of the crescent formation was classified into prominent (> 10%), mild (0-10%), and none (0%). The renal outcome was death-censored graft failure (DCGF).

Results: During the follow-up duration of 7.0 (3.7-14.3) years, 122 (32.3%) patients were diagnosed as recurrent IgAN by allograft biopsy. Median time to recurrence was 4.1 (1.9-8.1) years. Recipients who recurred their IgAN were younger. They were donated allograft from younger donor and received less induction immunosuppressive treatment. Among the recurred IgAN patients, 36 (29.5%) reached graft failure after 9.3 (5.7-12.2) years from their transplantation. Moreover, IgAN recurrence itself was a strong time-dependent risk factor for DCGF (adjusted HR 2.703, 95% CI 1.608-4.545, P<0.001). Regarding the pathologic findings, crescent was identified in 20 patients with recurrent IgAN, in those with relatively old graft age, decreased renal function at the time of IgAN recurrence, and higher MEST scores. All five patients with prominent (>10%) crescent formation in their allograft biopsies progressed to consequent DCGF within from 0.4 to 4.6 years after the IgAN recurrence. Also, the presence of prominent (>10%) crescent in transplanted kidney was a strong risk factor for DCGF when compared with other recurrent IgAN patients without crescent formation (adjusted HR 6.313, 95% CI 1.699-23.458, P=0.006), even after adjustment of MEST scores and coexisting rejection.

Conclusions: Despite its rarity, a prominent allograft crescent (>10%) was demonstrated to attribute to rapid renal deterioration in recurrent IgAN patients. Treatment strategies for those patients should be investigated.

SA-PO529

When Post-Transplant IgA Deposition Is Not Recurrence Claire Kennedy,[5,6] Darren McMahon,[4] Orna Waldron,[7] Andrea M. Fitzmaurice,[1] Patrick O'kelly,[1] Megan R. Finan,[3] Brendan Doyle,[1] Anthony M. Dorman,[1] Peter J. Conlon.[2] *[1]Beaumont Hospital, Dublin 9, Ireland; [2]Beaumont Hospital, Dublin 9, Co Dublin, Ireland; [3]Beaumont hospital, Dublin 1, Ireland; [4]University College Dublin, Monaghan, Ireland; [5]Department of Nephrology, Beaumont Hospital, Dublin, Ireland; [6]Royal College of Surgeons Ireland, Dublin, Ireland; [7]Royal College of Surgeons in Ireland, Dublin, Ireland.*

Background: Immunoglobulin A (IgA) deposition in the post-transplant setting usually represents disease recurrence but can occasionally represent donor-related or *de novo* disease. We aimed to examine post-transplant outcomes in the setting of donor-related or *de novo* IgA deposition and compare patient and graft outcomes in these cohorts to those in all other Irish renal transplant recipients during a similar time period.

Methods: All renal biopsy records from 1/1/1995 to 31/12/2012 (n=7296) were reviewed to identify those with post-transplant IgA deposition. Detailed chart review was performed to identify those in whom the IgA deposition was deemed donor-related (<6 months post-transplant) or *de novo* (>6 months post-transplant) as opposed to recurrent. A retrospective research MEST score (0-7) was assigned to each biopsy. The National Kidney Transplant Service database was accessed to facilitate a comparison of patient and graft outcomes in these cohorts and all other renal transplant recipients.

Results: Fifteen cases of post-transplant IgA deposition were deemed to be donor-related (fourteen deceased donors) and had a mean research MEST score of 1.65 (range 0.32-3.03). Serial biopsies in seven of these cases showed resolution of the deposits over time. Eight cases were deemed to represent *de novo* IgA deposition. The mean research MEST score, which is less specific in this setting, was 2.60 (range 1-4). There were no differences in patient and graft survival rates in these groups compared to all other transplants performed during a similar time period. Cox regression multivariate analysis did not identify either donor-related or *de novo* IgA deposition as a contributing factor to patient or graft survival.

Conclusions: Cases of donor-related or *de novo* IgA deposition were infrequently encountered in our review of 'for-cause' biopsies. Neither condition, when histologically mild-moderate, was found to impact on patient or graft survival rates. These results cannot be extrapolated to the setting of living donation. This information is important for prognostication and counselling purposes in selected future cases.

SA-PO530

Long-Term Prognosis of Kidney Transplant Patients with Rapidly Progressive Glomerulonephritis (RPGN) Talar Kharadjian,[2] Brad C. Astor,[1] Sarah E. Panzer,[2] Tripti Singh.[2] *[1]University of Wisconsin, Madison, WI; [2]School of Medicine and Public Health, University of Wisconsin, Madison, WI.*

Background: ANCA associated vasculitis (AAV) and anti-GBM are the leading cause of ESRD due to RPGN. We report our institution's experience with renal transplant patients in patients with ESRD due to RPGN.

Methods: We compared the outcomes for patients with ESRD due biopsy-proven AAV and anti-GBM with patients with ESRD due to IgA nephropthy (IgAN) and autosomal dominant polycystic kidney disease (ADPKD) who underwent kidney transplant between 1994 to 2013.

Results: 72 patients with biopsy proven RPGN (AAV N=46, anti-GBM N=26) underwent kidney transplant between 1994-2013. The mean follow up time was 7.2 years (± 4.7 years). The incidence of graft loss was 2.9/100 person years for AAV and 5.2/100 persons year for anti-GBM. The incidence of patient death was 3.8/100 person years for AAV and 3.2/100 person years for anti-GBM. The risks of graft loss and patient death were similar to those for IgAN (2.8 and 2.2/100 person years) in multivariable analysis (Table 1). 10-year death censored graft survival for AAV and anti-GBM was similar to IgAN and ADPKD (Fig1).

Conclusions: Long-term patient and graft survival for patients with ESRD due to AVV and anti-GBM after kidney transplant was good and similar to ESRD due to IgAN and ADPKD post transplantation.

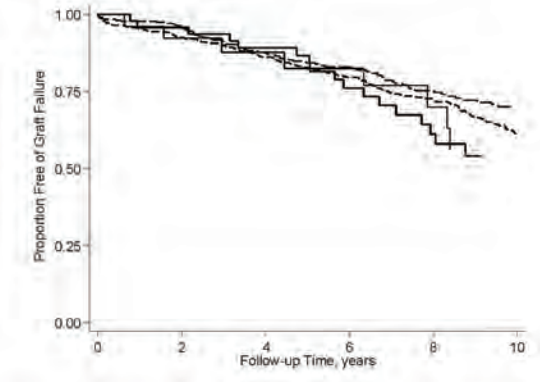


Fig 1. Kaplan-Meier curve of allograft survival in transplant recipients with GPA (thin black line), anti-GBM (bold black line), IgAN (thin dashed line), ADPKD (bold dashed line)

		Glomerular disease diagnosis		
		AAV	Anti-GBM	IgAN
Death-censored graft loss	Incidence Rate (per 100 person-years)	2.9 (p=.87)	5.2 (p=.06)	2.8 (Reference)
	Adjusted relative HR*	1.09 (.49, 2.47) p=.83	1.31 (.52, 3.33) p=.57	1.0 (Reference)
Death	Incidence Rate (per 100 person-years)	3.8 (p=.06)	3.5 (p=.25)	2.2 (Reference)
	Adjusted relative HR*	1.18 (.53, 2.66) p=.69	0.55 (.17, 1.79) p=.32	1.0 (Reference)

SA-PO531

PLA2R De Novo Membranous Nephropathy and Antibody Mediated Rejection in a Renal Allograft Marika Manolopoulou,[1] Kathy L. Jabs,[1] Mark Lusco,[2] Paisit Paueksakon.[1] *[1]Vanderbilt University Medical Center, Nashville, TN; [2]Vanderbilt University School of Medicine, Nashville, TN.*

Background: The pathophysiology of de novo membranous nephropathy (dnMN) is not clearly understood but may be associated with antibody-mediated rejection (AMR) in the allograft. The presence of phospholipase A2 receptor (PLA2R) antibodies usually indicates recurrent MN or dnMN not associated with AMR. We present a case of PLA2R positive dnMN in the presence of AMR and its resolution by histologic evidence upon rejection targeted treatment.

Methods: Our patient is a 19-year old male with end stage renal disease due to obstructive uropathy who received a deceased donor kidney transplant in 6/2015.

His immunosuppression included anti-thymocyte globulin (ATG) induction therapy, and maintenance with prednisone, mycophenolate mofetil, and tacrolimus. Post-transplant his serum creatinine (sCr) was stable at 0.99 mg/dl. Fourteen months post-transplant he presented with with a creatinine of 2.2 mg/dl in the setting of likely medication nonadherence. A renal transplant biopsy revealed acute cellular rejection (ACR), AMR (peritubular capillaritis with C4d positivity in >50% of capillaries) and serum donor specific antibody (DSA) positivity. There was also PLA2R positive membranous nephropathy. His infectious workup was negative. He was treated with pulse methylprednisolone, ATG, plasma exchange, intravenous immunoglobulin (IVIG) and rituximab. His sCr decreased to 1.03 mg/dl at hospital discharge. His interval follow up demonstrated stable renal function. At nineteen months post-transplant his sCr was 1.57 mg/dl, he had negative DSA and undetectable tacrolimus trough level. He was next seen 3 months later with allograft pain and a sCr of 7.0 mg/dl. Renal biopsy was consistent with ACR, microcirculation inflammation suspicious for AMR (negative C4d, positive DSA) and no evidence of membranous nephropathy. He was treated with ATG, methylprednisolone, rituximab, plasma exchange, and IVIG and his sCr decreased to 3.7 mg/dl.

Results:

Conclusions: While the pathophysiology of dnMN remains to be elucidated, this disease entity is currently viewed as an alloimmune disease mediated by chronic AMR. In contrast to idiopathic MN, dnMN associated with AMR has not been found to be PLA2R positive. Although rare, the presence of PLA2R positive dnMN should be considered in the setting of AMR. Further study and long term follow up of these patients will help us gain a better understanding.

SA-PO532

Characteristics of Donor Transmitted Membranous Nephropathy in Kidney Transplantation Yasuhiro Otsuka, Yoshihiko Watarai, Asami Takeda. *Nagoya Daini Red Cross Hospital, Nagoya, Japan.*

Background: Donor transmitted membranous nephropathy (MN) is unique entity that shows histological features of MN even though donor urinalysis is negative for protein before kidney transplantation (KTx). Donor transmitted MN is rarely seen in KTx, but its prognosis and histological changes are unclear.

Methods: Retrospective data were collected from 2002 to 2016. Out of 1113 KTx cases, eight patients were diagnosed with donor transmitted MN by 1 hour biopsy. All eight cases were living KTx, and posttransplant renal function and urinary protein of both donor and recipient were analyzed. Protocol renal allograft biopsies were performed one hour, three weeks, and one year after KTx, and light microscopy, immunofluorescent study for IgG, C3, C4d, and IgG subclass, and electron microscopy were performed.

Results: Donor age was 61.1 ± 13.1 years, and four were male. Urinalysis was negative for protein in all eight donors. Donor eGFR and urinary albumin creatinine ratio (UACR) before KTx was 83.0 ± 11.2 ml/min/1.73m^2 and 38.0 ± 38.7 mg/g. Donor eGFR and UACR one year after KTx was 51.5 ± 9.1 ml/min/1.73m^2 and 3.5 ± 0.9 mg/g. Donor follow up period was 43.1 ± 43.9 months, latest eGFR and urinary protein was 50.6 ± 10.1 ml/min/1.73m^2 and 0.08 ± 0.12 g/day. Recipient age was 38.6 ± 7.0 years, five were male, and all eight cases were ABO compatible KTx. Recipient eGFR and urinary protein one year after KTx was 41.6 ± 11.9 ml/min/1.73m^2 and 0.14 ± 0.08 g/g. Recipient follow up period was 52.0 ± 43.0 months, latest eGFR and urinary protein was 37.5 ± 6.8 ml/min/1.73m^2 and 0.11 ± 0.20 g/day. In immunofluorescence study for IgG, one case out of five cases was negative at three weeks biopsy and five out of six was negative at one year biopsy. Four out of five were positive for C4d on capillary wall at one year biopsy. IgG subclass stain revealed that one case was negative for IgG4. By light microscopy, bubbling appearance was observed at one hour and one year biopsy in all available cases. By electron microscopy, stage did not change at one year biopsy except one case from Ehrenreich–Churg stage III to stage IV.

Conclusions: This study suggest that deposition of IgG in donor transmitted MN decreases within one year after KTx. Clinical data showed a good renal function and urinary protein within normal limit at latest follow-up in both donor and recipient.

SA-PO533

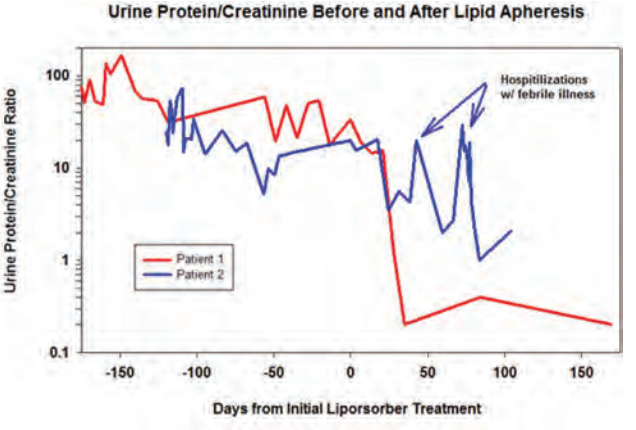
Successful Remission of Recurrent FSGS Following Lipid Apheresis in Renal Transplant Recipients Lokesh N. Shah,[8,9] Christopher J. LaRosa,[7] Justine Speckhals,[2] Carolyn Tait,[1] Kimberly A. Lasalvia,[6] Kyla Clark-Freeman,[4] Divya G. Moodalbail,[3] Joshua Zaritsky.[5] *[1]Nemours A.I. duPont Hospital for Children, Wilmington, DE; [2]Nemours/ Alfred I. DuPont Hospital for children, Avondale, PA; [3]Nemours/ Alfred I. duPont Hospital for Children, Wilmington, DE; [4]Nemours/Alfred I DuPont Hospital for Children, Wilmington, DE; [5]Nemours/Alfred I. duPont Hospital for Children, Wilmington, DE; [6]Nemours/ duPont Hospital for Children, Wilmington, DE; [7]None, Wilmington, DE; [8]Thomas Jefferson University, Philadelphia, PA; [9]Alfred I duPont Hospital for Children, Wilmington, DE.*

Background: The Liposorber® LA-15, a lipoprotein apheresis device, has been used as a rescue therapy in patients with recurrent primary focal segmental glomerulosclerosis (FSGS). Using a protocol of weekly lipid apheresis in combination with IV methylprednisolone, we describe the remission of recurrent FSGS in two pediatric kidney transplant recipients.

Methods: Both patients were diagnosed with steroid-resistant biopsy-proven FSGS at age 2. They failed to respond to multiple interventions (high dose steroids, high dose calcineurin inhibition, mycophenolate, and rituximab). They eventually underwent renal transplantation due to ensuing ESRD. Both post-transplantation courses were complicated by immediate recurrence of FSGS with urine protein/creatinine (Up/cr) ratios > 50. Again, both failed to respond to high dose steroid and calcinuerin inhibition; nor did they respond to 3 months of thrice weekly standard plasmapheresis. As a rescue therapy both patients underwent weekly lipid apheresis using the Liposorber® LA-15 system with a treatment volume of 60 mL/kg along with a 10 mg/kg dose of IV methylprednisolone. The final cycle of lipid apheresis occurred approximately 80 days after its initiation in both patients. In both cases there was a dramatic decrease in the urine protein to creatinine ratios (FIGURE). After stopping lipid apheresis both patients have remained in clinical remission without further treatment.

Results:

Conclusions: Lipid apheresis has shown promise in the treatment of both primary and recurrent FSGS; however, experience with this modality is limited. Our successful use of lipid apheresis in combination with methylprednisolone to induce remission in treatment resistant recurrent FSGS provides a protocol for future studies, and provides a better understanding of the ill-defined pathophysiology of hyperlipidemia and nephrotic syndrome.



SA-PO534

Recurrent FSGS in Renal Transplantation: A Single Centre Experience Marilina Antonelou,[1] Omid sadeghi-alavijeh,[1] Daniel P. Gale,[1] Gareth L. Jones,[2] Alan D. Salama.[1] *[1]University College London, Centre For Nephrology, London, United Kingdom; [2]Royal Free London NHS Trust, London, United Kingdom.*

Background: Renal transplantation in patients with Focal segmental glomerulosclerosis (FSGS) is often complicated by disease recurrence which is associated with poor outcome. There are no reliable tests to predict recurrence of FSGS after transplantation. The aim of this study was to evaluate if clinical criteria can identify patients at high risk for recurrent disease.

Methods: Retrospective review of patients diagnosed with FSGS who received a renal transplant in our centre between 1995 and 2017. The diagnosis of primary FSGS was based on a native renal biopsy or unexplained proteinuria and a family history of kidney disease. Recurrence of FSGS was defined as the occurrence of proteinuria, greater than 100 mg/mmol after transplantation with histological evidence of FSGS.

Results: We identified 99 patients with FSGS who received a kidney transplant. Twenty five (25.2%) had biopsy proven recurrent FSGS. The median interval from transplantation to onset of proteinuria was 3.1(1-28)months. A comparison of baseline and follow-up data is shown in Table 1. The median interval between onset of proteinuria and a renal biopsy confirming the diagnosis of recurrent FSGS was 2.7(1.1-4.3) months. Nine patients did not have histological evidence of FSGS on their initial biopsy. None of the 25 patients with recurrent FSGS had a family history of kidney disease. Seven patients had a previous failed transplant, four following FSGS recurrence.

Conclusions: Our data suggest that primary, as opposed to secondary FSGS is a reliable marker of increased recurrence risk in patients with FSGS undergoing renal transplantation. The family history is a useful tool for risk stratification. Close monitoring for proteinuria is important for the initiation of treatment as histological changes might not be present at the early disease stage.

	Recurrence (n=25)	No recurrence (n=74)	p value
Gender (male,%)	14(56)	45(60.8)	0.81
Age of onset of disease (years)	26(16-43)	37(30-47)	0.14
Primary FSGS (n,%)	24(96)	57(77)	0.03
Family history of kidney disease (n,%)	0	9(12.2)	0.10
Live donor (n,%)	8(32)	22(29.7)	0.80
Cadaveric donor (n,%)	17(68)	52(70.3)	
Patients with ≥1 failed transplant (n,%)	7(28)	5(6.8)	0.001
Interval from transplantation to last follow-up (LTFU) (years)	2.9(1.5-15.4)	8.1(3.1-15.3)	0.09
Creatinine at LTFU (mmol/L)	167(123-347)	139(108-188)	0.19

Clinical Findings, Pathology, Treatment, and Outcomes of PGNMID after Kidney Transplantation Hassan A. Salameh, Hatem Amer, Ladan Zand, Fernando C. Fervenza, Nelson Leung. *Mayo Clinic, Rochester, MN.*

Background: Proliferative glomerulonephritis with monoclonal immunoglobulin deposits (PGNMID) is a rare form of glomerular disease caused by monoclonal immunoglobulin (Ig) deposition localized to the glomeruli. The outcome of recurrent PGNMID in renal allografts is not well known and to our knowledge has been reported in only 12 patients. We describe a single centers' experience with PGNMID after kidney transplantation (KTx).

Methods: Between 2000 and 2016 we identified 20 patients with PGNMID who underwent KTx. We describe their clinical findings, labratory data, recurrence rates, biopsy findings, treatment and outcomes during the study period.

Results: The median age at the time of native kidney biopsy-proven PGNMID was 54 (range 23-74) years. Median time between the initial kidney biopsy to ESRD (KTx or dialysis) was 36 (range 2-146) months. Post-transplant, PGNMID recurred in 18 out of 20 patients (90%). The median time to recurrence in the kidney biopsy was 4 (range 1-48) months (Figure 1). Four patients did not receive targeted treatment for the PGNMID recurrence and no graft loss was noted with median follow-up of 48.5 months. Three patients were treated with additional immunosuppressive agents including steroids and cyclophosphamide and 33% (n=1) had graft loss in this group. Seven patients received B-cell targeted therapy with Rituximab with graft loss rate of 28% (n=2). Four patients received plasmapheresis in addition to immunosuppressive therapy; graft lost in 75% (n=3); however; only 25% (n=1) was attributed to PGNMID with the other two loses due to rejection.

Conclusions: In our experience, PGNMID was associated with a very high rate of recurrence in allografts reaching 90%. Graft loss occurred in 33% of recurrent cases. The median time to graft loss was 67 (range 31-132) months. Graft loss incidence due to PGNMID was similar between the immunosuppression, Rituximab and plasmapheresis groups; however, the plasmapheresis group had more aggressive disease that lacked response to other treatment options.

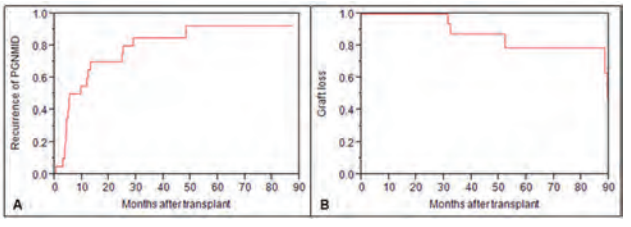

Figure 1. Kaplan-Meier plots of (**A**) Cumulative incidence of PGNMID recurrence in grafts and (**B**) Graft loss in recurrent PGNMID.

SA-PO536

Determinants of Renal Progenitor Cell Responsiveness to the Inductive Wnt9b Signal from the Ureteric Bud Kyle Dickinson,[2] Thomas J. Carroll,[3] Paul R. Goodyer.[1] *[1]McGill University, Montreal, QC, Canada; [2]McGill University, Montreal, QC, Canada; [3]UTSW Medical Center, Dallas, TX.*

Background: The canonical Wnt-signalling pathway is essential for kidney development as fully primed renal progenitor cells (RPC) appear in the metanephric mesenchyme. RPCs receive inductive Wnt9b signals from the adjacent ureteric bud to initiate a proliferative program. Specificity of Wnt ligand binding is determined by the co-receptor complex, consisting of a Frizzled (Fzd1-10) and Lipoprotein related receptor protein (Lrp5/6), however, the specific molecular components conferring responsiveness in RPCs have yet to be identified. The receptor complex is stabilized by R-spondin1 and R-spondin3 (Rspo1 and Rspo3), amplifying the Wnt signal.

Methods: We obtained M15 cells, derived form E10.5 mesonephric mesenchyme (Hastie et al, 1999) and systematically analyzed Wnt receptor/signalling components required for a canonical Wnt response. To measure activation of the canonical Wnt pathway, we transfected our M15 cells with reporter plasmid 8X TOPFlash and measured luciferase activity using a luminometer. RNA was analyzed by qRT-PCR.

Results: Exposing M15 cells to external Wnt9b resulted in minimal luciferase activity suggesting a signalling component is missing. We analyzed M15 cells for components of the β-catenin/TCF pathway and found mRNA expression of Fzd1-6, Lrp6 but neither Rspo1/3. To ascertain whether absence of R-spondin accounts for the lack of response, we transfected M15/TOPFlash cells with Wnt9b and added recombinant Rspo1 or Rspo3 and observed a 4.8-fold and 7.8-fold increase in luciferase activity, respectively. In the presence of Rspo1, we transfected the cells with Fzd1-10 and observed an additional 5-fold increase in the presence of Fzd5 but not the other Fzds. Knockdown of Lrp6 with siRNA (60% reduction in mRNA level) resulted in a 60% reduction in luciferase activity which was not rescued by Lrp5.

Conclusions: Our results suggest that early RPCs must acquire a specific receptor complex consisting of Fzd5, Lrp6 and Rspo1/3 before they can transduce an optimal β-catenin/TCF signal in response to Wnt9b during nephrogenesis. We speculate that putative RPCs lacking these components are incompetent for primary nephrogenesis and/or regeneration of damaged adult kidneys.

DNMT1-Dependent Cytosine Methylation Is Essential for the Control of Progenitor Cell Differentiation in Early Nephron Development Szu-Yuan Li,[1,2] Jihwan Park,[1] Rojesh Shrestha,[1] Katalin Susztak.[1] *[1]University of Pennsylvania, Philadelphia, PA; [2]Medicine, Taipei Veterans General Hospital and Yang-Ming University, Taipei, Taiwan.*

Background: The basic functional units of the mammalian kidney, nephrons, are generated repetitively during kidney organogenesis. Six2 positive cells represent a multipotent nephron progenitor population within cap mesenchyme and give rise to all epithelial cells in the kidney. Cytosine methylation changes play a key role in gene expression regulation; however, the role of cytosine methylation changes in kidney development has not been studied. Cytosine methylations are established by DNA methyltransferases (Dnmt) and are further modified by Tet eleven hydroxylase (TETs). Dnmts function as methylation writers and maintainers, and Tets act as methylation erasers.

Methods: To examine the role of cytosine methylation in renal epithelial cells, we crossed mice with DNMT1, 3a, 3b, Tet1 or Tet2 conditional allele (flox) with Six2cre mice. To understand the role of cytosine methylation in differentiated epithelial cells, we crossed Dnmt1, 3a, 3b and Tet1,2 mice with podocin Cre mice. Genome wide transcript level and cytosine methylation changes were analyzed by RNA sequencing and reduced representation bisulfate sequencing (RRBS).

Results: DNMT1, 3a, 3b and Tet1 are highly expressed in embryonic kidneys, and their expression levels decrease remarkably after kidney organogenesis is completed. Mice with podocyte-specific ablation of Dnmt1, 3a, 3b, Tet1 or Tet2 did not show functional or structural changes. We have induced glomerular disease in these animals by Adriamycin injection and found no differences in injury response when compared to controls, indicating the dispensable role for these enzymes. On the contrary, Six2 cre DNMT1 f/f mice died on day1 after birth; their kidneys were small and their bladders void of urine. Histological analysis revealed that although the progenitor cell population was maintained in absence of DNMT1, nephron maturation stopped in early stages (renal vesicle/ C-shape body). Expression of the cap mesenchymal genes including Gdnf were increased while nephron maturation genes including Fgf8 and Lhx1 were decreased.

Conclusions: DNMTs and TETs expression are dynamic during kidney development. Dnmt1 dependent DNA methylation is essential to complete nephron maturation.

HIF Prolyl-4-Hydroxylation in FOXD1 Lineage Cells Is Essential for Normal Kidney Development Hanako Kobayashi,[1] Volker H. Haase.[2] *[1]Vanderbilt University Medical Center, Nashville, TN; [2]Vanderbilt University Medical Center, Nashville, TN.*

Background: Hypoxia in the embryo is a frequent cause of intra-uterine growth retardation, low birth weight and multiple organ defects. In the kidney this can lead to low nephron endowment predisposing to chronic kidney disease and arterial hypertension. A key component in cellular adaptation to hypoxia is the hypoxia-inducible factor (HIF) pathway, which is regulated by prolyl-4-hydroxylase domain (PHD) dioxygenases PHD1, PHD2 and PHD3. In the adult kidney, PHDs function as oxygen-sensors, are differentially expressed in a cell type-dependent manner and control the production of erythropoietin in interstitial cells. The role of interstitial cell PHDs in renal development, however, has not been examined.

Methods: In order to examine the role of interstitial HIF oxygen sensing in renal development and homeostasis, we used the Cre-loxP system to target all 3 HIF-PHDs in conjunction with HIF-1α or HIF-2α in FOXD1-expressing stromal cells.

Results: PHD2 and PHD3 are essential for normal kidney development as the combined inactivation of stromal PHD2 and PHD3 resulted in renal failure that was associated with reduced kidney size, decreased numbers of glomeruli and abnormal postnatal nephron formation. In contrast, nephrogenesis was normal in animals with individual PHD inactivation. We furthermore demonstrate that the defect in nephron formation in PHD2/PHD3 double mutants required intact HIF-2 signaling and was dependent on the extent of stromal HIF activation.

Conclusions: The ability to regulate HIF prolyl-4-hydroxylation in FOXD1 stroma-derived cells is essential for normal nephron formation. Our data have implications for the therapeutic use of HIF prolyl-4-hydroxylase inhibitors, which are currently in phase 3 clinical development for renal anemia.

Hedgehog-TGFβ Signaling in Foxd1+ Stromal Cells Controls Stromal Patterning and Nephron Formation Christopher Rowan, Norman D. Rosenblum. *The Hospital for Sick Children, Toronto, ON, Canada.*

Background: In the embryonic mammalian kidney, signals from *Foxd1+* stromal cells are critical in establishing a full complement of nephrons. Yet, the molecular mechanisms that control stromal-nephrogenic cell interactions are largely unknown. Previously, we demonstrated that homozygous deficiency of SMO, a cell surface Hedgehog signaling effector, in the stromal lineage (*Smo-null*^{stroma}) results in a 42% decrease in nephron number. Remarkably, low nephron number is preceded by expansion of SIX2+ nephron progenitors and a relative block of mesenchymal to epithlial conversion [ASN 2014]. Here, we identify molecular mechanisms that control nephrogenesis in *Smo-null*^{stroma} mice.

Methods: RNA expression was assayed by RNASeq, quantitative (q)PCR, and *in situ* hybridization. Functional assays were performed in cultured mouse embryonic kidney explants using neutralizing antibodies and vivo-morpholinos (MO). TGFβ receptor II deficiency was generated in a CRE-dependent manner under the control of cell-specific promoters.

Results: RNASeq of wild type and *Smo-null*^{stroma} E13.5 kidney tissue demonstrated decreased expression of *Tgfb2* in mutant tissue. qPCR showed a 30% decrease in *Tgfb2* in *Smo-null*^{stroma} mutant kidney tissue and in FACS-isolated mutant *Foxd1+* stromal cells. *In situ* hybridization demonstrated decreased *Tgfb2* expression, and immunostaining demonstrated decreased expression of the TGFβ intracellular effector pSMAD2/3 in *Smo-null*^{stroma} mutant kidneys. Treatment of wild type embryonic kidney explants with neutralizing antibody or MO specific to TGFβ2 resulted in 65% (P=0.017) and 35% (P=0.003) fewer nephrons, respectively (n=3 per group). CRE-dependent deletion of TGFβ receptor II (*Tgfbr2*, specific to TGFβ ligands) within *Foxd1+* stromal cells (*Tgfbr2-null*^{stroma}) caused a 1.3-fold increase in SIX2+ nephron progenitors (P=0.01, n=8/genotype), as observed in *Smo-null*^{stroma} mice, and mispatterning of stromal cells *in vivo*. *Tgfbr2* deficiency targeted to either ureteric or SIX2+ nephron progenitor cells, alone, caused neither of these pathologic effects (n=3/genotype). However, *Tgfbr2* deficiency in both *Foxd1+* and *Six2+* cells concurrently caused hypoplasia in addition to defects observed in *Tgfbr2-null*^{stroma} mice.

Conclusions: We conclude that HH-TGFβ signaling exerts both cell autonomous and non-cell autonomous effects to control nephron formation and stromal patterning.

Stromal Progenitor-Derived Netrin-1 Signals Are Required for Proper Kidney Development Lori L. O'Brien, Deanna M. Hardesty, Shamus L. Cooper. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Background: Kidney morphogenesis is driven by reciprocal signaling between progenitor populations. However, novel signaling pathways may remain unknown. We recently uncovered targets of Six2/SIX2 in the nephron progenitors of mouse and human kidneys through a combination of ChIP-seq and RNA-seq. We analyzed these lists to identify novel signaling pathways acting in the developing kidney.

Methods: We identified *Unc5C/UNC5C* as a common target expressed within nephron progenitors. Unc5c is a receptor for the ligand Netrin-1 (Ntn1) which has roles in axon guidance as well as vascular, lung, and mammary gland development. *In situ* analyses show that *Ntn1* expression is restricted to the stromal progenitors. Other receptors for Ntn1 such as *Unc5b* are expressed in the vascular endothelium and medullary collecting ducts. Therefore, we focused on assessing the knockout phenotype of their common ligand Ntn1. We utilized the *Foxd1*^{GC} line to conditionally ablate *Ntn1* in the stromal progenitors.

Results: *Ntn1* mutant kidneys are hypoplastic. At E15.5, immunostaining for Six2, cytokeratin, and Wt1 reveals relatively normal nephron progenitor and ureteric tree organization with developing nephrons and glomeruli present despite kidneys being smaller. Since Ntn1 has roles in vascular development and axon guidance, we also stained kidneys for CD31 (endothelium) and Tuj1 (neuron). Mutant kidneys often had additional endothelial and neuronal projections extending over the outer cortex. Subsets of P0 mutant collecting ducts showed extensive dilation. Numbers of each genotype were assessed at P14 and indicate that most conditional *Ntn1* mutants die postnatally.

Conclusions: We have identified a novel signaling pathway acting in the embryonic kidney. Stromal progenitor-derived Ntn1 may play several roles including regulating the nephron progenitor population through Unc5c as well as guiding vascular and neuronal cell networks. Current studies are underway to assess cell and tip numbers, proliferation, and any consequences to ureteric, vascular, and neuronal networks. Additionally, we are analyzing Unc5c mutant kidneys. Our studies will help shed light onto new signaling pathways controlling mammalian kidney development and may have implications on vascularization and innervation of the kidney where much less in known about their development and regulation during morphogenesis.

Study on Morphogenesis of Renal Vasculature Architecture Based on Computer-Assisted 3D Reconstruction Jie Zhang,[1] Jie Yang,[1] Shi-Jie Chang,[2] Ling Gu,[1] Kaiyue Wang,[1] Jesper S. Thomsen,[3] Arne A. Andreasen,[3] Erik I. Christensen,[3] Xiao-Yue Zhai.[1] *[1]Department of Histology and Embryology, China Medical University, Shenyang, China; [2]Department of Biomedical Engineering, China Medical University, Shenyang, China; [3]Department of Biomedicine-Anatomy, Aarhus University, Aarhus, Denmark.*

Background: The architecture of the renal vasculature (RV) is formed so that the renal function is highly efficient. However, a relationship has been suggested between the morphogenesis of RV and the progression of renal fibrosis in CKD, due to the close proximity of peritubular capillaries and tubules. Present study demonstrates the transformation of RV trees from young to adult kidneys based on histological serial sections, and provides a quantitative reference with establishment of microcirculation, aiming at better understanding the morphogenic processes, meanwhile the progression of the nephron pathophysiology.

Methods: Serial paraffin and epoxy sections from E14.5, E17.5, P5, and adult kidneys were prepared for vessel tracing on aligned micrographs, using custom-made computer software. In addition, glomerular and medullary capillaries volume densities were measured on sections immunostained for CD34, from 3 mouse kidneys of each of 11 developing days.

Results: At E14.5, the RV trees consisted of six main arteries running between cortex and medulla and dozens of lateral branches along them. These smaller branches further divide in even smaller branches connecting to the earliest formed immature glomeruli. Soon after, with rapidly increasing number of nephrons, a burst branching network of RV formed with tremendous lateral and bifid branching until P5. After that, with expansion of especially the medullary volume, the RV tree remodeled into the typical spatial arrangement, including main, arcuate, and interlobular arteries, as well as afferent and efferent arterioles (AA and EA). The typical medullary vascular bundles (VB) originated from the EAs of earlier born nephrons intimately accompanying with Henle's ascending limb, and gradually formed by branching of the EA accompanied by more thin limbs and vessels when penetrating into the deep medulla. Consistently, the volume density of medullary microcirculation increased with the VB formed.

Conclusions: A large number of RV branches are completed by cessation of nephrogenesis. The RV is not only formed by iterative branching, but also by lateral and sprouting branches. In addition, the RV trees undergo remodeling corresponding to an increasing volume density, driven by the spatial arrangement of the neighboring tubules during the postnatal life.

Hypoxia-Regulated MicroRNA-210 Expression and Role in Nephrogenesis Shelby L. Hemker,[2,3] Andrew S. Clugston,[2,3] Yu Leng Phua,[2,3] Jacqueline Ho,[2,3] Dennis Kostka.[1,4] *[1]Developmental Biology, University of Pittsburgh, Pittsburgh, PA; [2]Rangos Research Center, Children's Hospital of Pittsburgh of UPMC, Pittsburgh, PA; [3]Pediatrics, Division of Nephrology, University of Pittsburgh, Pittsburgh, PA; [4]Computational & Systems Biology, University of Pittsburgh, Pittsburgh, PA.*

Background: Placental insufficiency causes fetal hypoxia, reduced blood flow to the kidneys, and is the main cause of intrauterine growth restriction (IUGR). IUGR and fetal hypoxia adversely affects kidney development, resulting in decreased nephron number and increased chance of congenital anomalies of the kidney and urinary tract (CAKUT), the leading cause of kidney failure in children. Furthermore, IUGR puts affected individuals at an increased risk for developing hypertension and chronic kidney disease. We hypothesize that key regulators of normal kidney development are responsive to changes in oxygen tension. *microRNA-210* (*miR-210*) is the most consistently induced miRNA in hypoxia and is directly regulated by the Hypoxia Inducible Factor (HIF) transcription factor family. microRNAs (miRNAs) are ~22nt small noncoding RNAs that fine-tune gene expression through post-transcriptional regulation of specific target mRNAs and are essential for proper mammalian development.

Methods: First, we defined *miR-210* expression throughout murine kidney development using small RNA sequencing and *in situ* hybridization. Then, we cultured *ex vivo* kidney explants in different oxygen levels and examined the effect on both miRNA and mRNA expression through RNA sequencing. Furthermore, we investigated the effect of a global *miR-210* mouse knockout on kidney development using real time RT-qPCR and histological analyses.

Results: We found that *miR-210* is broadly expressed in the developing kidney, including in nephron progenitors (cells that differentiate to form the nephron) and ureteric bud epithelium (cells that form the collecting duct system). Our transcriptomic studies found that *miR-210* is upregulated in hypoxia, while several of its target mRNAs are down-regulated. Most interstingly, the *miR-210* knockout mouse has altered expression of key genes in nephron progenitors, ureteric bud, and endothelial cells during kidney development.

Conclusions: Together, our data suggests that *miR-210* plays a role in normal kidney development.

Understanding Normal and Hoxa9,10,11-/-; Hoxd9,10,11-/- Kidney Development Through Single Cell RNA-Seq Bliss Magella,[2] Robert Mahoney,[5] Meenakshi Venkatasubramanian,[1] Nathan Salomonis,[3] Steven Potter.[4] *[1]Cincinnati Children's Hospital, Cincinnati, OH; [2]Cincinnati Children's Hospital Medical Center, Sharonville, OH; [3]Cincinnati Children's Hospital Medical Research Center, Cincinnati, OH; [4]Cincinnati Children's Hospital, Cincinnati, OH; [5]Cincinnati Childrens, Fairfield, OH.*

Background: The kidney is a complex organ that is made of many different cell types. In an effort to better understand the cell diversity within the developing kidney we have performed single cell RNA-seq on embryonic day 14.5 mouse kidneys. Of particular interest is the apparent lack of a Hox code within the developing kidney. Previous studies have determined that Hox 10 and 11 paralogous groups are functioning within kidney development. Interestingly, thirty-six of the thirty-nine mammalian Hox genes are expressed during kidney development.

Methods: Analysis of wild type and mutant E14.5 kidneys was performed using data obtained through Drop-seq. Additional data sets were gathered using Fluidigm and Chromium In-Drop for wild type validation. Hoxa9,10,11; Hoxd9,10,11 mutants were used to determine the functional role of the Hox genes during kidney development. Altanalyze and Seurat based analyses are being used to determine the normal and mutant expression profiles.

Results: Sixteen cell groups were identified in the wild type data set; medullary collecting duct, cortical collecting duct, ureteric bud tip, loop of Henle, distal comma shaped body, podocyte, mid S-shaped body, early proximal tubule, pre-tubular aggregate, three cap mesenchyme groups, endothelium, nephrogenic zone stroma, cortical stroma,

and medullary stroma. In addition to the known identifier genes, novel specific gene associations were also discovered during analysis. One such example is the discovery of *Gdnf* expression from within the stromal population, which was previously thought of as being exclusively expressed from the cap mesenchyme. Morphological analysis of the Hox mutants shows alterations in mature nephron segment identity, medullary zone specification, and the formation of a pelvic opening.

Conclusions: Obtaining a comprehensive data set allows for the visualization of the expression profile of many genes within the wild type developing kidney. These data can then be used as an atlas for comparing mutant data sets. By combining the Hox mutant morphological phenotypes with the single cell expression profiles we can better understand the molecular regulation of kidney development. This greater understanding provides necessary information for future studies looking to make kidneys through organoid cultures.

Chemical Genetic Screen Reveals Novel Role for PPAR Signaling in Renal Progenitor Development Joseph M. Chambers, Rebecca A. Wingert. *University of Notre Dame, Notre Dame, IN.*

Background: The genetic and molecular mechanisms directing nephron segmentation during kidney development are not well understood. Deregulation of genes involved in kidney development result in a variety of diseases broadly categorized as Congenital Anomalies of the Kidney and Urinary Tract (CAKUT). Embryonic zebrafish have a simplified kidney, the pronephros, comprised of proximal and distal segments that display conservation with mammalian nephrons, including humans, thus enabling CAKUT modeling.

Methods: Through a novel chemical genetic screen, we discovered that peroxisome proliferator-activated receptor (PPAR) signaling is essential for normal nephron segment development. PPARs are a group of nuclear receptor proteins that are activated by ligands such as fatty acids and act as transcription factors by heterodimerization with retinoid X receptor (RXR) to regulate cell differentiation and perform diverse roles in metabolism. We found that treatment with the PPAR agonist bezafibrate during nephrogenesis alters the balance of proximal and distal cells. Interestingly, *pparg* co-activator, *ppargc1a*, which binds to activated PPARs to regulate transcription of target genes, is dynamically expressed in renal progenitors.

Results: To test the functional role of this co-activator during nephron segmentation, we examined nephron development in *ppargc1a*^{sa13186} mutants, where a lesion in exon 8 with a TàA substitution results in a premature STOP codon and an anticipated loss of the RNA processing domain. *ppargc1a*^{sa13186} mutants have an abrogated distal tubule and increased proximal tubule domain, which was recapitulated in subsequent knockdown studies as well. Further, *ppargc1a* knockout and knockdown models development renal cysts, a hallmark of dysplastic CAKUT. Interestingly, there is a decrease in cilia within the nephrons of mutant and knockdown examples. Assessment of essential nephron regulators revealed that *ppargc1a* acts to inhibit *irx3b* and promote *tbx2b*.

Conclusions: Taken together, our studies suggest a novel mechanism by which PPAR signaling coordinates lineage choices during nephrogenesis. These findings may lead to a better understanding of the therapeutic value of PPARs in relation to renal birth defects and cystic disease conditions as well.

SA-PO545

Genetic Mechanisms of Multiciliated Cell Development during Renal Ontogeny Amanda N. Marra, Rebecca A. Wingert. *University of Notre Dame, Notre Dame, IN.*

Background: Multiciliated cells (MCCs) are found in a wide variety of species and tissues, ranging from the embryonic kidney of frogs and fish to the reproductive and respiratory systems of mammals. Differentiation of MCCs has become an increasingly attractive area of research due to their association with fluid flow and disease. There is evidence for a core, conserved pathway of MCC development that includes the Notch signaling pathway as a negative regulator of MCC fate.

Methods: The embryonic zebrafish kidney, or pronephros, has emerged as a useful tool to study MCC genesis *in vivo*, where the transcription factor *mecom* acts upstream of Notch to restrict MCC development while Retinoic Acid (RA) signaling promotes MCC fate by inhibiting *mecom* and promoting expression of the ETS transcription factor *etv5a*.

Results: Here, we report phenotype analysis of the *etv5a*^{sa16031} allele, which encodes a nonsense mutation in the conserved ETS DNA-binding domain of *etv5a*. Embryos with one copy of this allele display decreased expression of MCCs, suggesting that *etv5a* is a haploinsufficient gene. Next, we found that *mecom* inhibits *etv5a* expression in the kidney, as knockdown of *mecom* caused an expansion of the *etv5a* domain. Additionally, we have identified a role for the transcription factor *irx2a* in MCC development, where knockdown of *irx2a* results in a loss of MCCs similar to that seen in *etv5a*-deficient embryos. Lastly, we have uncovered a role for prostaglandin (Pg) signaling in MCC development through a large-scale chemical screen. Inhibition of the Pg pathway via Indomethacin or concomitant knockdown of the Pg biosynthesis enzymes Cox1 and 2 significantly reduced MCC number. Interestingly, Pg inhibition did not produce a detectable change in the *etv5a* pronephros domain, suggesting that Pg signaling promotes MCC development separate from *etv5a*.

Conclusions: In conclusion, we have discovered a novel relationship between *etv5a* and *mecom* during MCC development, established *irx2a* as a MCC fate factor, and have identified an essential role for Pg signaling in MCC genesis.

Silencing of cep104 in Zebrafish Embryos Gives Rise to a Ciliopathy Phenotype Elisa Molinari, Simon Ramsbottom, John Sayer. *University of Newcastle, Newcastle upon Tyne, United Kingdom.*

Background: Joubert syndrome (JBTS) is a rare autosomal recessive ciliopathy characterized by a cerebellar hypoplasia which may be accompanied by additional symptoms including developmental delay, ataxia, intellectual disabilities, retinal dystrophy and juvenile cystic renal disease (nephronophthisis, NPHP). To date, JBTS-causing mutations have been identified in 28 genes (JBTS1-JBTS28). JBTS25 is associated with the *CEP104* gene. Of note, the cilia phenotype of *CEP104* mutation carriers has not yet been reported nor has genetic silencing been tested in vertebrate models. Our results demonstrate for the first time *in vivo* a function for *cep104* in zebrafish development.

Methods: Using antisense morpholino oligonucleotide (MO) technology, we silenced *cep104* in *Danio rerio* (zebrafish). To assess specific phenotypes, we used wild type zebrafish *golden* and AB strains, alongside the transgenic *islet-1*:GFP strain which expresses GFP in cranial motor neurons under the control of *islet1* promoter and the *cmlc2*:GFP transgenic strain, expressing the GFP gene under the control of the *cmcl2* promoter.

Results: *cep104* MO-injected zebrafish embryos at 48 hpf displayed cardiac phenotypes, tail curvature and microophthalmia, which can be rescued by co-injection of a human *CEP104* mRNA, confirming the specificity of the MO. Analysis of Kupffer's vesicle, a ciliated organelle important for left-right axis formation, showed a ciliary defect, with a reduction in ciliary length. Morphant embryos display *situs inversus*, with reversed cardiac looping. Most relevant in respect to JBTS, characteristic developmental defects were observed within the brains of *cep104* zebrafish morphants, with a major involvement of oculomotor neurons. These specific defects were also rescued by co-administration of *CEP104* mRNA.

Conclusions: These data reveal that *cep104* morphant phenotypes are highly consistent with a ciliopathy syndrome, and suggest a role for cep104 in cilia formation within Kupffer's vesicle as well as development of the heart and cranial nerves.

SA-PO547

Morphological and Morphometrical Analyses of Renal Tubules in Danio rerio Regarding Nephrogenesis Jasmin Hochstuhl, Markus Islinger, Marlies Elger. *Heidelberg University, Medical Faculty Mannheim, Mannheim, Germany.*

Background: Recent studies indentified functional markers for individual segments of the zebrafish pronephros and the definitive kidney. However, those studies largely lack direct correlations of segment markers with the substructure of the respective segment.

Methods: The pronephric kidney and the definitive kidney were studied in zebrafish, Danio rerio. We investigated larvae (72h), juveniles (26d) and adults (sexually mature fish). By using light and transmission electron microscopy as well as fluorescence labeled lectins, we established criteria for identification of nephron segments, cell types and their substructure.

Results: The pronephric kidney consists of six segments: neck segment (NS), first proximal tubule (PI), second proximal tubule (PII), early distal tubule (EDT) and late distal tubule (LDT), followed by a short collecting tubule. The nephrons of the definitive kidney showed the same sequence of segments as found in the pronephric kidney. However, in fully developed nephrons the second proximal tubule (PII) could be subdivided into two parts (PIIa and PIIb). For every segment, distinct morphological and morphometrical criteria could be identified. Based on segment location and cellular substructure, in most cases the major function of the segments could be assumed by comparison with physiological data of the respective segments in fish and mammals. Measurements of segment length and epithelial height allowed to classify different developmental stages of the entire nephron and of individual nephron segments. Nephron anlagen of different developmental stages were found exclusively apposed to the pronephric duct and the collecting duct. In all cases the prospective distal end of the anlagen invaded the pronephric duct or the collecting duct, respectively.

Conclusions: This study presents comprehensive morphological data of the tubular substructure of the pronephros and the definite kidney and may serve as a structural basis for the investigations dealing with transport mechanisms and renal disorders in this established model organism.

SA-PO548

Generation of Interspecies Chimeric Nephrons from Nephron Progenitor Cells by Conditional Elimination and Replacement Shuichiro Yamanaka,[1] Kei Matsumoto,[1] Susumu Tajiri,[1] Toshinari Fujimoto,[1] Shohei Fukunaga,[1,2] Takashi Yokoo.[1] *[1]Division of Nephrology and Hypertension, Department of Internal Medicine, Jikei University School of Medicine, Minato, Japan; [2]Shimane University, Izumo, Japan.*

Background: The animal embryonic organ niche may have applications in the generation of regenerative organs, and progenitor cells may be an appropriate cell source for this purpose because of their safety and availability. Therefore, we established a combination method through which donor cells could be precisely injected into the nephrogenic zone and native nephron progenitor cells (NPCs) be eliminated in a time- and tissue-specific manner. We successfully removed Six2+ NPCs within the nephrogenic niche and replaced transplanted NPCs. The transplanted cells differentiated into

neo-nephrons. Furthermore, we generated rat neo-nephrons in the mouse nephrogenic zone by conditional elimination and replacement.

Methods: We used Cre-LoxP technology in combination with diphtheria toxin receptor-loxP (DTR-loxP) and Six2-Cre mice for Diphtheria Toxin (DT)-mediated NPC elimination. Metanephros (MN) was isolated from the Six2/DTR +/+ mouse embryos. Wild-type rat NPCs were transplanted into the Six2/DTR +/+ mouse nephrogenic zone and simultaneously administered DT, followed by co-culture in an organ culture dish for seven days. We examined donor NPCs differentiation into neo nephrons by immunostaining of nephron markers (WT1, PAX8, GATA3, Cytokeratin8, E-cadherin, LTL).

Results: Donor rat NPCs were observed in the broad engraftment in host mouse cap mesenchyme, which eliminated native mouse NPCs on DT administration. The interspecies chimeric nephrons expressed glomerular and tubular markers. We also observed a connection between host collecting ducts and the neo-nephrons.

Conclusions: Using progenitor cells conditional elimination system, we demonstrated that donor rat NPCs replaced host mouse NPCs in the mouse nephrogenic zone, and that generation of neo-nephrons is possible by other species. Thus, this technique enables the differentiation of progenitor cells into nephrons, providing insight into the nephrogenesis and organ regeneration processes. We believe that this technique could effectively be used to evaluate the differentiation of NPCs from pluripotent stem cells (PSCs).

SA-PO549

Regeneration of Rat Nephrons in the Mouse Metanephros: In Vivo Regeneration of Nephrons between Different Species under the Administration of Optimal Immunosuppressive Agents Toshinari Fujimoto, Shuichiro Yamanaka, Susumu Tajiri, Kei Matsumoto, Shohei Fukunaga, Takashi Yokoo. *Division of Nephrology and Hypertension, Department of Internal Medicine, Jikei University School of Medicine, Tokyo, Japan.*

Background: The transplant of exogenous nephron progenitor cells(NPCs)to a nephrogenic niche has demonstrated very low engraftment efficiency, possibly due to the competition with existing native host NPCs occupying the niche. Previously, we generated a transgenic mouse model with ablation of NPCs by using a drug for induction. We demonstrated that host mouse NPCs were replaced with donor mouse NPCs by eliminating existing native host NPCs, and that donor cells regenerate neo nephrons that connect with host collecting ducts. In the future, we aim to regenerate human nephrons in different species using the NPCs elimination and replacement system, and apply this novel strategy to the treatment of kidney failure. As a first step, we needed to examine the possibility of interspecies regeneration of nephrons. We already succeeded in regenerating rat nephrons in the mouse metanephros(MN)on an organ culture dish using this system. In this work, we verified the in vivo regeneration of nephrons between rat and mouse models.

Methods: In the transgenic mouse, diphtheria toxin receptor is specifically expressed on Six2-positive NPCs. The MN was isolated from the E13 embryo, following which donor rat NPCs that were not affected by the diphtheria toxin were transplanted into the MN. Diphtheria toxin was simultaneously added to the MN for the elimination of native NPCs only. Subsequently, the mouse MN-implanted rat NPCs were transplanted into the abdominal para-aortic area of an adult rat under the administration of tacrolimus and Mycophenolate mofetil. After 3 weeks, regeneration of rat nephrons in the transplanted mouse MN was examined through immunohistological analysis.

Results: Donor rat NPCs were noted engraftment in the host mouse cap mesenchyme, which ablated native NPCs using diphtheria toxin. Additionally, donor rat NPCs differentiated into neo nephrons in the host mouse metanephros transplanted into the adult rat.

Conclusions: We demonstrated interspecies regeneration of nephrons within a living organism under the administration of optimal immunosuppressive agents by using the NPCs elimination and replacement system. This novel strategy is considered an effective method for kidney regeneration.

SA-PO550

Maintenance of Mature Collecting Duct Principal Cells Is Dependent on Notch Signaling Malini Mukherjee,[1] Jennifer DeRiso,[1] Kameswaran Surendran.[1,2] *[1]Sanford Research, Sioux Falls, SD; [2]Pediatrics, University of South Dakota, Sioux Falls, SD.*

Background: During kidney development Notch signaling endows the collecting ducts with proper urine concentrating capacity by ensuring that a sufficient number of collecting duct cells differentiate into mature principal cells instead of selecting intercalated cell fates. Based on the continued expression of Notch ligands in intercalated cells adjacent to mature principal cells we tested the hypothesis that Notch signaling is required for the maintenance of the mature principal cell state.

Methods: Three different mouse models were generated to study the role of Notch signaling in the mature mouse collecting ducts: (i) ectopic expression of dominant-negative mastermind like-1 (dnMaml), a known inhibitor of Notch/RBPJ-mediated transcriptional activation, in mature mouse kidney epithelial cells, (ii) conditional genetic inactivation of Notch1 and Notch2 in the mature kidney epithelial cells of mice starting at three weeks of age, and (iii) conditional genetic inactivation of the down-stream Notch-signaling target Hes1 in the renal epithelium starting at three weeks of age.

Results: Inhibition of Notch signaling in the adult mouse kidneys resulted in a significantly decreased urine concentrating capacity when compared with that of control littermates in all three mouse models. Induction of dnMaml expression in the renal epithelia of three week old mice for three days reduced expression of *Nrarp*, a gene known to be transcriptionally regulated by Notch signaling, along with principal cell specific genes such as *Aqp2* and *Avpr2*, while expression of intercalated cell specific genes, *Foxi1* and *Slc4a9*, were increased. Genetic inactivation of Notch1 and Notch2 or Hes1 in the mature epithelial cells of the mouse kidneys resulted in reduced number of principal cells and increased number of intercalated-like cells as determined by immunohistochemistry.

Conclusions: Notch signaling is required for maintaining mature principal cells in a functional state by ensuring continued expression of critical principal cell specific genes, and repressing essential intercalated cell specific genes. Lineage tracing of principal cells during kidney development revealed that inhibition of Notch signaling causes principal into intercalated-like cell transdifferentiation. Similarly, Notch signaling appears to prevent transdifferentiation of mature principal cells in the adult mouse kidneys.

Human Missense Variants in Integrin-Linked Kinase Abrogate Renal Branching Morphogenesis by Disrupting MAPK Signaling Dana Kablawi,[1] Kirsten Y. Renkema,[2] Nine V. Knoers,[2] Norman D. Rosenblum.[1] *[1]The Hospital for Sick Children, Toronto, ON, Canada; [2]University Medical Center Utrecht, Utrecht, Netherlands.*

Background: Integrin-linked kinase (ILK) is required for murine renal branching morphogenesis and acts via p38MAPK/ATF2 signaling. Yet, its contribution to human congenital kidney-urinary tract anomalies (CAKUT) is undefined. The objective of these studies is to identify *ILK* variants in CAKUT and define their functional consequences.

Methods: Patients with CAKUT were analyzed by exome sequencing. Variants were verified by Sanger sequencing. Cells stably expressing human *ILK* variants were generated by lentivirus transduction and clonal selection. Signaling pathway activity and transcription factor activation were analyzed using immunoblotting. Subcellular localization of transcription factors was imaged by immunofluorescence. Gene expression and pathway enrichment were assayed using whole genome microarray and quantitative (q) PCR. *Ex vivo* assays were conducted using lentivirus-based transduction of mouse embryonic kidney explants.

Results: Exome sequencing of 208 CAKUT candidate genes in 453 probands with CAKUT identified ILK^{T173I} (1 proband) and ILK^{N22S} (4 probands), both of which are missense variants in ILK ankyrin repeat domains. Stimulation of mIMCD3 cells stably expressing ILK^{T173I} (versus ILK^{WT}) with EGF (15 minutes) revealed increased phosphorylation of each of JNK, C-Jun and AKT ($P<0.05$, n=3), as well as increased nuclear translocation of P-C-Jun ($P<0.05$, n=3). *c-Jun* RNA, a JNK signaling target, was increased 2.6-fold ($P<0.05$, n=6, qPCR). Pathway enrichment analysis of genome-wide RNA expression after 1 hour of EGF stimulation revealed dysregulation of AKT/MTOR target genes (n=3). In contrast to ILK^{T173I}, EGF mediated stimulation of mIMCD3 cells expressing ILK^{N22S} increased ERK phosphorylation ($P<0.05$, n=3). Treatment of E12.5 kidney explants with lentivirus expressing ILK^{T173I} resulted in hypoplasia with a 45% decrease in ureteric bud (UB) tip number ($P< 0.025$, n=9 kidneys). Treatment with lentivirus expressing ILK^{N22S} generated a spectrum of phenotypes including reduced number of UB tips (n=6 kidneys, $P<0.009$), increased (1.5-fold) number of UB tips (n=6 kidneys, $P<0.048$), and ectopic branching of the main ureter (n=3 kidneys).

Conclusions: ILK ankyrin-repeat domain missense variants associated with human CAKUT cause distinct abnormalities in MAPK signaling and variable patterns of disrupted kidney explant development.

Loss of Zeb2 in Ureteric Mesenchymal Cells Causes CAKUT Phenotype in Mice Sudhir Kumar, Richa Sharma, Xueping Fan, Weining Lu. *Boston University Medical Center, Boston, MA.*

Background: Congenital anomalies of the kidney and urinary tract (CAKUT) are major causes of renal failure in children. ZEB2 is a SMAD-interacting transcriptional factor that causes Mowat-Wilson Syndrome (MWS), a congenital disorder with an increased risk for CAKUT phenotype including hydroureter and hydronephrosis. However, no defined underlying cellular and molecular mechanisms for hydroureter and hydronephrosis in MWS have been established.

Methods: We generated *Zeb2* ureteric mesenchyme-specific conditional knockout mice (*Zeb2* cKO) by crossing *Zeb2* flox mice with *Tbx18Cre* mice. Urinary tract phenotypes in *Zeb2* cKO mice and their wild-type littermate controls were analyzed by gross and histological examination. ZEB2 expression in developing ureter was analyzed by immunofluorescence staining. Ureteral cellular and molecular phenotypes were studied using cell specific markers, apoptosis assay, and anti-SMAD antibodies.

Results: We found that ZEB2 is highly expressed in the ureteric mesenchymal cells and is co-localized with TBX18 in developing mouse ureter at E14.5. Deletion of *Zeb2* flox allele using *Tbx18Cre* mice leads to hydroureter and hydronephrosis phenotype in E18.5 embryos. At E16.5, *Zeb2* cKO mice showed reduced ureteral smooth muscle cells as well as abnormal urothelium morphology compared to wildtype littermates. Immunohistochemical analysis further revealed a downregulation of TBX18 expression in the ureteric mesenchyme in E14.5 *Zeb2* cKO mice, indicating abnormal ureteric mesenchyme development. We also found increased apoptosis and upregulation of pSMAD1/5/8 expression in ureteric mesenchyme cells in E14.5 *Zeb2* cKO, suggesting loss of ureteric mesenchymal cells and abnormal SMAD signaling in developing ureter.

Conclusions: ZEB2 is required for normal ureteric mesenchymal cell development. Loss of *Zeb2* in ureteric mesenchymal cells leads to reduced TBX18+ mesenchymal cells

and abnormal ureteral smooth muscle formation due to aberrant SMAD signaling, which eventually causes hydroureter and hydronephrosis in *Zeb2* cKO mice.

A Morphogenetic Study of Murine Renal Collecting System Based on 3D Visualization Ling Gu,[1] Jie Zhang,[1] Shi-Jie Chang,[2] Kaiyue Wang,[1] Jesper S. Thomsen,[3] Arne A. Andreasen,[3] Erik I. Christensen,[3] Xiao-Yue Zhai.[1] *[1]Department of Histology and Embryology, China Medical University, Shenyang, China; [2]Department of Biomedical Engineering, China Medical University, Shenyang, China; [3]Department of Biomedicine – Anatomy, Aarhus University, Aarhus, Denmark.*

Background: The iterative bifid branching of ureteric bud (UB) lays basis for formation of the collecting system (CS), and for generation of nephrons as the tip of the UB induces nephrogenesis at the nephrogenic zone (NZ). A low nephron number is associated with adult defect, such as hypertension. Therefore, a full knowledge of the morphogenesis and the connections of CS with nephrons is crucial to understand the development of such adult defects. The present study provides a spatial morphologic transformation of UB branching into adult CS based on 3D reconstruction.

Methods: Serial paraffin and epoxy sections of 3 mouse kidneys from each of different embryonic (E) and postnatal (P) days were prepared. The branching paths of UB at E14.5, E17.5, and CS from P7 and adult kidneys were traced on aligned micrographs using custom-made software. The architecture of adult CS was first established for comparison of UB branching trees.

Results: 1) The morphology of cortical CS was asymmetric. One ICT rapidly bended down into the juxta-medullary cortex from the main CD at the middle to superficial cortex forming an abrupt arcade. The other ICT went straight outwards to the superficial cortex and ran a certain distance beneath the renal capsule. 2) The connection of nephrons with CS in a specific temporospatial order. The earlier formed nephrons connected with the arcade in distal to proximal order along the trunk, while the later formed nephrons, connected with the ICT in proximal to distal order. 3) The association of UB branching morphogenesis with nephrogenesis was established. By E14.5 when the first mature nephrons appeared, the UB bifurcations reached up to 7 to 10 cycles, laying basis for adult CD formation. With time until P3, the tips at NZ increased in number, consistently inducing nephrogenesis instead of branching.

Conclusions: The CS is formed by more than one type of branching: 1) the traditional bifurcation for formation of CD; 2) lateral branching along the arcade for formation of the ICT and connecting segments; and 3) sprouting for formation of the CNT connecting directly with individual nephrons. This suggests that the number of the nephrons is closely associated not only to the iterative branching, but also to the formation of lateral and sprouting branches, the latter mainly occurred near NZ.

Loss of the Planar Cell Polarity Gene Fuzzy Leads to Defective Branching Morphogenesis and Cystogenesis in Embryonic Kidneys Yanran Wang,[1,2] Elena Torban.[1,2] *[1]Division of Experimental Medicine, Department of Medicine, McGill University, Montreal, QC, Canada; [2]McGill University Health Centre, Montreal, QC, Canada.*

Background: The PCP effector gene Fuzzy is essential for organogenesis. In Drosophila, it is critical for establishing planar cell polarity via controlling the actin cytoskeleton. In vertebrates, the role of Fuzzy is less clear, but it appears to control some aspects of trafficking protein cargos to the basal body. Fuzzy has been designated as a Ciliogenesis and PCP effector (CPLANE) gene. Disruption of Fuzzy in mice results in severe malformations, including neural tube defects, polydactyly, facial defects andetc, suggesting its participation in various signaling pathways.

Methods: To study kidney development, homozygous E14.5 and E16.5 embryos carrying a gene-trap Fuzzy mutation and wildtype littermates were harvested for immunofluorescense and in situ hybridization (ISH) studies.

Results: Fuzzy$^{-/-}$ mutants exhibited profound renal hypoplasia at E14.5. Although Six2-positive progenitor cells and their differentiation into early nephron structures were unaffected, the number of the ureteric buds was decreased to 50% of control. This was accompanied by a ~ 50% reduction in the number of glomeruli without a decrease in the number of podocytes per glomerulus. ISH studies indicated that GDNF expression was unaffected, but c-Ret expression was upregulated in Fuzzy$^{-/-}$ mutants. The expression of the Hippo kinase pathway effector Yap was decreased significantly in ureteric buds. At E16.5, Fuzzy$^{-/-}$ mutants exhibited glomerular cysts in the medullary layer, manifested by the dilation of Bowman's capsule. E16.5 Fuzzy$^{-/-}$ mutants also developed proximal tubular cysts but collecting ducts remained intact.

Conclusions: Impaired UB branching is a major cause of renal hypoplasia in E14.5 Fuzzy$^{-/-}$ mice and is associated with increased Ret signaling and a decrease in Yap expression in the UBs. This phenotype is reminiscent of the phenotype of Yap mutants, suggesting that Fuzzy may participate in Hippo signaling pathway. The mechanisms of glomerular and proximal tubular cysts formation are being investigated.

SA-PO555

Robo2 Mediated Raldh2 Signaling in Bladder Mesenchyme Is Crucial for Ureter Development Qinggang Li,[2] Xiangmei Chen.[1] *[1]Chinese PLA General Hospital, Beijing, China; [2]Chinese PLA general Hospital, Beijing, China.*

Background: Congenital anomalies of urinary-tract are a significant cause of morbidity in infancy, many of the congenital anomalies are linked to ureter development. Despite the frequent occurrence of the ureter abnormalities, little is known about their cause that normally control ureter-bladder development. Robo2 loss can cause congenital abnormalities of the urinary-tract, with ureter defect and vesicoureteral reflux. While mechanistic aspects of this pathway are increasingly well defined, it remains unclear how Robo2 modulation impacts ureter development.

Methods: We performed in immunofluorescence on mouse embryonic whole mount kidney and section with E-cadherin, and Co-IP and Mass spectrometry analysis on mouse embryonic kidneys and urogenital tracts with a specific ROBO2 polyclonal antibody. Laser scanning confocal microscopy and real time RT-PCR were used to observe expression of Robo2 in frozen section and urogenital tract samples. Kidney explants dissected from E12.5 embryo were cultured in DMEM/10%FCS.

Results: Robo2 is expressed in common nephric duct (CND) and primitive bladder, and interact with Raldh2. Moreover, the ureter elongation is depend on signaling in bladder, not kidney morphogenesis, reveals how Robo2 impact ureter cell fate decisions. Delayed apoptosis due to failure of CND fusion with primitive bladder in Robo2$^{-/-}$embryo, resulting in the abnormal ureter remain connected to CND. Analysis of Robo2$^{-/-}$ mice reveals hydronephrosis and defective ureter development by the CND remodeling defects and delayed fusion with primitive bladder. Using retinoic acid rescued ureter anomalies in Robo2$^{-/-}$embryo.

Conclusions: We found Robo2 impacts CND migration and fusion with primitive bladder via its novel protein partner Raldh2 signaling, this may have relevance for diverse disease conditions, associated with altered signaling from primitive bladder.

Tubular Immaturity Underlies Erythropoietin-Deficiency Anemia of Prematurity Nariaki Asada. *Keio University School of Medicine, Tokyo, Japan.*

Background: Kidneys are physiologically hypoxic and produce erythropoietin (EPO) after birth by sensitively detecting oxygen levels. Preterm neonates, especially those less than 32 weeks of gestation, develop EPO-deficiency anemia, known as anemia of prematurity (AOP). In AOP, immature kidneys cannot produce sufficient EPO in response to anemia even when renal injuries are absent. It remains unclear how kidneys start to produce EPO after birth.

Methods: Neonatal mice were used as AOP model since they are physiologically born premature. To confirm factors associated with AOP in human, correlation of hemoglobin levels with fraction excretion of sodium (FENa), urinary creatinine to beta 2-microglobulin ratio (uCr/uβ2MG), serum creatinine, birth weight, or gestational age were evaluated in prospective observational study of 18 preterm patients at age 14 days and 21 days.

Results: Mice at postnatal day 14 (P14) showed physiological anemia and elevated renal EPO production. Mice at P7, however, showed AOP-like deficient renal EPO production regardless of the same degree of anemia. Pimonidazole staining showed that kidneys at P14 were more hypoxic than those at P7. There were no difference in the expression of αSMA or the density of peritubular capillaries. The expression of transporters NHE3, NKCC2, NCC, αENaC, and Megalin were significantly low at P7 compared to P14. Suppression of tubular reabsorption by losartan or short-term use of diuretics decreased EPO, pimonidazole-positive area, and hematocrit at P14. Upregulating reabsorption by long-term use of diuretics increased the expression of sodium transporters, EPO production, pimonidazole-positive hypoxic area, and hematocrit at P7, suggesting that low tubular oxygen consumption for reabsorption is a cause of deficient EPO production at P7. Prolyl hydroxyrase inhibitor (PHDi) also ameliorated AOP. In preterm patients, hemoglobin levels were correlated with FENa and uCr/uβ2MG, but not with serum creatinine, birth weight, or gestational age.

Conclusions: AOP is caused by insufficient hypoxic environment due to low oxygen consumption by immature tubules. Kidneys start to produce EPO as tubules mature and renal oxygen levels decrease. PHDi can be a therapeutic option for AOP in preterm patients.

DNA Hydroxymethylation Is Altered by Maternal Nutrient Restriction in Rat Kidney Mariko Hida,[1] Mayumi Oda,[2] Midori Awazu.[1] *[1]Department of Pediatrics, Keio University School of Medicine, Tokyo, Japan; [2]Department of Systems Medicine, Keio University School of Medicine, Tokyo, Japan.*

Background: DNA hydroxymethylation is an epigenetic modification that oxidizes 5-methylcytosine (5mC) into 5-hydroxymethylcytosine (5hmC). Increasing evidence suggests that the role of DNA hydroxymethylation is different from DNA methylation in various organs but that in the kidney is unclear. We previously showed that the global DNA methylation was reduced and the gene-specific DNA methylation was altered in kidney of rat embryos from nutrient-restricted mothers. In the present study, we investigated DNA hydroxymethylation in the same model.

Methods: The kidneys of embryonic day 18 fetuses (E18) from dams given food ad libitum (CON) and those subjected to 50% food restriction throughout pregnancy (NR) were examined (n=3 litters for each group). Global hydroxymethylation levels were assessed by ELISA. The local 5hmC detection by hMe-Seal method followed by high throughput sequencing (5hmC-seq) was used to analyze the changes in hydroxymethylation patterns by NR. 5hmC enriched regions (5hmC peaks) were identified using a peak finding algorithm (MACS1.4) and then annotated to the nearest genes.

Results: Global hydroxymethylation levels in E18 metanephroi was significantly increased in NR vs CON (0.31±0.02% vs 0.20±0.03%). On the other hand, the number of 5hmC peaks detected by 5hmC-seq analysis was smaller in NR; 582 peaks in CON only and169 peaks in NR only. There were 362 peaks common in CON and NR. Annotated genes present in these regions were 581 and 169 in CON and NR, respectively. Most of the identified 5hmC sites reside in intergenic regions, followed by introns, while the sites near the transcriptional start sites were few. Among genes with CON-specific hydroxymethylated peaks, some genes were related to the kidney development (Amph1, Glcci, Gli3, Igfbp3, Cdh11, FGF10, Ihh, and Agtr1a, in descending order of peak score). Genes with NR-specific hydroxymethylated peaks also had a few kidney development genes (Edn2, Igfbp3, and Fst). Protein expression of Amph1 and Cdh11 was upregulated in NR. The transcript level of Agtr1a assessed by PCR was not different between CON and NR.

Conclusions: Maternal nutrient restriction increased the global DNA hydroxymethylation and changed the local hydroxymethylation in genes involved in kidney development.

SA-PO558

Intrauterine Growth Restriction (IUGR) by Maternal Protein Undernutrition Disrupts the Transcriptional Networks of Energy Metabolism in Nephron Progenitors Francesca Edgington-Giordano, Hongbing Liu, Sylvia Hilliard, Jiao Liu, Yuwen Li, Renfang Song, Zubaida R. Saifudeen, Samir S. El-Dahr. *Tulane University School of Medicine, New Orleans, LA.*

Background: Fetal IUGR from maternal undernutrition is linked to reduced nephron endowment, resulting in suboptimal renal function and a predisposition towards hypertension and chronic kidney disease. Using an established protein-deficiency mouse model of IUGR, we examined the impact of maternal undernutrition on nephron progenitor cell (NPC) maintenance and gene expression.

Methods: CD1 mice were fed isocaloric low-protein (6%) or control (20% protein) diets 3 weeks prior to timed mating. Kidneys were harvested at P0 to assess NPC pool size (Six2, NCAM) and differentiating nephrons (NCAM, Lhx1, WT1) by IF. RNA-Seq was performed on RNA isolated from native NPC of P0 kidneys (n=3), and data analyzed by IPA and GO-Panther. Bonferroni correction was applied.

Results: Significantly reduced ($p<0.0001$) P0 body and kidney weight were observed. However, kidney/body weight ratios are not significantly changed in 6% vs 20% pups. 6% pups show diminished nephrogenic zone, a smaller Six2+ NPC pool and nascent nephron deficit ($p<0.0001$, n=4). Increased immunostaining for p53, phospho-p38 and phospho-ATF2 indicate activation of fetal cellular response to maternal nutritional stress. Mitosis marker phospho-histone H3 staining in the NPC is decreased. RNASeq data show 1,694 upregulated and 2,114 down-regulated genes (1.5-fold cut-off). Top gene enrichment in Biological Processes include RNA splicing/metabolism, cellular metabolic process and cellular component biogenesis. Highest enrichment of genes in Cellular Component was observed for ribonucleoprotein complex and mitochondrion. Energy metabolism categories (EIF2 signaling, Glycolysis, mTOR, eIF4/p70S6K) top the canonical pathways. Expression of renewing NPC markers Cited1, Six2 and Meox are unchanged. Differentiation/induction marker Wnt4 expression was unchanged, however Lhx1 and Jag1 expression decreased more than 2-fold. ISH show decrease in Bmp7, Wnt11 and Wnt9b mRNA.

Conclusions: Pups from undernourished moms demonstrate decreased NPC pool and nascent nephrons. Cellular processes and metabolism are the profoundly altered at the transcriptional level in the NPC. For the long-term, this mouse is an excellent model to analyze how maternal undernutrition impacts offspring kidney development and function.

SA-PO559

The Quantitative and Qualitative Characteristics of Glomerular Basement Membrane in Rat Kidney Development and Glomerulonephritis Liang Fei,[1,2] Dedong Kang,[2] Ping Lan,[3,2] Shinya Nagasaka,[2] Akira Shimizu.[2] *[1]Department of Histology and Embryology, China medical university, Shenyang, China; [2]Department of Analytic Human Pathology, Nippon Medical School, Tokyo, Japan; [3]First Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China.*

Background: The renal glomerulus is filtrate function of primary urine through glomerular tuft, which consists of podocytes, glomerular basement membrane (GBM) and endothelial cells. Mature GBM is mainly composed of α3/α4/α5 chain of type IV collagen (IV).

Methods: In order to clarify the maturation process of renal glomerular tuft during renal development, and injured and recovery of glomerular tuft from injuries in glomerulonephritis (GN), we evaluated the pathology and α chains (IV) of GBM and glomerular capillaries of 1-day-old and 10-week-old rat kidneys, as well as experimental Thy-1 GN on day 7 and 10 (n=3) and clinical biopsy cases of membranoprolferative GN (n=7).

Results: In the development, glomerular capillaries with endothelial cells migrated from interstitium into the cleft of S-shape body to form the glomerulus. The basement membrane (BM) of S-shape nephron and glomerular capillaries formed GBM, which were mainly composed by α1/α1/α2 chain (IV) in S-shape stage. In the early capillary loop stage of glomerulus, the cleft of the S-shaped body was occupied by a primitive capillary network. GBM was consisted of two BMs, such as continuous GBM of primitive podocytes with α3/α4/α5 chain (IV) and discontinuous capillary BM with α1/α1/α2 chain (IV). At late capillary loop stage of glomerulus, two layers of GBM such as continuous podocytes'BM and discontinuous or continuous capillary BM change to one layer of GBM with only α3/α4/α5 chain (IV). In early to late capillary stage, formation of foot processes and fenestrated structures was found in podocytes and endothelial cells, respectively. In experimental and biopsy cases of GN, injured glomerular tuft showed double contour of GBM, α3/α4/α5 chain (IV) of podocytes'GBM and α1/α1/α2 chain (IV) of capillary BM, with irregular effacement of foot processes of podocytes and irregular loss of fenestra of endothelial cells, resembling the pathology of glomerular tuft of early capillary stage. However, after recovery, glomerular tuft showed one layer of GBM with α3/α4/α5 chain (IV) and mature podocytes and endothelial cells.

Conclusions: Our findings suggest that injured glomerular tuft was accompanied by quantitative and qualitative alterations of GBM in GN, and recovery of glomerular tuft after injuries may be following similar processes in the development of glomerular tuft.

SA-PO560

RP-103 Controls WBC Cystine Levels and Promotes Growth in Treatment-Naive Patients ≤6 Years with Nephropathic Cystinosis Craig B. Langman,[3] Juliana C. Ferreira,[1] Kyleen Young,[2] Maria Helena Vaisbich.[4] *[1]Instituto da Criança do HCFMUSP, São Paulo, Brazil; [2]Lurie Children's Hospital Chicago, Chicago, IL; [3]Feinberg School of Medicine, Northwestern Univ., Chicago, IL; [4]Nephrology, Sao Paulo University Medical School, Sao Paulo, Brazil.*

Background: Nephropathic Cystinosis (NC) is a recessive disease in which the lysosomal cystine exporter is deficient, intralysomal cystine accumulates, and the biomarker, WBC ½ cystine/mg protein is > 1 nmol. Cysteamine bitartrate (Cys-Bi), is used to lower levels to <1 nmol. Previous trials of RP-103 have converted patients from an every 6h form of Cys-bi to this every 12h formulation.

Methods: We conducted a long-term, prospective, controlled, open-label study of RP-103 in 17 Cys-Bi naive patients with NC in the US & Brazil. The RP103 starting dose was gradually escalated (10%, every 2 weeks) until the WBC ½ cystine level was <1 nmol. We evaluated height and weight at each visit, and safety (incidence of TEAEs and SAEs). Data reported (mean±SD) below will be for 15/17 subjects ≤ 6y of age.

Results: Age was 2.2±0.9y, range 1.04–4.53y. Ten were ♂. Prior to RP-103, the WBC cystine concentration was 3.1± 2.9 nmol ½ cystine/mg protein. At each subsequent time, the mean concentration was < than at Day 1: 2.2±3, Week(wk) 2; 1.1 ±1.3 wk 12; 0.73±0.64, Month(m) 18. By end of study, 76.9% of subjects had a WBC cystine <1nmol. On Day 1, standing height was in the 2.59 ± 4.00 %ile of the reference population, and increased to 3.27±5.69 at wk 2, 6.95±10.88 at wk 12, and 55.36±43.88 %ile at m18. Z-scores for height were –3.16±1.55 at Day 1 and increased to 0.11±1.96 at study end. On Day 1, weight was in the 3.46 ±11.13 %ile and increased at study exit to 32.85±35.58 %ile. All 17 subjects in the Safety Population had at least 1 TEAE, and 8 had at least 1 TEAE considered related to the study drug. Twelve had an SAE, 5 (29.4%) had a TEAE ≥ Grade 3, and 1 (5.9%) died (unrelated to study drug). No TEAEs led to permanent discontinuation of study drug.

Conclusions: RP-103 safely and effectively lowered the biomarker to target (<1 nmol) in young Cys-Bi naive patients with NC. Linear Growth and body mass increased into the normal range for age (z-score) for those ≤ 6y. Thus, Cys-Bi naive patients ≤ 6y with nephropathic cystinosis may safely and efficiently be started on cystine-reduction therapy with RP-103 (Procysbi).

ATP-Binding Cassette A–13 (ABCA13) Is a Candidate Gene for Familial FSGS Gentzon Hall,[3,5] Megan Chryst-ladd,[1] Liming Wang,[3] Gina E. Kovalik,[2] Guanghong Wu,[4] Brandon M. Lane,[2] Eugene C. Kovalik,[3] Robert F. Spurney,[3] Rasheed A. Gbadegesin.[3] *[1]Duke Molecular Physiology Institute, Durham, NC; [2]Duke University, Durham, NC; [3]Duke University Medical Center, Durham, NC; [4]Duke university, Durham, NC; [5]Duke Molecular Physiology Institute, Durham, NC.*

Background: FSGS is a major cause of ESKD that is characterized by steroid-resistant nephrotic syndrome, rapid progression to ESKD, focal scarring of the glomerular capillary tuft and effacement of podocyte foot processes. Characteristic features of FSGS-associated podocytopathy include 1.) dysregulation of actin cytoskeletal dynamics and dysmotility, 2.) inappropriate cell cycle re-entry and hyperproliferation, and 3.) apoptosis. We carried out whole exome sequencing (WES) on a family with FSGS. Three variants segregated with disease in the family. Of the three variants, only the change in *ABCA13* (p.2330fsX2354) is a novel, loss-of-function (truncating) variant. *ABCA13* is the largest member of a family of 13 transport proteins involved in cellular drug and lipid efflux. Given the established role of *ABCA1* deficiency in cholesterol-induced podocyte injury in diabetic nephropathy, we hypothesized that *ABCA13* knockdown (KD) in immortalized human podocytes may induce dysfunction via a mechanism that involves impaired

cholesterol efflux. Futher, given the known role of cholesterol as an activator of Rac1 signaling, we postulated that *ABCA13* KD may induce inappropriate activation of Rac1 and promote podocyte dysmotility through the Rac1-mediated upregulation of JNK/paxillin signaling.

Methods: Whole-exome sequencing, direct sequencing, lentivirus-mediated siRNA gene silencing, scratch wound healing assays, and immunoblotting.

Results: *ABCA13* KD induced an upregulation of JNK activation ($p < 0.01$) and an increase in Rac1 membrane recruitment in podocytes. Additionally, cell migration in *ABCA13* KD podocytes was significantly increased ($p < 0.01$) relative to scramble siRNA controls. This enhanced podocyte motility was significantly attenuated by the cholesterol extracting agent methyl-b-cyclodextrin ($p = 0.03$) and the JNK inhibitor tanzasertib ($p < 0.01$). Additionally, *ABCA13* KD enhanced paxillin phosphorylation at the JNK target site Ser178 in podocytes.

Conclusions: *ABCA13* KD enhances podocyte motility possibly through the dysregulation of Rac1/JNK/Paxillin signaling axis. These data suggest that: 1. Rac1/JNK/Paxillin signaling may play an important role in the pathogenesis of FSGS, and that 2. targeting this signaling pathway may be a novel therapeutic approach for the treatment of FSGS.

A Homozygous Missense Mutation in VWA2, Encoding an Interactor of the Fraser-Complex, as a Likely Cause of Vesico-Ureteral Reflux Shirlee Shril,[1] Amelie van der Ven,[1] Birgit Kobbe,[2] Stefan Kohl,[1] Hans-Martin Pogoda,[2] Hadas Ityel,[1] Jing Chen,[1] Daw-yang Hwang,[1] Eugen Widmeier,[1] Dervla M. Connaughton,[1] Nina Mann,[1] Matthias Hammerschmidt,[2] Raimund Wagener,[2] Friedhelm Hildebrandt.[1] *[1]Boston Children's Hospital, Boston, MA; [2]University of Cologne, Cologne, Germany.*

Background: Congenital anomalies of the kidney and urinary tract (CAKUT) are the most common cause of chronic kidney disease in the first 3 decades of life. About 38 monogenic causes of CAKUT are known so far, explaining <20% of CAKUT cases.

Methods: To identify additional monogenic causes of CAKUT, we performed whole exome sequencing in a consanguineous patient with CAKUT from Indian origin.

Results: We identified a homozygous missense mutation (c.1336C>T, p.Arg446Cys) in the gene *Von Willebrand factor A domain containing 2 (VWA2)*. By immunohistochemistry on kidneys of newborn mice, we show that Vwa2 and Fraser extracellular matrix complex subunit 1 (Fras1) co-localize in the nephrogenic zone of the renal cortex. There was pronounced staining for Vwa2 in the basement membrane of the UB and derivatives of the MM (comma-shaped and S-shaped bodies). By applying cell-based protein expression studies, we demonstrate that the Arg446Cys mutation decreases secretion of the VWA2 protein into the extracellular space *in vitro*: Lack of secretion is most likely due to increased intracellular aggregate formation of VWA2 secondary to the additional, unpaired cysteine residue in the mutated protein. Recombinant mutant VWA2 additionally forms disulfide-linked higher aggregates *in vitro*.

Conclusions: VWA2 is a known, direct interactor of FRAS1 of the Fraser-Complex (FC). FC-encoding genes *FRAS1*, *FREM1*, *FREM2* and interacting proteins GRIP1 and ITGA8 have previously been implicated in the pathogenesis of syndromic and isolated CAKUT phenotypes in humans (Kohl *JASN* 25, 2014). The results from *in vitro* experiments indicate a dose-dependent, gain-of-function effect of the Arg446Cys homozygous mutation in *VWA2*. *VWA2* therefore constitutes a very strong candidate in the search for novel CAKUT-causing genes.

Mutations of GAPVD1 and ANKFY1 Are Novel Causes of Nephrotic Syndrome Tobias F. Hermle,[1] Ronen Schneider,[1] David Schapiro,[1] Sherif M. El desoky,[2] Jameela A. Kari,[2] Daniela A. Braun,[1] Friedhelm Hildebrandt.[1] *[1]Boston Children's Hospital/Harvard Medical School, Boston, MA; [2]King Abdul Aziz University Hospital, Jeddah, Saudi Arabia.*

Background: Steroid resistant nephrotic syndrome (SRNS) is a frequent cause of end-stage renal disease within the first 3 decades of life. The discovery of more than 50 different monogenic causes has helped to elucidate the pathogenesis of SRNS.

Methods: To identify novel monogenic causes of SRNS we performed homozygosity mapping and whole exome sequencing (WES) in a worldwide cohort of ~600 individuals with nephrotic syndrome. Co-immunoprecipitation using HEK cells was employed to analyze protein interaction.

Results: By WES we identified two homozygous missense mutations of *GAPVD1 (*c.1240C>G, p.L414V and c.2810G>A, p.R937Q) in two patients from unrelated families with early-onset nephrotic syndrome. Both mutated amino acids are conserved to *C. intestinalis.* One patient did not respond to steroids while the other showed the unusual combination of congenital nephrotic syndrome and spontaneous remission. This has previously been observed in few alleles of *NPHS1*. The histology in both cases was characterized by mesangial hypercellularity while electron microscopy revealed podocyte foot process effacement. *GAPVD1* is a known regulator of endosomal trafficking and interacts with *RAB5*. *GAPVD1* harbors both, a GTPase activating and an inactivating domain. We further identified a mutation of *ANKFY1* (c.284G>T, p.R95L, conserved to *D. melanogaster*) in a patient with SRNS and FSGS with an affected sibling sharing the mutation. *ANKFY1* is also an interaction partner of *RAB5* and serves as a *RAB5*-effector. Western blotting revealed expression of *GAPVD1* and *ANKFY1* in a human podocyte cell line. Using co-immunoprecipation we observed physical interaction between both proteins. We further found interaction of *GAPVD1* and the slit diaphragm protein *NPHS1*. Mapping experiments suggest that both functional domains of *GAPVD1* bind to *NPHS1*.

Conclusions: We discover mutations of *GAPVD1* and *ANKFY1* as novel monogenic causes of nephrotic syndrome. Interestingly, both proteins interact with each other and *RAB5*. *GAPVD1* further interacts with *NPHS1,* mutations in which cause SRNS.

SA-PO564

Whole Exome Sequencing Identifies a Monogenic Cause in ~43% of Families with Hypertension from Midaortic Syndrome Jillian K. Warejko,[1] Markus Schueler,[1] Asaf Vivante,[1] Jennifer A. Lawson,[1] Weizhen Tan,[1] Ankana Daga,[1] Shirlee Shril,[1] Shrikant M. Mane,[2] Deborah R. Stein,[1] Michael A. Ferguson,[1] Friedhelm Hildebrandt.[1] *[1]Boston Children's Hospital, Boston, MA; [2]Genetics, Yale University, New Haven, CT.*

Background: Midaortic syndrome (MAS) is a cause of severe hypertension in children with narrowing of the abdominal aorta. It involves the renal vessels in >80% of cases (*Ped Nephrol* 24:2225, 2009). Treatment requires antihypertensive medications and operative or endovascular interventions. Morbidity is high with hypertensive encephalopathy, stroke, heart failure and renal dysfunction. MAS may occur as part of a genetic syndrome, such as neurofibromatosis 1. However, most cases have been considered idiopathic until now.

Methods: We hypothesized that in patients with MAS, a monogenic cause of disease may be detected in one of 38 candidate genes of syndromic or non-syndromic vasculopathies. We studied 36 individuals from 35 different families by whole exome sequencing (WES).

Results: Patients were recruited at Boston Children's Hospital from 1/2014 to 12/2016. Individuals were included in WES if MAS was diagnosed before age <25 years with evidence of narrowing of the abdominal aorta on imaging. We examined WES data for mutations in all 38 candidate genes. In 15/35 families (42.9%), we identified a causative dominant or recessive mutation. Mutations were identified in five candidate genes: *NF1* (6/15 families), *JAG1* (4/15), *ELN* (3/15), and one each for *GATA6* and *RNF213*. A total of 15 different mutations were detected, 10 of which were novel. In 2/6 families with *NF1* mutation and 1/4 families with *JAG1* mutation the appropriate diagnosis of NF or Alagille syndrome respectively, had not yet been made by clinical criteria.

Conclusions: We demonstrate that WES in combination with an *a priori* candidate gene approach can provide a conclusive molecular genetic diagnosis in a high fraction of individuals with syndromic or isolated MAS. We present data that there may be genotype/phenotype correlations between the severity of the mutation and the phenotype observed.

SA-PO565

New Interaction between Galectin-3 and Cystinosin Reveals a Role of Inflammation in Kidney Pathogenesis in Cystinosis Tatiana V. Lobry,[5] Roy Miller,[5] Nathalie Nevo,[2] Celine Rocca,[5] Marie-Claire Gubler,[4] Tristan Y. Montier,[1] Corinne Antignac,[3] Stephanie Cherqui.[6] *[1]Faculté de médecine de Brest, Brest, France; [2]INSERM, Paris, France; [3]Imagine Institute, Paris, France; [4]None, Paris, France; [5]UCSD, San Diego, CA; [6]University of California, San Diego, La Jolla, CA.*

Background: Cystinosis is a lysosomal storage disorder caused by mutations in the *CTNS* gene, encoding a lysosomal cystine transporter, leading to cystine accumulation. Affected individuals typically present with proximal tubulopathy, end-stage renal disease and multi-organ failure. Cystinosin has now been shown to have other cellular functions and an unbiased screen revealed a direct interaction of cystinosin with a member of the galectin's family, galectin-3. This protein is implicated in different biological processes like cell death, cell cycle and inflammation.

Methods: We generated a murine model deficient for both cystinosin and galectin-3, the $Ctns^{-/-}Gal3^{-/-}$ mice.

Results: We showed that cystinosin enhances galectin-3 lysosomal localization and degradation. In the $Ctns^{-/-}$ mouse model, expression of galectin-3 was increased compared to wild-type. Moreover, absence of galectin-3 in cystinotic mice led to a better renal function and preservation of kidney morphology. Less inflammatory cell infiltration was observed in kidney of $Ctns^{-/-}Gal3^{-/-}$ mice compared to $Ctns^{-/-}$ mice, suggesting that galectin-3 mediated inflammation is involved in progression of the kidney disease in cystinosis.

Conclusions: We are currently investigating the mechanism by which galectin-3 induces recruitment of inflammatory cells in the kidney of cystinosis and we already found an interaction between galectin-3 and a chemokine implicated in the recruitment of monocytes/macrophages. This work brings new insights on the pathogenesis of the kidney disease in cystinosis and may lead to the identification of new drug targets to delay its progression to renal failure.

SA-PO566

Whole Exome Sequencing Identifies the Causative Mutation in 50% of Families with Adult-Onset CKD Dervla M. Connaughton,[1,2] Claire Kennedy,[2] Shirlee Shril,[1] Amelie van der Ven,[1] Hadas Ityel,[1] Nina Mann,[1] Shrikant M. Mane,[3] Mark A. Little,[4] Peter J. Conlon,[2,5] Friedhelm Hildebrandt.[1] *[1]Boston Children's Hospital, Boston, MA; [2]Department of Nephrology, Beaumont Hospital, Dublin 9, Ireland; [3]Department of Genetics, Yale University School of Medicine, New Haven, MA; [4]Trinity Health Kidney Centre, Tallaght Hospital, Dublin, Ireland; [5]Department of Medicine, Royal College of Surgeons in Ireland, Dublin 2, Ireland.*

Background: Over 250 monogenic causes of chronic kidney disease (CKD) have been identified (Nat Rev Nephrol 12:133, 2016), mostly in pediatric populations. However, the frequency of monogenic causation in adult-onset CKD has not been extensively studied.

Methods: We conducted whole exome sequencing (WES) in 16 Irish families (27 cases) with CKD. Selection criteria were: A positive family history of CKD (n=12 families) and/or history of extra-renal disease manifestations (n=8 families). Individuals with autosomal dominant polycystic kidney disease or Alport's syndrome were excluded.

Results: WES identified a causative mutation in one of 250 known monogenic CKD genes in 50% of families (n=8/16 families, 12 individuals). Six of the 8 families had no prior diagnosis of the cause of CKD. The 8 families in whom a causative mutation was identified included nephronophthisis (n=4, *IFT140, NPHP1, BBS9, DYNC2H1*), autosomal recessive polycystic kidney disease (n=1, *PKHD1*), congenital abnormalities of the kidneys and urinary tract (n=1, *PAX2*), Lowe's syndrome (n=1, *OCRL*) and interstitial nephritis (n=1, *FAN1*). In 3 families, in whom known CKD genes were excluded, 3 different potential novel candidate genes were identified.

Conclusions: This study establish that WES can detect specific causative mutations in 50% of families with adult-onset CKD. Furthermore, WES allows the identification of novel candidate genes. WES is therefore an important diagnostic tool to establish an etiologic diagnosis in an adult-onset CKD.

SA-PO567

The ANLNR431C FSGS Mutation Alters AKT and Rac1 Activation in Podocytes Brandon M. Lane,[1] Gentzon Hall,[2] Robert F. Spurney,[2] Megan Chryst-ladd,[1] Guanghong Wu,[1] Rasheed A. Gbadegesin.[1] *[1]Department of Pediatrics and Duke Molecular Physiology Institute, Duke University School of Medicine, Durham, NC; [2]Department of Medicine, Duke University School of Medicine, Durham, NC.*

Background: We previously reported that a heterozygous missense mutation (*R431C*) in *ANLN* caused focal and segmental glomerulosclerosis (FSGS) in a kindred with familial FSGS. Anillin has been shown to play a significant role in the regulation of cell motility and survival signaling through the phosphoinositide 3-kinase (PI-3K)/AKT pathway. We hypothesized that the *ANLN R431C* mutation may exert its pathogenic effects in FSGS by inducing aberrant PI3K/AKT pathway signaling.

Methods: Immortalized human podocyte cell lines were stably transfected with tGFP vector control, tGFP-tagged WT (ANLNWT) or mutant (ANLNR431C) constructs using a lentiviral gene delivery system. We examined the effect of the R431C mutation on cell migration, cell proliferation and apoptosis. Pharmacologic inhibitors were used to determine the role of PI3K/AKT signaling pathways in the observed podocyte phenotypes.

Results: Overexpression of $ANLN_{R431C}$ increased cell migration (p=0.002), proliferation (p=0.003), and apoptosis (p=0.0015) compared to cells overexpressing equivalent levels of $ANLN_{WT}$. Western blot analyses and Rac1 activity pulldown assays showed an increase in AKT and Rac1 activation in the $ANLN_{R431C}$-overexpressing podocytes relative to $ANLN_{WT}$-overexpressing podocytes. The increase in podocyte motility was attenuated by the mTor inhibitor rapamycin and the selective Rac1 inhibitor NSC-23766.

Conclusions: The $ANLN_{R431C}$ mutation causes dysregulation of podocyte motility and survival signaling through enhanced activation of PI3K/AKT and Rac1. Targeting PI3K/AKT and Rac1 signaling may have a role in the treatment of FSGS.

Whole Exome Sequencing Identifies a Monogenic Cause of ESRD in 33% of Pediatric Kidney Transplant Patients Nina Mann,[1] Shirlee Shril,[1] Daniela A. Braun,[1] Weizhen Tan,[1] Amelie van der Ven,[1] Hadas Ityel,[1] Dervla M. Connaughton,[1] Shrikant M. Mane,[2] Kassaundra Amann,[1] Leslie D. Spaneas,[1] Khashayar Vakili,[1] Heung B. Kim,[1] Michael J. Somers,[1] Nancy M. Rodig,[1] Friedhelm Hildebrandt.[1] *[1]Boston Children's Hospital, Boston, MA; [2]Yale University, New Haven, CT.*

Background: Renal transplantation is the treatment of choice for children with end-stage renal disease (ESRD). Living donation is preferred as it leads to longer graft survival. However, it has been suggested that living related donors (LRDs) are at a higher relative risk for ESRD (Poggio, *JASN*, advance online publication, 2017). We hypothesized that LRDs may have increased genetic susceptibility to kidney disease and aimed to determine the percentage of pediatric kidney transplant patients in whom a genetic cause of ESRD can be identified.

Methods: Patients who underwent kidney transplantation at Boston Children's Hospital from 2010 to 2016 were recruited. We performed targeted gene sequencing in 11 individuals and whole exome sequencing (WES) in 49 individuals. When WES was performed, data were analyzed for variants in known and candidate ESRD genes.

Results: 60 individuals from 58 families were recruited. 37/60 (62%) patients had congenital anomalies of the kidney and urinary tract (CAKUT), 11/60 (18%) had nephrotic syndrome (NS), and 12/60 (20%) had nephronophthisis (NPHP). We identified a monogenic cause of ESRD in 19/58 (33%) families. Pathogenic mutations were identified in 16% of families with CAKUT, 60% of families with NS, and 64% of families with NPHP. One individual developed insulin-dependent diabetes post-transplantation, which was attributed to steroid use. However, we identified a heterozygous *WFS1* mutation in this patient, which can cause impaired glucose regulation and may better explain his clinical picture.

Conclusions: We detected a cause of ESRD in 33% of pediatric patients who undergo renal transplantation. Knowledge of this genetic information can have implications in decision-making for living related donor transplant ascertainment, and may also help to guide future management of transplant patients.

Funding: Other NIH Support - NIH DK088767, NIH DK086306, and NIH DK076683 to F.H.

SA-PO569

Follow Up of Patients with ADCK4 Associated Glomerulopathy and the CoQ10 Treatment Jia Rao,[4] Xiaoxiang Song,[2] Qian Shen,[3] Hong Xu.[1] *[1]Children's Hospital of Fudan university, Shanghai, China; [2]Children's hospital of Suzhou university, Suzhou, China; [3]Children's Hospital of Fudan University, Shanghai, China; [4]Renal department, Children's Hospital of Fudan university, Shanghai, China.*

Background: ADCK4 related glomerulopathy is an important differential diagnosis in adolescents with steroid resistant nephrotic syndrome (SRNS) and/or chronic kidney disease (CKD) of unknown origin. ADCK4 interacts with components of the coenzyme Q10 (CoQ10) biosynthesis pathway.

Methods: The incidence and phenotypes of patients with ADCK4 mutations were investigated in a cohort of Chinese pediatric patients with SRNS non-nephrotic proteinuria, or CKD.

Results: We identified 12 patients from 11 families with bi-allelic mutations of ADCK4. Patients with ADCK4 mutations showed a largely renal-limited phenotype, with three subjects exhibiting occasional seizures, two subject exhibiting mild mental retardation, and one subject exhibiting retinitis pigmentosa. ADCK4 nephropathy presented during adolescence (median age, 7.6 years) with nephrotic-range proteinuria in 58.3% of patients and advanced CKD in 63.6% of patients at time of diagnosis. Renal biopsy specimens uniformly showed FSGS. ESRD occurred almost after age of 6 in patients with ADCK4 nephropathy. CoQ10 supplementation was administered following genetic diagnosis. Median estimated glomerular filtration rate (eGFR) just before CoQ10 administration was 120.4 (IQR 69.5-135.9) ml/min/1.73m^2, proteinuria was evaluated by the ratio of urinary protein and creatinine (Up/cre) showing 3.9 (IQR 2.4-6.0). After a median follow-up of 21 (range 12–24) months following CoQ10 administration, proteinuria was significantly decreased (median Up/cre 2.2, IQR 1.5-2.5),whereas the eGFR was preserved (median eGFR 128.0 ml/min/1.73m^2, IQR 68.2-137.4).

Conclusions: ADCK4 mutations are one of the most common causes of adolescent-onset albuminuria and/or CKD of unknownetiology in China. CoQ10 supplementation appears efficacious at reducing proteinuria, and may thereby be renoprotective.

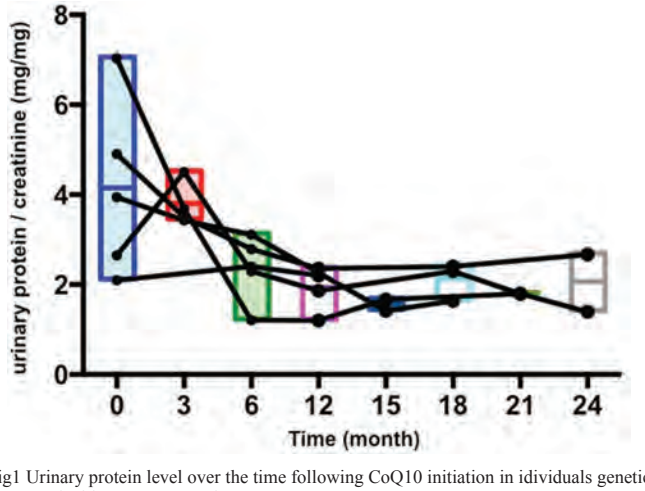

Fig1 Urinary protein level over the time following CoQ10 initiation in idividuals genetic diagnosed with ADCK4 mutation.

SA-PO570

Recessive Mutation in CD2AP Causes Focal Segmental Glomerulosclerosis in Humans and in Mice Tomoko Takano,[1] Lamine Aoudjit,[1] Cindy Baldwin,[1] Jasmine El andalousi,[2] Lina Muhtadie,[3] Indra R. Gupta.[2] *[1]Medicine, McGill University Health Centre, Montreal, QC, Canada; [2]Pediatrics, Montreal Children's Hospital, Montreal, QC, Canada; [3]Medicine, Lakeshore General Hospital, Montreal, QC, Canada.*

Background: CD2-associated protein (CD2AP) is an adaptor protein expressed in podocytes. Cd2ap$^{-/-}$ mice develop early-onset severe nephrotic syndrome and die at 6 weeks old, while Cd2ap$^{+/-}$ mice show susceptibility to insults and glomerulosclerosis at 9 months old. However, only a few patients have been described with mutations in *CD2AP*.

Methods: Whole exome sequencing (WES) was performed on genomic DNA. C57B6 mouse-derived ES cells were electroporated with Cas9, two guide sequences and a donor oligo to allow CRISPR-mediated insertion of 4 base-pairs into the *Cd2ap* gene. One ES clone with the desired insertion was used to generate chimeric mice that were crossed to C57B6 mice for germline transmission.

Results: Three siblings (2 males and 1 female) born of consanguineous parents developed FSGS in their teens and progressed to ESRD by 20 years of age. WES identified an insertion of 4 nucleotides in the *CD2AP* gene, causing a frame shift at Ser198, resulting in a stop codon (p.Ser198fs). All three siblings were homozygous for the mutation, while the unaffected father was heterozygous. Mother's DNA was not available. When heterozygous mice carrying the insertion were bred, wild-type (WT), heterozygous, and homozygous mice were born at the expected Mendelian frequency. By 2-3 weeks, homozygous mice showed heavy albuminuria, glomerulosclerosis, tubular atrophy, and interstitial leukocyte infiltration. By 4-6 weeks, histological changes worsened and were accompanied by elevated serum creatinine and BUN and hypoalbuminemia. These changes were not seen in heterozygotes or WT. Homozygous mice died at 7-8 weeks, likely from kidney failure.

Conclusions: CRISPR/Cas9 gene editing has been utilized to generate a mouse model with a recessive mutation in *Cd2ap*, p.Ser198fs that results in FSGS, nephrotic syndrome, and kidney failure in mice. The results prove that this recessive mutation in *CD2AP* is causal in human FSGS.

SA-PO571

Acute Regulation of the Proximal Tubule Endocytic Pathway in Cell Culture and Ex-Vivo Kidney Slices Catherine J. Baty,[1] Kimberly R. Long,[2] Ora A. Weisz.[1] *[1]University of Pittsburgh, Pittsburgh, PA; [2]University of Pittsburgh School of Medicine, Pittsburgh, PA.*

Background: The proximal tubule (PT) of the kidney is highly specialized for apical endocytosis of megalin/cubilin ligands that pass through the glomerular filtration barrier into the tubule lumen. Impaired uptake of these ligands results in tubular proteinuria, which is observed in genetic diseases such as Lowe syndrome, Dent disease, and sickle cell disease. Despite the critical role of endocytosis for PT function, we know little about how the apical endocytic pathway is regulated in these cells. Studies in PT cells demonstrate that endocytosis of megalin/cubilin ligands is rapidly responsive to changes in fluid shear stress (FSS). However, currently available PT cell culture models lack many key features needed for PT function. Additionally, it is not known whether cells lining the PT *in vivo* also respond endocytically to changes in FSS.

Methods: We have established an OK cell culture system that dramatically enhances cell differentiation and more closely recapitulates the morphology and robust apical endocytic capacity of PT cells *in vivo*. We used fluorescence-based assays and confocal imaging to visualize endocytic uptake in PT cells exposed to variable levels of FSS. As a complementary approach, we optimized conditions to study endocytic uptake in *ex vivo* ultra-thin (<150 mm) murine kidney slices. C57Bl/6J mice (Jackson Laboratory) were anesthetized with isoflurane and kidneys were perfused, surgically harvested and immediately sectioned for culture and functional assays to visualize endocytosis.

Results: Our cell culture model demonstrates dramatically increased apical endocytic capacity compared with OK cells cultured under standard conditions. Additionally, endocytosis of megalin/cubilin ligands is rapidly and reversibly modulated by changes in FSS. Consistent with our studies in cell culture, endocytic uptake was enhanced in slices exposed to shear stress. Studies are in progress to assess the mechanism of FSS-mediated uptake in PT cells and whether this is impaired in diseases that result in tubular proteinuria.

Conclusions: Together, these complementary models offer a useful approach to dissect the effect of physiologically-relevant stimuli on the PT apical endocytic pathway and its disruption in genetic and other diseases that result in tubular proteinuria

SA-PO572

OXGR1 Mutations Present a Novel Cause of Nephrolithiasis Amar J. Majmundar,[1] Ankana Daga,[1] Daniela A. Braun,[1] Heon Yung Gee,[5] Shirlee Shril,[1] Jan Halbritter,[2] Shrikant M. Mane,[6] John A. Sayer,[4] Hanan Fathy,[3] Michelle A. Baum,[1] Friedhelm Hildebrandt.[1] *[1]Medicine, Div Nephrology, Boston Children's Hospital, Boston, MA; [2]University Clinic Leipzig, Leipzig, Germany; [3]El Shatty Children's Hospital, Alexandria, Egypt; [4]Newcastle University, Newcastle, United Kingdom; [5]Yonsei University College of Medicine, Boston, Republic of Korea; [6]Yale University School of Medicine, Yale Center For Mendelian Genomics, New Haven, CT.*

Background: Nephrolithiasis (NL) affects 1 in 11 individuals worldwide and causes significant morbidity and cost including surgical intervention. There are >30 genes, for which causative mutations have been identified in 11% of adult and 17-20% of pediatric NL cases (Halbritter *JASN* 26:543, 2015; Braun c*JASN* 11:664, 2016). Identifying novel NL genes can reveal new pathogenic mechanisms.

Methods: We employed whole exome sequencing (WES) to identify novel genes in familial NL cases.

Results: By WES, we identified a heterozygous missense variant (c.371T>G, p.L124R) in the gene *OXGR1* that segregated in 4 affected children and 1 affected mother from an Egyptian family with an autosomal dominant inheritance pattern of calcium oxalate containing NL and/or nephrocalcinosis (NC). *OXGR1* encodes oxoglutarate receptor 1, a G-protein coupled receptor (GPCR) that is expressed in the distal nephron and promotes urinary alkalinization (Tokonami *JCI* 123:3166, 2013). The affected amino acid residue is conserved through vertebrate orthologues and in 72% of 300 human GPCR sequences. The predicted protein change showed strong SIFT and PolyPhen-2 scores. In the ExAC Exome Database, the allele is not found in the homozygous state and found once heterozygously in 60,632 individuals. Targeted sequencing of *OXGR1* in 599 additional families with calcium oxalate containing NL and/or NC identified 3 additional alleles (c.649T>C, p.C217R; c.697A>C, p.S233R; c.860C>T, p.S287F) in 4 additional families (0.8% of cohort).

Conclusions: We identified *OXGR1* mutations as novel monogenic cause of NL. As *OXGR1* is implicated in urine alkalinization, further study of the disease mechanisms may provide insight into novel therapeutic options for NL.

SA-PO573

TBC1D8B Mutations Are a Novel Cause of Nephrotic Syndrome Ronen Schneider,[4] Tobias F. Hermle,[3] David Schapiro,[1] Afig Berdeli,[5] Reyner F. Loza,[6] Daniela A. Braun,[2] Friedhelm Hildebrandt.[1] *[1]Boston Children's Hospital, Brookline, MA; [2]Boston Children's Hospital, HMS, Boston, MA; [3]Boston Children's Hospital/Harvard Medical School, Boston, MA; [4]Nephrology, Boston Childrens Hospital, Boston, MA; [5]Ege University Medical Faculty, Izmir, Turkey; [6]Cayetano Heredia Hospital, Los Olivos, Peru.*

Background: Nephrotic Syndrome (NS) is the second most frequent cause of end-stage renal disease in the first 3 decades of life. RAB proteins are regulators of endocytosis, which is an important feature of podocyte function. Identification of 50 monogenic genes that if mutated cause NS, has rendered first insights into disease mechanisms of NS. To date no monogenic mutations affecting RAB proteins or related proteins have been implicated in the pathomechanism of NS.

Methods: To identify novel monogenic causes of NS we combined homozygosity mapping with whole exome sequencing (WES) in a worldwide cohort of ~600 individuals with NS.

Results: In patient B931 with steroid resistant NS (SRNS) and FSGS, who presented at the age of 9 years, we detected a hemizygous mutation in the X-chromosomal gene *TBC1D8B* (c.2338A>T; p.Thr780Ser). Thr780 is conserved since *D. Rerio*. In patient A2563 who presented with steroid sensitive NS (SSNS) at the age of 7 years, and had minimal change disease on renal biopsy, we detected a hemizygous *TBC1D8B* mutation (c.190C>T; p.Arg64Cys). Arg64 is highly conserved since *S. Cerevisiae*. Both *TBC1D8B* mutations are predicted to be disease causing by SIFT, MutaTaster and PolyPhen2 software programs. Both variants are not present hemizygously in the ExAC database. The yeast orthologue for *TBC1D8B*, *Msb3*, has GTPase Activating Protein (GAP) activity for RAB proteins, which play a role in the endocytic pathway (Lachmann, Mol Biol Cell, 23: 2516, 2012). By Western blot and gene specific siRNA knockdown we show that TBC1D8B is expressed in a human podocyte cell line. By Co-IP studies we show that RAB5, a key regulator of endocytic trafficking, interacts with TBC1D8B protein when overexpressed in human HEK cells. TBC1D8B also interacts with endogenous RAB5. In human podocytes TBC1D8B localizes to vesicles but does not co-localize with RAB5, RAB7, or RAB11.

Conclusions: We here identify recessive mutations of *TBC1D8B* as a likely novel monogenic cause of nephrotic syndrome. Interaction with RAB5 without co-localization of both proteins suggests that another RAB protein may be the primary target of TBC1D8B. Further functional studies will shed light on the pathomechanism of TBC1D8B loss-of-function in NS.

Funding: Other NIH Support - NIH DK076683 to Friedhelm Hildebrandt

A Rare Kidney Disease Family with CCDC114 Mutation and Cilia Xiangmei Chen. *PLA Genaral Hospital, Beijing, China.*

Background: Ciliopathies is a group of diseases characteriaed by dysfunction of cilia and patients with ciliapathies have a variety of developmental and degenerative disorders.

Methods: We present the case of a 15-year-old child with dysplasia and multiple organ damage who was initially diagnosed as nephrotic syndrome. Her parents and sister are in good health. Physical examination shows normal blood pressure;edema of face and lower limb;sensorineural deafness and hypopsia. She also has dysplasia including congenital heart disease and duplex kidney. The patient also has intermittent cough. Laboratory investigation shows creatinine is 1.88 mg/dl;eGFR is 39.12 mL/min/1.73 m^2;proteinuria is 3.42g/24h;albumin is 23.1g/L;hemoglobin is 88g/L;decreased thyroid function. The brain MRI shows abnormal signal in bilateral parietal lobe of the brain groove in FLAIR sequence which indicates decreased cerebrospinal fluid flow rate. Renal biopsy shows focal segmental glomerular sclerosis. The patient progressed to renal failure and received hemodialysis 10 months after renal biopsy. The patient's clinical manifestations are consistent with cilioapathies, very similar to Alström syndrome. Cilia immunofluorescence of renal tissue showed a decrease number of cilium of the patient compared to normal kidney. Then WES shows a site mutation in *CCDC114*(NM_144577 exon7 c.596C>T p.Ala199Val)in patient. We found that CCDC114 located in centrosome and knock down *CCDC114* could affect the occurrence of cilia in hRPE1 cells.

Results:

Conclusions: We found a decrease in the number of cilium in the kidney of patient with ciliapathies and identified *CCDC114* as the main target gene by WES. We found that CCDC114 affected primary cilia formation in hRPE1 cells.

NOS1AP Mutations Cause Steroid-Resistant Nephrotic Syndrome Amar J. Majmundar,[1] Daniela A. Braun,[1] Eugen Widmeier,[1] Shirlee Shril,[1] Shrikant M. Mane,[4] Neveen Soliman,[3] Christoph Aufricht,[2] Friedhelm Hildebrandt.[1] *[1]Medicine, Div Nephrology, Boston Children's Hospital, Boston, MA; [2]Medical University of Vienna, Vienna, Austria; [3]Pediatrics, Cairo University, Cairo, Egypt; [4]Genetics, Yale University, New Haven, CT.*

Background: Steroid resistant nephrotic syndrome (SRNS) is the second leading cause of chronic kidney disease in the first three decades of life. Mutations in >39 genes provide a monogenic cause in 29.5% of SRNS cases (Sadowski *JASN* 26:1279, 2015) and have defined patho-mechanisms (Lovric *NDT* 31:1802, 2016).

Methods: We performed whole exome sequencing (WES). Live cell imaging was performed following wild-type and mutated cDNA construct expression in immortalized human podocytes.

Results: By WES, we identified homozygous recessive mutations in 2 unrelated individuals with SRNS in the gene *NOS1AP* (c.428G>A; p.C143Y in subject A1018 and c.345-3T>G; p.I116Afs*4 in subject A5016). *NOS1AP* encodes an adaptor protein that interacts with nitric oxide synthase (NOS) and with NOS effectors through its phosphotyrosine binding domain (PTB) (Fang *Neuron* 28:183, 2000). The C143 residue within the PTB is conserved through invertebrate orthologues and in 85% of 101 human PTB sequences. The p.C143Y change registered strong SIFT and PolyPhen-2 scores. The c.345-3T>G coding change is predicted to reduce splicing of the acceptor site of intron 4. Skipping of adjacent exon 5 results in the truncating coding change p.I116Afs*4. Neither mutation is observed in the ExAC Exome Database. NOS1AP is expressed in podocytes but not endothelial or mesangial cells of rat kidney glomeruli. Transfection of wild-type NOS1AP induced filopodia in 58% of immortalized human podocytes versus only 1% of mock GFP transfected cells. Podocytes transfected with mutated NOS1AP p.C143Y and NOS1AP p.I116Afs*4, which we detected in the SRNS subjects, lacked filopodia formation, demonstrating loss of NOS1AP function.

Conclusions: We identified mutations in *NOS1AP* in 2 unrelated families with SRNS, revealing a novel monogenic cause of glomerular disease. These findings highlight a new pathogenic mechanism related to nitric oxide signaling and a potential therapeutic target for nephrotic syndrome.

SA-PO576

Whole Exome Sequencing Identifies Causative Mutations in 16% and Novel Candidate Genes in 24% of Individuals with a Diagnosis of CAKUT Dervla M. Connaughton,[1] Amelie van der Ven,[1] Hadas Ityel,[1] Shirlee Shril,[1] Nina Mann,[1] Makiko Nakayama,[1] Jing Chen,[1] Asaf Vivante,[1] Daw-yang Hwang,[1] Eugen Widmeier,[1] Julian J. Schulz,[1] Velibor Tasic,[2] Shrikant M. Mane,[3] Friedhelm Hildebrandt.[1] *[1]Boston Children's Hospital, Harvard Medical School, Boston, MA; [2]University Children's Hospital, Skopje, Macedonia (the former Yugoslav Republic of); [3]Genetics, Yale University, New Haven, CT.*

Background: Congenital anomalies of the kidney and urinary tract (CAKUT) cause 50% of chronic kidney disease in children. Several lines of evidence support the hypothesis that CAKUT has a monogenic origin: i) congenital nature, ii) monogenic multi-organ syndromes with CAKUT, iii) familial occurrence, iv) monogenic mouse models and v) the complex genetics underlying renal morphogenesis. About 40 monogenic causes of CAKUT are known so far, explaining ~17% of cases.

Methods: We applied whole exome sequencing (WES) to 135 individuals from 76 families with CAKUT. WES data were evaluated for mutations in known causes of CAKUT in humans (~40 genes), and novel candidate genes for syndromic (~200 genes) or murine CAKUT (~180 genes). In consanguineous or multiplex families, we also performed a search for novel recessive CAKUT genes (14/76) or trio analysis (24/76), respectively.

Results: In 9/76 (12%) families, a causative mutation in a known gene for isolated or syndromic CAKUT was identified that sufficiently explained the respective patients phenotype. In 3/76 (4%) of families, a mutation was identified in a gene causing a kidney disease that may represent a phenocopy of CAKUT (e.g. small kidneys). When evaluating candidate genes for human syndromic CAKUT, we detected deleterious mutations in 5/76 (7%) families with isolated CAKUT. In 1 family, mutations in a mouse candidate gene was identified. In 14/76 consanguineous and 24/76 non-consanguineous families we additionally applied a targeted search for homozygously mutated genes or trio analysis, respectively, and identified 12 potential novel candidate genes for CAKUT.

Conclusions: By WES, we detected causative mutations in 16% of cases with a diagnosis of CAKUT and identified 12 potential novel CAKUT genes. We show that syndromic and murine candidate genes are useful to identify genetic causes of isolated human CAKUT.

Group/Team: Precision In CAKUT Italian Study Group.*

Background: Congenital anomalies of the kidneys and urinary tract (CAKUT) are a leading cause of end stage renal disease. Pathogenetic mechanisms behind CAKUT are mostly unknown. Point mutations and copy number variations (CNVs) account for 10-30% of the cases. Genetic tests are often not performed, thus limiting prognosis and management.

Methods: We present a multi-institutional Italian study group on CAKUT, composed of adult and pediatric nephrology and urology investigators. The group aims at recruiting and charactering CAKUT patients to a) conduct clinical characterization and prospective studies b) perform research DNA microarrays and whole exome sequencing (WES) c) perform clinically certified CLIA confirmation of results d) implement genetic results into clinical practice and e) devise novel precision medicine approaches.

Results: 30 Italian centers have recruited and characterized 1,482 index cases. 658 of them have been subjected to DNA microarrays for GWAS and CNVs, and 393 have been subjected to WES. The most commonly identified CNVs were the deletion at the loci 17q12, 22q11.2, 1q21 and 16p11.2, while the most commonly point mutations were in *PAX2*, *EYA1*, *HNF1B*, *SIX5*, *GATA3*. Most of these genetic lesions predispose to extra-renal diseases and would benefit for early intervention strategies. The remaining samples are undergoing DNA microarrays/WES.

Conclusions: We plan to enroll 5,000 patients. The deep clinical and phenotypic characterization will allow precise anatomical classification of disease. Genetic data will be used to guide deep phenotyping. The longitudinal design will allow identification of genetic and non-genetic prognostic factors in order to improve renal and overall patient outcome.

Development of DCR-PHXC, an Optimal Treatment Approach for Primary Hyperoxalurias Chengjung Lai,[1] Natalie Pursell,[1] Wei Zhou,[1] Michael D. Dills,[1] Chaitali Dutta,[1] Utsav H. Saxena,[1] Girish R. Chopda,[1] Martin L. Koser,[1] Rebecca Lescarbeau,[1] Naim Nazef,[1] Boyoung Kim,[1] Rachel A. Storr,[1] Weimin Wang,[1] Marc Abrams,[1] Hank Dudek,[1] Eduardo C. Salido,[2] Bob D. Brown.[1] *[1]Dicerna Pharmaceuticals, Inc., Cambridge, MA; [2]Hospital Universitario Canarias, La Laguna, Tenerife, Spain.*

Background: Primary hyperoxalurias (PHs) are autosomal recessive disorders caused by the overproduction of oxalate leading to calcium oxalate precipitation in the kidney and eventually to end stage renal disease. Currently, the only treatment effective in reducing oxalate production in patients who do not respond to high-dose vitamin B6 therapy is a combined liver and kidney transplant. We have previously demonstrated that a potential strategy to treat PH Type I (PH1), the most severe form of PH, is to reduce the hepatic production of oxalate using an RNA interference (RNAi) approach targeting *hydroxyacid oxidase 1*, which encodes glycolate oxidase (GO). Reduction of GO in the livers of mice and non-human primates blocks the conversion of glycolate to glyoxylate, the main precursor to oxalate in the liver. Alternatively, reducing the amount of hepatic lactate dehydrogenase (LDH) expression, the key enzyme responsible for converting glyoxylate to oxalate, should more effectively prevent the accumulation of oxalate in PH1, as well as PH Type 2, PH Type 3, and Idiopathic PH, patients.

Methods: Here we report the development of DCR-PHXC, an investigative RNAi therapeutic targeting hepatic LDH, for the treatment of PHs. DCR-PHXC was administered via subcutaneous injection to genetically engineered and chemically-induced mouse and non-human primate models of multiple PHs.

Results: We demonstrate that reduction of hepatic LDH achieves more effective and durable oxalate reduction than suppression of GO in mouse and non-human primate models of PHs. Continued repression of hepatic LDH in mice and non-human primates showed no adverse effects.

Conclusions: The results presented here support the further development of hepatic-specific inhibition of LDH as a highly efficient therapeutic approach to treat all types of primary hyperoxaluria.

SA-PO579

PRDM15 Mutations Cause Steroid-Resistant Nephrotic Syndrome with Microcephaly, Polydactyly, and Heart Defects Shazia Ashraf,[1] Denny Schanze,[4] Amelie van der Ven,[1] Shasha Shi,[3] Svjetlana Lovric,[1] Neveen Soliman,[2] Mohamad A. Jairajpuri,[5] Jan Kadlec,[3] Martin Zenker,[4] Friedhelm Hildebrandt.[1] *[1]Boston Childrens Hospital, Harvard Medical School, Boston, MA; [2]Cairo University, Cairo, Egypt; [3]INSERM, Grenoble, France; [4]Institute of Human Genetics, Magdeburg, Germany; [5]Jamia Millia Islamia University, New-Delhi, India.*

Background: Steroid-resistant nephrotic syndrome (SRNS) causes 15% of chronic kidney disease in children and young adults. First insights into the pathogenesis of SRNS came from identification of >50 single-gene causes. PRDM proteins contain SET domain and multiple zinc fingers domains, and are involved in transcriptional regulation.

Methods: We performed whole exome sequencing (WES) to identify novel monogenic causes of SRNS in >1,000 individuals with SRNS.

Results: We identified 3 different recessive mutations in *PRDM15* (PR domain containing 15) (p.M483K, E519K and C1173Y) in 6 unrelated families. Interestingly, 4 affected individuals with the C1173Y mutated allele exhibited SRNS (childhood-onset) with microcephaly, polydactyly, and heart defects, while the 2 mutations in the SET domain of PRDM15 only caused isolated SRNS. C1173 is a critical "cysteine" residue at the "knuckle" of the Cys-x-x-Cys sequence necessary to complex the zinc ion. We tested the stability of wild type (WT) protein *versus* two mutations (M483K and E519K) in the SET domain of PRDM15, using thermal stability assay by tryptophan absorption. We demonstrate that the M483K mutant was significantly less stable than WT, while the E519K mutant was insoluble. Further, we show that stable knockdown of *PRDM15* results in decreased cell migration and severe proliferation defects in cultured human podocytes. WT, but not 3 mutant, constructs rescue the migration defects in podocytes, confirming deleteriousness of the mutations that we identified in SRNS patients. By immunofluorescence studies, we find that PRDM15 colocalizes with fibrillarin at nucleoli of human podocytes.

Conclusions: We have identified *PRDM15* mutations as a novel cause of childhood-onset SRNS with microcephaly, polydactyly and heart defects. Our findings may implicate a defect in a transcriptional program as a new cause of SRNS.

Defects in All Components of the t6A Biosynthesis Pathway Lead to Galloway-Mowat Syndrome Geraldine Mollet,[1] Bruno Collinet,[2] Dominique Liger,[2] Christelle Arrondel,[1] Laurine Buscara,[1] Gaelle Martin,[1] Olivier Gribouval,[1] Olivia Boyer,[1] Daniela A. Braun,[3] Anne-Claire Boschat,[4] Sylvia Sanquer,[5] Daniella Magen,[6] Audrey Laurent,[7] Friedhelm Hildebrandt,[3] Herman Van tilbeurgh,[2] Corinne Antignac.[1] *[1]Laboratory of Hereditary Kidney Diseases, Inserm UMR1163-Imagine Institute-Paris Descartes University, Paris, France; [2]Institut de Biologie Intégrative de la Cellule, Université Paris Sud CNRS UMR9198, Orsay, France; [3]Boston Children's Hospital, Boston, MA; [4]Mass spectrometry Facility, Inserm U1163 Imagine Institute, Paris, France; [5]Metabolomic and proteomic Biochemistry Department-Necker Hospital, AP-HP, Paris, France; [6]Pediatric Nephrology Institute-Rambam Health Care Campus-Technion Faculty of Medicine, Haifa, Israel; [7]Service de Néphrologie, Rhumatologie et Dermatologie pédiatriques, Hospices Civils de Lyon-Hôpital Femme-Mère-Enfant, Bron, France.*

Background: The universal threonylcarbamoyladenosine (t6A) modification on tRNAs, essential for translation initiation and translational efficiency, is catalyzed by two enzymes, YRDC and OSGEP, the last one being part of the highly conserved multiprotein complex KEOPS composed of 5 subunits (C14ORF142, LAGE3, OSGEP, TP53RK and TPRKB). Lately, we identified mutations in all 5 subunits of KEOPS in patients with Galloway-Mowat Syndrome (GAMOS, OMIM 251300) associating steroid-resistant nephrotic syndrome with microcephaly and neurological impairment. However, the role of the newly identified C14ORF142 (C14) subunit is still unclear.

Methods: To identify new genes of GAMOS and better understand the role of C14, we performed whole exome sequencing, measured t6A modification by mass-spectrometry and performed western blot and qRT-PCR of KEOPS subunits in lymphoblastoid cell lines (LCLs) from GAMOS patients.

Results: We identified compound heterozygous missense mutations in the *YRDC/Sua5* gene in one patient with an extremely severe GAMOS phenotype. Interestingly, primary fibroblasts from this patient present growth defects likely due to t6A deficiency. By contrast, we did neither observe any growth defects in C14-null fibroblasts, nor any change in the t6A level in C14-mutated LCLs. Nevertheless, we demonstrated that the absence of C14 leads to a decreased expression level of the four other KEOPS subunits, likely through the shortening of the half-life of KEOPS subunits since without any effect on mRNA levels.

Conclusions: We identified mutations in an additional gene known to be involved in the biosynthesis of the t6A modification that confirms the crucial role of this modification in the pathogenesis of GAMOS. The differences in the clinical phenotypes between YRDC and C14 patients can be explained by the different role of these proteins in t6A

modification, YRDC being directly involved in its biosynthesis, whereas C14 would stabilize the KEOPS complex to modulate its function(s).

SA-PO581

Visualization of Force Dynamics and Actin Remodeling in ACTN4 Mutant Podocytes Subjected to Stretch Di Feng,[1] Ava Benjamin,[1] Jacob Notbohm,[2] Minxian Wang,[1] Ramaswamy Krishnan,[3] Martin R. Pollak.[1] *[1]Nephrology, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, MA; [2]University of Wisconsin-Madison, Madison, WI; [3]Emergency Medicine, BIDMC/ Harvard Medical School, Boston, MA.*

Background: Alpha-actinin-4 gene (ACTN4) mutations cause a rare form of familial focal segmental glomerulosclerosis (FSGS) and podocyte injury in humans. Our study aimed to better understand the mechanism by which mutant ACTN4 contributes to podocyte dysfunction by assessing the effect of the mutation on a podocyte's response to transient stretch.

Methods: We used primary podocytes isolated from Actn4 K256E Knock in mutant mice (n=3) and WT littermates (n=3) as a cellular model. Measurements were performed in isolated single cells and data were pooled across multiple mice. We used traction force microscopy to quantify contractile forces exerted by podocytes on their underlying substrate in response to transient stretch. We used live cell imaging to examine the distribution of actin.

Results: Compared to WT, mutant ACTN4 podocytes bear more actin stress fibers bundles and exert greater contractility before stretch. After the first transient stretch, WT and mutant podocytes demonstrated similar reductions in their contractile forces. During the recovery period, WT podocytes demonstrated recovery of their contractile forces close to pre-stretch baseline values, whereas the majority of mutant podocytes showed impaired recovery. After a total of 3 transient stretches, WT podocytes on average recovered 79% of their baseline contractile forces, whereas the majority of mutant podocytes (10/15) recovered less than 50% of their baseline, with 7 failing entirely (completely losing their ability to generate contraction forces). Additionally, representative WT podocytes demonstrated cracks in their cytoskeletons after the first stretch that were subsequently repaired during the recovery period, whereas representative mutant podocytes whose contractile forces failed demonstrated cracks that persisted during the recovery period.

Conclusions: Our findings provide the first direct evidence of a mutant ACTN4 podocyte's inability to maintain its structure and function in response to mechanical stress, suggesting a clearer path through which mutant ACTN4 leads to podocyte detachment and kidney injury.

MicroRNA Content in Cells Is Globally Disrupted by the Nephrotic Syndrome-Related Point Mutation in XPO5 Devorah Gur-Wahnon, Iddo Z. Ben-Dov. *Nephrology and Hypertension, Hadassah - Hebrew University Medical Center, Jerusalem, Israel.*

Background: MicroRNA (miRNA) are small noncoding RNA that regulate gene expression. Mature miRNA are crucial for the development and homeostasis of podocytes. Maturation of miRNA entails a multistage process that involves several proteins. Recently, steroid-resistant nephrotic syndrome (SRNS) in a child was attributed to a point mutation in Exportin-5 (*XPO5*), a protein that exports miRNA precursors from the nucleus to the cytoplasm (Braun DA 2016). However, whether or not the mutation affects the miRNA-related function of Exportin-5 is not known. We hypothesized that the V552I mutation impedes miRNA maturation, and that the association with SRNS may shed light on the roles of specific miRNA in podocytes.

Methods: We transfected XPO5-knockout (*XPO5*$^{-/-}$) HCT116 cells with plasmids encoding either wt *XPO5* or *XPO5*[V552I] and compared global miRNA content with non-rescued *XPO5*$^{-/-}$ cells and parental cells via small RNA sequencing.

Results: miRNA quantification confirmed global depletion of mature miRNA in *XPO5*$^{-/-}$ compared to parental cells. Transfection experiments showed partial rescue of miRNA content with wt XPO5. Transfection of a plasmid encoding XPO5 harboring the V552I mutation did not rescue miRNA maturation (Figure). Conversely, mapping of small RNA reads to mRNA and rRNA was relatively higher in *XPO5*$^{-/-}$ cells and mutant XPO5-transfected *XPO5*$^{-/-}$ cells compared to parental and wt XPO5-transfected *XPO5*$^{-/-}$ cells.

Conclusions: Together with predictions of disrupting impact of the V552I mutation, our experiments show that the SRNS-related *XPO5* mutation may cause global reduction of mature miRNA. Further experiments should pinpoint specific miRNA and miRNA targets responsible for the podocyte phenotype.

Funding: Government Support - Non-U.S.

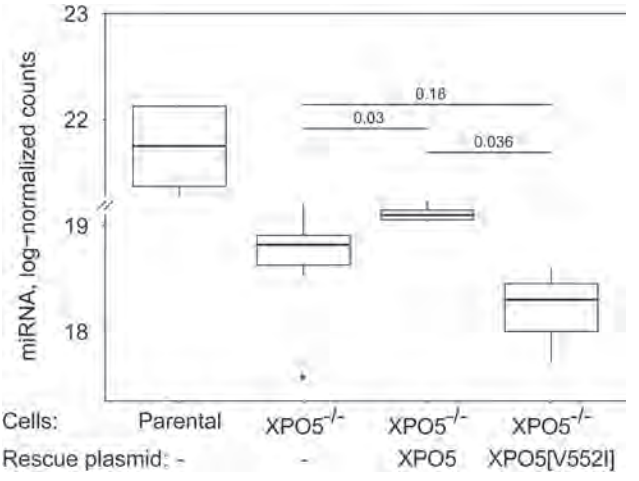

Figure: Log-normalized global miRNA counts in HCT116 cells, XPO5$^{-/-}$ HCT116 cells, XPO5$^{-/-}$ HCT116 cells transfected with wildtype XPO5-encoding plasmid and XPO5$^{-/-}$ HCT116 cells transfected with mutant (V552I) XPO5-encoding plasmid

SA-PO583

Primary Genetic Mechanism with Secondary Focal Segmental Glomerulosclerosis Is the Prevalent Cause of Early-Onset Proteinuria Resistant to Treatment Francesca Becherucci,[2] Benedetta Mazzinghi,[2] Samuela Landini,[1] Rosa maria Roperto,[2] Fiammetta Ravaglia,[1] Giulia Sansavini,[2] Marco Allinovi,[1] Sabrina Giglio,[1] Paola Romagnani.[1,2] *[1]University of Florence, Florence, Italy; [2]Nephrology and dialysis Unit, Meyer Children's Hospital, Florence, Italy.*

Background: Proteinuria is a hallmark of kidney diseases and represents an important determinant to the progression toward chronic kidney disease (CKD), especially in children and young adults. The importance of genetic causes is clearly emerging and has already been reported in about 30% of patients with steroid-resistant nephrotic syndrome (SRNS) and in 25% of patients with early-onset CKD.

Methods: To assess the role of genetic variants in the pathogenesis of proteinuria and CKD we applied whole-exome sequencing (WES) followed by bioinformatic filtering for 308 genes reported as even rare causes of CKD to 107 patients with different types of proteinuric diseases and an age at onset younger than 20 yeras, excluding immuno- and complement-mediated forms.

Results: This strategy allowed us to find a prevalence of potentially pathogenic genetic variants as high as 71.7% in patients presenting with SRNS and severe proteinuria, whereas no genetic defect was present in patients with steroid-sensitive nephrotic syndrome. These variants occurred in podocyte genes in 48.8% of cases and in *COL4A* genes associated with variants in modifier genes in 20.9% of cases. Among patients with mutations, the most frequent pathologic finding was focal segmental glomerulosclerosis, irrespectively of the different genetic causes, whereas the clinical phenotype at onset mirrored the type of gene involved. In addition, the presence of pathogenic variants was associated with the lack of response to immunosuppressive treatments and complete remission of the disease could only be observed in the group of negative patients. Finally, progression toward CKD was significantly higher in patients with pathogenic variants than in negative patients, suggesting that the presence of genetic defects is highly predictive of the clinical outcome of these patients.

Conclusions: These results suggest that genetic abnormalities are key elements in the pathogenesis of proteinuric diseases and are predictive of specific phenotypic features, such as the response to therapies and the outcome of the disease, thus supporting the opportunity of including WES in the diagnostic flow-chart of these disorders, especially in patients with an early onset of the disease.

SA-PO584

Rare GREB1L Mutations Contribute to the Genetic Heterogeneity of Congenital Kidney Malformations Simone Sanna-Cherchi,[2] Kamal Khan,[4] Rik Westland,[11] Priya Krithivasan,[2] Hila Milo Rasouly,[2] Iuliana Ionita-Laza,[2] David Fasel,[3] Krzysztof Kiryluk,[2] Monica Bodria,[5] Edgar A. Otto,[10] Matt G. Sampson,[10] C. Gillies,[10] Adele Mitrotti,[2] Loreto Gesualdo,[8] Friedhelm Hildebrandt,[1] Joanna Van Wijk,[11] Marijan Saraga,[7] Francesco Scolari,[9] Velibor Tasic,[6] Gian Marco Ghiggeri,[5] Anna Materna-Kiryluk,[12] David B. Goldstein,[2] Nicholas Katsanis,[4] Erica Davis,[13] Ali G. Gharavi.[2] *[1]Boston Children's Hospital, Boston, MA; [2]Columbia University, New York, NY; [3]Columbia University Medical Center, New York, NY; [4]Duke University, Durham, NC; [5]G. Gaslini Children Hospital, Genoa, Italy; [6]University Children's Hospital, Skopje, Macedonia (the former Yugoslav Republic of); [7]University Hospital in Split, Split, Croatia; [8]University of Bari, Altamura, Italy; [9]University of Brescia, Montichiari (Brescia), Italy; [10]University of Michigan, Ann Arbor, MI; [11]VU University Medical Center, Amsterdam, Netherlands; [12]Poznan University of Medical Sciences, Poznan, Poland; [13]Duke University Medical Center, Durham, NC.*

Background: Renal agenesis and hypodysplasia (RHD) are a major cause of pediatric end-stage renal disease.

Methods: We conducted whole exome sequencing in 203 patients with RHD and identified diagnostic pathogenic mutations in 8/203 patients. In another 6 patients, we found non-recurrent novel loss-of-function (LOF) variants in genes associated with rare syndromes that include kidney defects (*SETBP1, WNT5A*), or in genes whose inactivation results in kidney malformations in the mouse (*SLIT3, HSPA4L, T, SCTR*).

Results: To define novel genetic drivers in the remaining cohort of 195 patients, we compared their LOF burden with 6,905 controls. We identified rare LOF variants in *GREB1L* (P=2.04x10^{-5}), a gene ubiquitously expressed in the developing mouse kidney. Expansion of our model with novel deleterious missense variants resulted in exome-wide significance for *GREB1L* (P=4.08x10^{-6}). Three mutations (2 LOF and 1 missense) segregated in an autosomal dominant fashion and one predicted deleterious missense was *de novo* (joint value for burden, inheritance and *de novo* occurrence: P<1.0x10^{-8}). In a replication cohort of 410 RHD cases, we identified 8 more qualifying LOF/missense variants in *GREB1L*. To directly test our genetic findings, we generated a *greb1l* zebrafish model. Knockdown and CRISPR/Cas9 deletion of *greb1l* in zebrafish showed specific pronephric defects that could be rescued by introduction of wild-type human mRNA. Randomized testing of missense alleles by *in vivo* complementation showed that 4/4 alleles found exclusively in patients were unable to rescue the phenotype.

Conclusions: Taken together, our study provides new insight into the genetic landscape of renal malformations and identifies *GREB1L* as a novel susceptibility gene for RHD.

The Novel, Non-Toxic Nonsense Suppressor Drug, ELX-02, Is Effective in Cystinosis Emma J. Brasell,[2] Lee lee Chu,[3] Iris Alroy,[1] Idit Eshkar-Oren,[1] Michal Shavit,[1] Meytal Shohat,[1] Pedro Huertas,[1] Yojiro Yamanaka,[2] Paul R. Goodyer.[2] *[1]Eloxx Pharmaceuticals, Rehovot, Israel; [2]McGill University, Montreal, QC, Canada; [3]RI-MUHC, Montreal, AB, Canada.*

Background: Cystinosis is caused by mutations in the cystinosin (*CTNS)* gene, encoding a lysosomal membrane transporter responsible for the efflux of cystine. Intralysosomal cystine accumulation drives progressive organ dysfunction in cystinosis. In Quebec, about 50% of patients harbor a W138X nonsense mutation, causing a premature termination codon (PTC) in exon 7. PTCs cause nonsense-mediated decay (NMD) of mutant transcripts and inhibit protein translation. Aminoglycosides have nonsense suppressor activity, which permits translational read-through of PTCs, but are too toxic to be used for therapy. In contrast, the novel compound ELX-02 was safe and generally well-tolerated in humans up to 5mg/kg.

Methods: To test the efficacy of ELX-02, we treated human fibroblasts harboring the W138X mutation and examined *CTNS* expression and intracellular cystine levels. Using zinc finger nuclease technology, we generated a *Ctns*$^{Y226X/Y226X}$ mouse and replicated the in vitro experiments in mouse fibroblasts. Mice were then injected with ELX-02 (10mg/kg s/c X2/week for 22days). Half-cystine levels were assessed in kidneys and pharmacokinetics (PK) studied in plasma and kidney tissue.

Results: After treatment with ELX-02, *CTNS* mRNA transcript levels in *CTNS*$^{W138X/W138X}$ fibroblasts increased to normal levels and intracellular cystine was reduced. These results suggest that ELX-02 reduces NMD of *CTNS*^{W138X} transcript and allows production of functional CTNS protein. In addition, ELX-02 had a similar therapeutic effect on the Y226X mutation in mouse fibroblasts. In ELX-02 treated mice, pathologic half-cystine was reduced to 55% of untreated levels. ELX-02 in plasma had similar Cmax (15ug/ml at 15 min), AUC and elimination half-life (~30 min) following single and repeated administration. ELX-02 was more concentrated in kidney (Cmax 40ug/g), with sustained levels of 15ug/g for > 8 hrs.

Conclusions: These data demonstrate read-through activity of ELX-02 on h*CTNS* W138X and m*Ctns* Y226X mutations, producing sufficient CTNS protein for cystine efflux from lysosomes. Thus, ELX-02 may be an effective therapy for cystinosis caused by PTCs.

Identifying Modifier Genes of X-Linked Alport Syndrome Using a Novel Multi-Parent Mouse Model Ron Korstanje, Daniel M. Gatti, Yuka Takemon. *The Jackson Laboratory, Bar Harbor, ME.*

Background: A major goal for precision medicine in genetic diseases is the identification of modifier genes as potential therapeutic targets. Using X-linked Alport Syndrome (XAS) as a model for heritable kidney diseases, we have developed a novel approach to identify modifier genes that modulate disease severity outcomes. To identify modifiers for XAS, we introduced a *Col4a5* mutation into the genetically heterogeneous Diversity Outbred (DO) mice and conducted high-resolution mapping for several renal phenotypes.

Methods: The DO mice are an ideal population for high-precision genetic mapping, containing 45 million SNPs originating from 8 founder strains. The diversity captured in the DO emulates the variation in the human genome. To introduce XAS into the DO population, we crossed female C57BL/6J-*Col4a5*$^{+/-}$ mice with 100 unique male DO mice. From each mating we selected one *Col4a5*$^{-/Y}$ male and one *Col4a5*$^{+/-}$ female F1 offspring to create a cohort of 200 mice. We measured albuminuria (ACR) at 6, 10, and 15 weeks, and glomerular function (GFR) at 14 weeks of age. We genotyped each animal, reconstructed haplotypes, and mapped loci associated with variation in ACR and GFR.

Results: There was large variation in GFR and ACR in our cohort. Similar to human XAS patients, males had increased severity with elevated ACR and reduced GFR relative to females. High-resolution linkage and association mapping revealed several loci as narrow as 1Mbp harboring genes responsible for driving variation in ACR and GFR. The most significant GFR locus contains only 5 annotated genes, including a transcription factor regulating microtubule network related protein expression. Similarly, a locus for ACR contains a gene associated with actin filament formation. Both candidates suggest an affect on the structure and therefore the function of podocyte foot processes, critical for kidney health.

Conclusions: Our study successfully identified several novel candidate genes implicated in modifying XAS disease severity outcomes. These candidates are prime therapeutic targets for XAS. This work demonstrates the power of high-resolution genetic mapping in the DO mice, an approach that can be applied to other forms for heritable renal diseases such as polycystic kidney disease.

Clinical Overview and Long-Term Prognosis of Dent Disease and Lowe Syndrome in Japan Ken-ichiro Miura,[1] Yutaka Harita,[2] Kiyonobu Ishizuka,[1] Tomoo Yabuuchi,[1] Naoto Kaneko,[1] Shoichiro Kanda,[2,1] Atsushi Sato,[2] Tsuyoshi Isojima,[2] Takashi Igarashi,[3] Motoshi Hattori.[1] *[1]Tokyo Women's Medical University School of Medicine, Tokyo, Japan, Tokyo, Japan; [2]Department of Pediatrics, University of Tokyo, Tokyo, Japan; [3]National Center for Child Health and Development, Tokyo, Japan.*

Background: Epidemiologic data of Dent disease (DD) and Lowe syndrome (LS) are lacking, and long-term prognosis of LS has not been surveyed. The aim of this study was to investigate the prevalence and long-term prognosis of patients with DD and LS in Japan.

Methods: Questionnaire was distributed to 1,814 departments of pediatrics, nephrology, endocrinology and internal medicine of major hospitals in Japan. Data of the patients who visited the hospitals in 3 years (between 2013 and 2015) were collected. This study was approved by the Ethics Committee of Tokyo Women's Medical University (IRB No.3916) and was supported by Health and Welfare Labour Sciences Research Grants.

Results: The response rate was 49% and 83% in the primary and the secondary survey, respectively. Clinical and laboratory data were obtained from 110 patients with DD and 67 patients with LS. A low response rate and small sample sizes did not allow estimation of patient numbers. The majority of patients with DD were diagnosed asymptomatically by annual urinary screening test at median age of 3 years. Prominent low molecular weight proteinuria (LMWP), hypercalciuria and nephrocalcinosis were noted in 100%, 49% and 37% of patients, respectively. Only 3 (19%) out of 16 adult patients developed CKD stages 3 or 4 in their 20s and 30s. Genetic analyses were performed in 37% and mutations in the CLCN5 and the OCRL genes were documented in 68% and 11%, respectively, the proportion of which was similar to the previous reports. Most patients with LS were diagnosed in infancy. All patients presented with prominent LMWP, cataract and mental retardation. Estimated GFR negatively correlated with age and indicated that most patients developed end stage renal disease in their 30s and 40s. OCRL mutations were documented in 21 (96%) out of 22 patients analyzed.

Conclusions: The prognosis of DD in Japan might be better than that in Europe and USA probably due to detection of individuals with milder phenotypes by annual urinary screening test. It might be suggested that the only required item for the diagnosis of DD is prominent LMWP in Japan. In addition, we described long-term renal prognosis of LS for the first time, which would contribute to treatment strategy and genetic counseling.

SA-PO588

Genetic Findings in Adults with Sporadic Steroid-Resistant Nephrotic Syndrome Aude Servais,[1,2] Olivier Gribouval,[2] Olivia Boyer,[1,2] Aurelie Hummel,[1] Jacques Dantal,[3] Marie-Josèphe Tête,[2] Corinne Antignac.[2,1] *[1]Necker University Hospital, Paris, France; [2]Inserm U1163, Imagine Institute, Paris Descartes University, Paris, France; [3]Institut de Transplantation Urologie Néphrologie, Nantes, France.*

Background: In recent years, proposals for genetic screening paradigms in Steroid-Resistant Nephrotic Syndrome (SRNS) preferentially addressed congenital, infantile onset and familial cases. Sporadic SRNS/FSGS adult patients are currently only tested for the *NPHS2* nonneutral p.R229Q polymorphism. To uncover the distribution of disease-causing gene mutations in an adult sporadic FSGS/SRNS population, we used a NGS panel in a cohort of adult patients.

Methods: We selected adult patients (age at onset of proteinuria above 18 years), with non syndromic biopsy proven FSGS and/or SRNS, without known family history. We used strict clinical criteria including no response to glucocorticoids but also to cyclosporine and no relapse after renal transplantation. We applied a NGS panel covering 37 genes to 135 unrelated patients.

Results: Mean age at onset of proteinuria was 30.1 (18.1-84.0) years. Eighteen (13.3%) presented with mutation (15/135, 11.1%) or variant of unknown significance (VOUS) (3/135, 2.2%) in known monogenic SRNS genes and 14 (10.4%) with *APOL1* high risk allele. We identified 11 novel mutations including mutations in *PAX2, INF2, NPHS2, MYO1E,* and *CD2AP* genes. Collagen mutations represented 38.8% of all mutations. Mean age at onset of proteinuria was lower in the group with mutations than in patients with no mutation or *APOL1* risk variant (24.9±7.9 vs 30.9±11.7, p=0.01). Mutations in non collagen genes were all found in patients younger than 30 years of age, whereas mutations in collagen genes were also identified in older patients until 50 years of age. Patients with mutations presented with lower eGFR at diagnosis (43.6±31.8 vs 87.4± 34.8 ml/min/1.73m2, p=0.006), reflecting a more severe disease. Age at ESRD was higher in patients with mutations in collagen genes than in patients with mutations in other genes (47.5±1.6 vs 26.6±4.6 years, p=0.01).

Conclusions: We identified a mutation or a VOUS in known monogenic SRNS genes in 13.3% of patients and *APOL1* high risk allele in 10.4%. Collagen mutations causing Alport Disease were the more frequent identified mutations.

SA-PO589

Cobalamin C Deficiency Induces a Specific Histopathological Pattern Associating Renal Thrombotic Microangiopathy and Characteristic Glomerular Lesions Dominique Guerrot,[5] Mathilde Lemoine,[5] Steven Grange,[5] Marion Rabant,[4] Valerie Chatelet Pouliquen,[5] Emilie Cornec-Le Gall,[3] Damien AMBROSETTI,[1] Georges Deschênes,[2] Arnaud Francois.[5] *[1]CHU Nice, Nice, France; [2]Hospital Robert Debre, Paris, France; [3]Mayo Clinic, Rochester, AL; [4]NECKER Hospital, PARIS, France; [5]Rouen University Hospital, Rouen, France.*

Background: CblC deficiency is the most common inborn error of vitamin B12 metabolism. CblC deficiency most frequently presents as failure to thrive, neurologic deterioration, and hematologic abnormalities during the first year of life. Renal failure attributed to thrombotic microangiopathy (TMA) has occasionally been described, in the rarer late-onset presentation of CblC deficiency, in children and young adults. Due to the rarity of the disease and of available kidney biopsies, kidney lesions associated with CblC deficiency remain poorly defined. This study aims to describe the characteristics of kidney disease in cblC deficiency, and to provide a comparative histological analysis with cblC-independent renal TMA.

Methods: We performed a multicenter retrospective study including 7 patients with cblC deficiency and available kidney biopsy, and 16 matched controls with cblC-independent TMA. The histological characteristics were established by a systematic centralized review.

Results: The patients included were aged 6 to 26 years at the time of the first manifestations. All patients presented with acute renal failure, proteinuria and hemolysis. Five required dialysis. The histological study revealed arteriolar and glomerular TMA in all patients. After comparison with the cblC-independent TMA control group, a vacuolated aspect of the glomerular basement membrane (GBM) (86% *vs* 7% cases, $p<0.001$) and the intensity of glomerular parietal IgM deposits (score 1.8±0.8 *vs* 0.4±0.5, $p<0.01$) were more present in cblC deficiency patients than in controls. Six patients were treated by hydroxycobalamin. All of them improved with disappearance of hemolysis and 3 of the 4 patients requiring renal replacement therapy were weaned off dialysis.

Conclusions: This study provides the first demonstration of characteristic kidney pathology in CblC deficiency, combining lesions of glomerular and arteriolar TMA, a vacuolated aspect of the GBM and glomerular IgM deposits. Due to major therapeutical implications, we suggest patients with renal TMA be screened for CblC deficiency regardless of age, particularly when the kidney biopsy shows a vacuolated aspect of the GBM and glomerular parietal IgM deposition.

SA-PO590

The Minor rs4293393 SNP Variant Is Associated with a Delayed Age of ESRD in Uromodulin Kidney Disease Anthony J. Bleyer,[9] Kendrah O. Kidd,[9] Petr Vyletal,[1] Jorge Reis Almeida,[7] Joaquim T. Calado,[9] Rosa J. Torres,[6] Sofia C. Jorge,[8] Catarina S. Silveira,[4] Eric G. Olinger,[3] Olivier Devuyst,[2] Stanislav Kmoch.[5] *[1]First Faculty of Medicine, Institute of Inherited Metabolic Disorders, Charles University, Prague, Czech Republic; [2]University of Zurich, Zurich, Switzerland; [3]University of Zürich, Zürich, Switzerland; [4]GenoMed, Instituto de Medicina Molecular, Faculdade de Medicina da Universidade de Lisboa, Lisbon, Portugal; [5]Institute of Inherited Metabolic Disorders, Prague, Czech Republic; [6]La Paz University Hospital, IdiPaz, Madrid, Spain; [7]Vanderbilt University, Nashville, TN; [8]Portuguese Society of Nepghrology, Lisbon, Portugal; [9]Wake Forest School of Medicine, Winston-Salem, NC.*

Background: Uromodulin kidney disease (UKD) is a form of autosomal dominant tubulo-interstitial kidney disease (ADTKD) caused by mutations in the *UMOD* gene encoding uromodulin. UKD is characterized by slowly progressive kidney failure. The minor variant of rs4293393 in the *UMOD* promoter is associated with 50% decreased uromodulin production. We hypothesized that if this minor variant is found in the mutated *UMOD* gene promoter in individuals with UKD, there will be decreased mutant *UMOD* production and a later ESRD onset.

Methods: Genotyping of the rs4293393 snp was performed in 365 individuals from 149 families. Association with the mutated UMOD gene was determined. Age of ESRD was determined.

Results: Hardy Weinberg equilibrium was not met, with only 8/149 (5%) families linked to the minor variant vs. 15% expected (p-value < 0.0001). The mean age of end stage renal disease (ESRD) for individuals linked to the minor variant was 59.5+/- 11.1 (n=6) vs. 45.3+/- 10.5 years for individuals linked to the major variant (n=139) (p=0.0008). No individual linked to the minor variant reached ESRD before age 45 as opposed to 71 individuals (51%) linked to the major variant (Figure 1).

Conclusions: The rs4299393 minor variant, previously linked to decreased uromodulin production has a significant protective effect on age of ESRD if it is found in the promoter of the mutant *UMOD* gene in individuals with UKD. The deviation from expected allele and genotype frequencies could be due to the preservation of kidney function such that families linked to the minor variant are not being diagnosed at the same rate as other UKD families. These findings identify a prognostic factor in age of ESRD in UKD and suggest that decreasing mutant uromodulin production will improve renal survival.

Funding: NIDDK Support

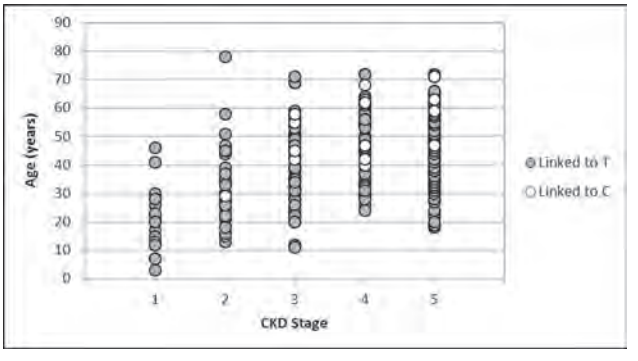

Figure 1: Association of CKD with rs4293393 linkage. The rs4293393 minor variant is C and the ancestral variant is T. CKD stages are based upon NKF KDOQI guidelines.

SA-PO591

Collagen IV Receptor Blockade as Add-On Therapy in Alport Syndrome Diana Rubel, Rainer Girgert, Gerhard A. Mueller, Oliver Gross. *University Medicine Goettingen, Goettingen, Germany.*

Background: Alport Syndrome (AS) is caused by a lack or misfolding of collagen IV alpha 3, 4 and 5 due to a mutation in one of these genes. Podocytes sense this abnormal glomerular basement membrane (GBM) by collagen receptors such as discoidin domain receptor 1 and Integrin $\alpha 2$. In our present study, we evaluated the nephron-protective effect of knocking-out both receptors in AS (TripleKO) with and without standard ACE-inhibition (ACEi). We hypothesized that the loss of collagen-receptors could inhibit recognition of the altered GBM in AS and improve the renal phenotype. ACEi as the standard off-label therapy delays renal failure until aldosterone escape. Therefore, it is important to evaluate new therapies on top of ACEi.

Methods: Here, we analyze the effect of ACEi and collagen receptor blockade as possible new therapy in wildtype (WT), mice with AS, TripleKO and ACEi treated mice. Mode of action was characterized by real-time PCR, light and electron microscopy with immunogold reactions.

Results: TripleKO mice showed a significant longer survival, less matrix accumulation and fibrosis compared to Alport mice. Additionally, the foot processes were preserved until later stages of disease and splitting of the GBM was considerably less. The relative expression of podocin in Alport mice was significant reduced compared to WT. In contrast, the TripleKO mice showed a podocin expression which was comparable

to WT. Nephrin expression was slightly reduced in TripleKO mice compared to WT, but significant elevated in ACEi treated mice. In Alport mice, the immunogold reactions revealed a podocin accumulation in the areas of podocyte effacement in an age-dependent manner. TripleKO mice showed the same ultrastructural changes, but at a later stage of disease. Nephrin aggregated in TripleKO mice in areas where footprocesses were still preserved.

Conclusions: ACEi and loss of collagen receptors both delay progression of AS in a similar manner, but have different ways of action. In contrast to ACEi therapy for example, podocin expression in TripleKO mice seemed to be maintained, but the protein was mislocated. This confirms a different mode of action resulting in a considerable add-on effect on delaying renal failure. Thus, these additive effects of collagen receptor blockade on top of ACEi should be in the focus of further studies.

SA-PO592

Deleterious Impact of a Novel CFH Splice Site Mutation in Atypical Hemolytic Uremic Syndrome Anna Seidel,[2] Ria Schönauer,[2] Carsten Bergmann,[1] Maik Grohmann,[1] Tom H. Lindner,[2] Jan Halbritter.[2] *[1]Bioscientia, Ingelheim, Germany; [2]University Clinic Leipzig, Leipzig, Germany*.

Background: Atypical hemolytic uremic syndrome (aHUS) is a rare disease typically based upon uncontrolled activation of the alternative complement pathway (ACP). Clinical signs and symptoms comprise microangiopathic haemolytic anemia (MAHA), thrombocytopenia, and acute kidney failure (AKI). Mutations in ACP regulating genes such as *C3*, *CFI*, *CFH*, and *MCP*/*CD46* are found in around 50% of patients.

Methods: A 27 year-old female without prior past medical history presented with nausea, confusion, petechial bleeding, and anuric AKI necessitating initiation of dialysis. Laboratory examination revealed MAHA with schistocytes but normal ADAMTS13-levels. Kidney biopsy showed glomerulary thrombotic microangiopathy (TMA), which was treated with steroids, plasmapheresis, and eculizumab (induction/maintenance), leading to complete hematological and clinical remission, as well as significant recovery of kidney function within 2 months. Targeted next generation sequencing for aHUS-associated genes identified a paternally transmitted novel heterozygous mutation in the *CFH* gene (c.3134-2A>G). *CFH* encodes complement factor H, a key inhibitory protein of the ACP. The mutation is located in the obligatory splice acceptor site of intron 19. Sanger sequencing of patient cDNA indicated that as a consequence of the mutation, alternative splicing results in a deletion of the first 27 base pairs of exon 20. On the protein level, CFH consists of 20 similar structural conserved Sushi domains, where each has four conserved cysteines forming two disulfide bonds. This in-frame deletion leads to a partial loss of the Sushi domain 18 (p.Asp1045_Thr1053del) including a cysteine (p.Cys1048). As this cysteine is thought to be essential for proper protein folding, its loss may consequently result in a defective protein structure, impairing binding to C3.

Results:

Conclusions: In summary, we detected a new *CFH* splice site mutation in a patient with aHUS, which probably leads to an incorrect protein structure impairing inhibitory control of C3 and thereby ACP activity. Incomplete penetrance demonstrated by the clinically asymptomatic father underlines the necessity of an additional disease trigger for aHUS manifestation.

SA-PO593

HLA Alleles Confer Risk to Primary Idiopathic Nephrotic Syndrome in Individuals of Caucasian Ancestry Dina Ahram,[6] C. Gillies,[15] Adele Mitrotti,[6] Priya Krithivasan,[6] Monica Bodria,[8] Paola Pontrelli,[12] Loreto Gesualdo,[11] Marida Martino,[9] Mario Giordano,[10] Maddalena Gigante,[14] Isabella Pisani,[16] Antonio Amoroso,[3] Vivette D. D'Agati,[5] Gerald B. Appel,[5] Andrew S. Bomback,[4] Francesco Scolari,[13] Riccardo Magistroni,[17] Y. Caliskan,[7] Ali G. Gharavi,[6] Krzysztof Kiryluk,[6] Gian Marco Ghiggeri,[2] Friedhelm Hildebrandt,[1] Matt G. Sampson,[15] Simone Sanna-Cherchi.[6] *[1]Boston Children's Hospital, Boston, MA; [2]G. Gaslini Children Hospital, Genoa, Italy; [3]University of Torino, Torino, Italy; [4]Columbia University, New York, NY; [5]Columbia University College of Physicians and Surgeons, New York, NY; [6]Columbia University Medical Center, New York City, NY; [7]Division of Nephrology, Department of Internal Medicine, Istanbul Faculty of Medicine, Istanbul, Turkey; [8]None, Langhirano, Italy; [9]Pediatric Hospital "Giovanni XXIII" Bari-Italy, Modugno (BA), Italy; [10]Pediatric Hospital Giovanni XXIII, Bari, Italy; [11]University of Bari, Altamura, Italy; [12]University of Bari-Dept. of Emergency and Organ Transplantation, Bari, Italy; [13]University of Brescia, Montichiari (Brescia), Italy; [14]University of Foggia, Foggia, Italy; [15]University of Michigan, Ann Arbor, MI; [16]University of Parma, Bozzolo (Mantova), Italy; [17]Università di Modena e Reggio Emilia, Modena, Italy*.

Background: Primary idiopathic nephrotic syndrome (NS) caused by focal segmental glomerulosclerosis (FSGS) or minimal change disease (MCD) is a frequent cause of end-stage renal disease (ESRD). Despite the identification of several genetic causes, the etiology of NS remains to be fully understood. We investigated the genetic basis of FSGS in a population of Caucasian descent.

Methods: We recruited a heterogeneous population of Caucasian descent (1,153 cases) ascertained for FSGS (88% of the cases) and MCD (12%). A set of independent and meta-analyzed case-control, genome-wide association studies (GWAS) were performed using an additive model with covariate-correction for population stratification in the three Caucasian cohorts (Western European: 301, Italian: 754, Turkish: 98), matched genetically with 2,393 controls. Quality control assessment was carried out according to standard practices.

Results: In a Meta-analysis of three, combined Caucasian cohorts (1153 cases, 2393 controls), a significant association was found for the SNP rs28383303 (OR=1.57, 95%CI: 1.29-1.67, P= 1.48×10^{-8}) (Figure 1). All three cohorts contributed to the signal without evidence for heterogeneity. The variant was identified in a 50kb haploblock on chromosome 6p21, which contains the gene encoding the HLA complex class II HLA-DQ alpha chain 1 (*HLA-DQA1*).

Conclusions: In line with previously reported findings implicating the HLA system in childhood-onset nephrotic syndrome and membranous nephropathy, our results indicate the association of HLA risk alleles with NS in individuals of Caucasian descent. Our findings allude to a role for HLA in modulating adaptive immunity and suggest a basis for understanding the complex genetic mechanisms of FSGS.

SA-PO594

A Bioinformatics Analysis of Gene Expression in Experimental Alport Syndrome Reveals an Fstl1 Signature in the Kidney Nicholas Maksimowski,[1] Xuewen Song,[2] Eun Hui Bae,[3] York P. Pei,[2] James W. Scholey.[1,2] *[1]University of Toronto, Toronto, ON, Canada; [2]University Health Network and University of Toronto, Toronto, ON, Canada; [3]Chonnam National University Hospital, Gwangju, Republic of Korea*.

Background: Alport syndrome (AS) is a rare inherited form of chronic kidney disease characterized by progressive nephropathy and the development of end stage renal disease. It is caused by mutations in the Col4a3, Col4a4, and Col4a5 genes. The goal of my studies is to better understand the pathogenesis of AS in the kidney.

Methods: We performed studies using a well-characterized experimental murine model of AS. Global gene expression profiling of renal cortical mRNA samples was performed in male Col4a3-/- mice and Col4a3+/+ control mice at 4 and 7 weeks of age to identify early differentially expressed genes. We performed a cluster analysis and constructed a heat map on the microarray studies at 4 and 7 weeks of age. Finally, studies using HK2 cells were conducted to analyze inflammation and apoptosis related to a protein of interest and its cognate receptor.

Results: The microarray analysis revealed that only 5 genes were differentially expressed in the kidneys of male Col4a3-/- mice at 4 weeks of age compared to Col4a3+/+. Amongst these genes was Follistatin-related protein 1 (FSTL1). We used search tool for the retrieval of interacting genes/proteins to predict protein-protein interactions (PPIs) thereby identifying a functional protein association network for FSTL1. The network included 39 proteins. Cluster analysis of the cognate genes from the FSTL1 protein network showed marked upregulation of gene expression at 7 weeks of age. FSTL1 increased NFκB mediated luciferase activity, caspase 3 activation and PARP cleavage in HK2 cells. These effects were due, at least in part to TLR4 receptor activation.

Conclusions: Our microarray and bioinformatics analyses identified early upregulation of FSTL1 in the kidneys of Col4a3-/- mice. A FSTL1 gene signature, based on predicted PPIs, emerged in the kidneys by 7 weeks of age. FSTL1 elicited an inflammatory response and activated apoptosis in HK2 cells. These findings support the hypothesis that FSTL1 may be a novel determinate of kidney injury in mice with experimental AS.

SA-PO595

Modelling Alport Syndrome in Zebrafish Richard W. Naylor, Saule N. Gasiunas, Rachel Lennon. *University of Manchester, Manchester, United Kingdom*.

Background: Alport syndrome is a hereditary renal disorder that manifests in early childhood with haematuria followed by proteinuria and ultimate progression to end stage renal disease. Genetic analysis has shown that patients with Alport syndrome carry mutations in genes encoding three isomers of collagen type IV: *COL4A3*, *COL4A4* and *COL4A5*. Type IV collagens are the most abundant collagens in basement membranes and exist as three different trimeric protomers, α1α1α2(IV), α3α4α5(IV) and α5α5α6(IV). In the glomerulus, podocytes deposit the α3α4α5(IV) trimer and the endothelium deposits the α1α1α2(IV) trimer. The fusion of these two extracellular matrices forms the glomerular basement membrane (GBM). In Alport syndrome, mutations in either *COL4A3*, *COL4A4* and *COL4A5* lead to depletion of the α3α4α5(IV) trimer in the

GBM. This loss of α3α4α5(IV) initially creates a thinner GBM that at later stages of the disease develops a 'basket-weave' appearance. Treatment of Alport syndrome is limited to angiotensin converting enzyme inhibitors but the mechanism of their action on the glomerulus has not been fully elucidated.

Methods: To improve our understanding of disease and treatment mechanisms we aimed to generate a zebrafish model of Alport syndrome. The zebrafish is a highly tractable system that has become a premier organism for disease modelling. Many of the cellular components of the glomerular filter are conserved between zebrafish and humans. We have used *in situ* hybridisation with RNA probes and immunofluorescence with collagen type IV antibodies to observe if the molecular components of the glomerular filter are also conserved. In addition, we have used the CRISPR/Cas9 system to generate *col4a3*, *col4a4* and *col4a5* knockout mutant lines.

Results: We find zebrafish podocytes express *col4a3*, *col4a4* and *col4a5* and have also identified collagen type IV isoforms in the zebrafish GBM. We have also found phenotypes in the glomerulus of our knockout lines and have performed functional and ultrastructural analyses.

Conclusions: We have demonstrated expression of the α3α4α5(IV) network in the zebrafish GBM and have created a new *in vivo* model for Alport syndrome. This model will allow the use of new approaches to investigate disease mechanisms in Alport syndrome and will facilitate high throughput compound screening for drug discovery.

Genetically Affected Individuals with UMOD and MUC1 Mutations Who Donate a Kidney Have Surprisingly Good Renal Outcomes Anthony J. Bleyer,[5] Kendrah O. Kidd,[6] Peter J. Conlon,[1] Peter J. Lavin,[7] Claire Kennedy,[4] Anna Greka,[2,8] Stanislav Kmoch.[3] *[1]Beaumont Hospital, Dublin 9, Co Dublin, Ireland; [2]Harvard Medical School, Boston, MA; [3]Institute of Inherited Metabolic Disorders, Prague, Czech Republic; [4]Beaumont Hospital, Dublin, Ireland; [5]Wake Forest University School of Medicine, Winston-Salem, NC; [6]Wake Forest School of Medicine, Winston-Salem, NC; [7]Trinity Health Kidney Centre, Dublin, Ireland; [8]Broad Institute, Cambridge, MA.*

Background: Some individuals with UMOD and MUC1 mutations who were mildly affected donated kidneys prior to genotyping being available. The outcome of these individuals has not been studied.

Methods: We studied renal outcomes in 4 individuals with UMOD mutations and 3 individuals with MUC1 mutations.

Results: All donors donated to family members with the same mutation. One donor had a cerebral hemorrhage with donation immediately prior to death. The eGFR post-donation was lower than seen in health donors, with a mean egfr of 46.5± 5.3 ml/min. However, kidney function remained stable, and no donors required renal replacement therapy at a mean follow up of 10.2 5± 6.6 (range 3-18) years follow up. Likewise recipients have done well with all allografts functioning 12.9± 9.6 (range 3-18) years post-transplant.

Conclusions: Some individuals with MUC1 or UMOD mutations are mildly affected, and their eGFR and that of their donors remains surprisingly stable in most instances after donation. However, at this time individuals with these mutations should not yet be considered as kidney donors until more data is available.

Funding: NIDDK Support, Private Foundation Support

Genetically Affected Donors

Donor	Mutation	Donor Age	Current Age	Current eGFR
1	MUC1	34	52	53
2	MUC1	39	44	43
3	MUC1	52	55	42
4	MUC1	36	Deceased	
5	UMOD	25	34	44
6	UMOD	No data		
7	UMOD	42	58	52

SA-PO597

Possible Link Between Aging Nephropathy and DHTKD1 in C57BL/6J Mice Nathan D. Susnik,[1] Ron Korstanje,[2] Laura Reinholdt,[2] Nils Hanke,[1] Jan Hegermann,[1] Christoph Wrede,[1] Heike Bähre,[1] Hermann G. Haller,[1] Mario Schiffer,[1] Roland Schmitt.[1] *[1]Hannover Medical School, Hannover, Germany; [2]The Jackson Laboratory, Bar Harbor, ME.*

Background: During renal aging experiments, we found a spontaneous phenotype in a cohort of 18-22 month old C57BL/6J mice. Old mice developed pronounced glomerulosclerosis, amyloidosis, and renal dysfunction with proteinuria (GARD). Here, we tested the assumption that the GARD phenotype was due to a spontaneous mutation.

Methods: Whole exome sequencing data from a GARD mouse was compared to publicly available C57BL/6J reference sequence (GRCm38). C57BL/6J and C57BL/6JRJ mice purchased from different suppliers were sequenced for mutations in DHTKD1. Cellular localization of DHTKD1 was examined in murine and human kidneys and in renal cells. *DHTKD1* expression was manipulated with Crispr-Cas9 and siRNA in cell lines and morpholino in zebrafish.

Results: Whole exome sequencing revealed that GARD mice had a single nucleotide polymorphism leading to an amino acid substitution (A335T) in the thiamine-binding motif of dehydrogenase E1 and transketolase domain containing 1 (*DHTKD1*). All C57BL/6J mice in the GARD cohort were homozygous for the *Dhtdk1* mutation (*Dhtkd1*$^{A335T/A335T}$) while C57BL/6JRJ mice with normal renal aging carried the reference allele (*Dhtkd1*$^{+/+}$). *DHTKD1* was expressed in podocytes, proximal tubules, and distal tubules. Contrary to previously reported data, knockout (KO) of *DHTKD1* left mitochondrial morphology, genes associated with mitochondrial function, and ATP production unchanged. Flow cytometry, however, revealed more MTC02 in *DHTKD1* KO cells. KO cells also had more 2-aminoadipic- and 2-oxoadipic acid, metabolites of lysine degradation. siRNA in human podocytes changed some mitochondria-associated genes, but made no difference in ATP production. Knockdown of *Dhtkd1* in zebrafish larvae led to proteinuria and podocyte foot process effacement. While these changes indicate a functional role for DHTKD1 in renal maintenance, C57BL/6J *Dhtkd1*$^{A335T/A335T}$ mice aged at our own facilities did not develop GARD.

Conclusions: Overall, knockdown of *DHTKD1* causes structural and functional changes in cells and zebrafish; however, the GARD phenotype in *Dhtkd1*$^{A335T/A335T}$ mice was not fully penetrant, suggesting that other variables like diet or housing are involved. .

A Novel Deletion in ACTN4 in a Patient with Renal FSGS and Concomitant TMA Johannes Muench,[4] Ralph Wendt,[3] Ria Schönauer,[4] Maik Grohmann,[1] Joachim H. Beige,[3] Thorsten Wiech,[2] Tom H. Lindner,[4] Carsten Bergmann,[1] Jan Halbritter.[4] *[1]Bioscientia, Ingelheim, Germany; [2]Department of Pathology, University Hospital Hamburg Eppendorf, Hamburg, Germany; [3]Hospital St. Georg, Leipzig, Germany; [4]Division of Nephrology, University Clinic Leipzig, Leipzig, Germany.*

Background: Thrombotic microangiopathy (TMA) of the kidney leading to renal failure is associated with genetic susceptibility due to variants of genes encoding complement components in the majority of cases. Recently, Challis et al (*JASN 2016*) reported two families with biopsy proven TMA who inherited mutations of *INF2*, a gene that is known to cause familial FSGS. As inverted formin 2 (INF2) is essential for podocytic cytoskeleton integrity by regulating the actin-polymerization and –depolymerization process, it is reasonable to assume, that genetically determined functional deficiency of further podocytic structural proteins might provoke renal TMA-phenotypes as well.

Methods: A 30-year old male patient presented with acute kidney failure and proteinuria (eGFR 11 ml/min, proteinuria 3563 mg/g creatinine). At the time of presentation, laboratory findings showed no signs of hemolytic anemia. Kidney biopsy revealed advanced glomerulosclerosis and TMA in preglomerular arterioles and glomeruli. Genetic testing regarding mutations of known aHUS-genes showed no pathogenic variants but the risk polymorphisms *MCP-H2* and *CFHR1*B.* However, a novel heterozygous three-base deletion in exon 8 of *ACTN4* was detected, leading to loss of lysine at amino acid residue 255 (c.763_765delAAG; p.Lys255del). A therapeutic approach with eculizumab was unsuccessful as control biopsy after four months revealed progressive glomerular and tubulointerstitial scarring.

Results:

Conclusions: *ACTN4*-mutations are known to cause autosomal dominant FSGS and most disease-causing mutations are located within the protein's actin-binding domain. The pathogenicity of the *ACTN4* mutation in our patient is assumable, as functional alterations upon amino acid substitution at the same position (C.763A>G; p.Lys255Glu) have been demonstrated previously (Feng et al, *PLoS One* 2015). However, *ACTN4* mutations have not been associated with renal TMA yet, although this phenotype was already reported in other forms of familial FSGS (Benz et al, *Pediatr Nephrol* 2007). We therefore propose that pathogenic variants in *ACTN4* may account for renal TMA, which adds to the clinical pleiotropy of mutated *ACTN4*. Hence, mutated *ACTN4* should be considered in patients with renal TMA, especially in those with an eculizumab-resistant progress and unremarkable complement genetics.

Comprehensive Analysis of the Renal and Systemic Phenotypes Associated with Familial Deficiency of Lecithin-Cholesterol Acyltransferase: a Case Series Carlos T. Sampaio,[1] Bruno E. Balbo,[1] Leonardo C. Saraiva,[1] Henrique R. Nakano,[1] Andressa G. Amaral,[1] Eliene Costa,[1] Elieser H. Watanabe,[1] Precil D. Neves,[1] Ana P. Chacra,[2] Raul Maranhao,[2] Antonio A. Guerra,[3] Ricardo M. Braga,[4] Ruth M. Santo,[4] Leonardo A. Testagrossa,[5] Marlene A. Reis,[6] Junior A. Silva,[7] Henrique Carrascossi,[8] Luiz F. Onuchic.[1] *[1]Nephrology and Molecular Medicine, University of Sao Paulo, Sao Paulo, Brazil; [2]Cardiopneumology, University of Sao Paulo, Sao Paulo, Brazil; [3]Hematology, University of Sao Paulo, Sao Paulo, Brazil; [4]Ophtalmology, University of Sao Paulo, Sao Paulo, Brazil; [5]Pathology, University of Sao Paulo, Sao Paulo, Brazil; [6]Pathology, Federal University of Triangulo Mineiro, Uberaba, Brazil; [7]Piaui Municipal Service, Sao Francisco, Brazil; [8]Araraquara Municipal Service, Araraquara, Brazil.*

Background: Lecithin cholesterol acyltransferase (LCAT) is involved in cholesterol metabolism. Familial LCAT deficiency (FLD) is a recessive disease associated with systemic lipid deposition, often resulting in CKD and fish-eye opacities.

Methods: Retrospective study, comprising clinical, laboratory and molecular genetic analyses of FLD patients.

Results: Twenty males and 18 females were diagnosed with FLD at an age of 38.6±16.4 yrs. Three pathogenic mutations in *LCAT* were identified: p.R268H, p.T298I and p.I227F, corresponding to distinct disease clusters. All patients had HDL-c ≤10mg/dL, ApoAI was 0.45±0.10g/L and ApoB 0.41±0.19g/L. Corneal opacities were seen in 36 cases; Scheimpflug densitometry revealed high corneal density in all 3 evaluated individuals. Anemia was present in 25 cases (Hb of 10.7±2.2g/dL) and hemolysis in 27. Increased resistance of red blood cells to osmotic stress was observed in all 5 evaluated patients. Estimated glomerular filtration rate (eGFR) displayed high intra- and interfamilial variability; 7 patients developed ESKD at an age of 38.3±14.2 yrs. Protein/creatinine ratio was 0.54g/g (p25-p75: 0.12-1.77) in nondialytic cases; 9 of 21 had hematuria. C3 was low in 1 patient while C4 was normal in all. Hypertension, present in most cases, was associated with age>30 yrs and eGFR<83mL/min/1.73m^2 (OR 15.5). Coronary artery calcium score was zero in the 2 evaluated patients. Kidney biopsy revealed glomerular deposits (8/8 patients), glomerular sclerosis (7/8), endocapillary proliferation (4/8), glomerular basement membrane splitting (4/8), and interstitial fibrosis (<5-60%). Thrombotic microangiopathy (TMA) was detected in 3 cases and dominance/codominance of C3 mesangial deposits in all. Treatment included RAS inhibitors and statins.

Conclusions: The renal phenotypic variability suggests that environmental and/or genetic factors may modify CKD progression in FLD. Our findings suggest that, in addition to cholesterol deposition, TMA and C3 mesangial deposits may also contribute to renal injury, supporting a pathogenic role for activation of the alternative complement pathway.

SA-PO600

Clinical Characterization of Families with Mutations in the MUC-1 Gene Anthony J. Bleyer,[8] Constantinos Deltas,[7] Gregory Papagregoriou,[7] Stanislav Kmoch,[4] Kendrah O. Kidd,[8] Seth L. Alper,[2] Peter J. Lavin,[9] Daniel P. Gale,[6] Peter J. Conlon,[1] Peter C. Harris,[5] Anna Greka.[3] *[1]Beaumont Hospital, Dublin 9, Co Dublin, Ireland; [2]Beth Israel Deaconess Medical Center, Boston, MA; [3]Harvard Medical School, Boston, MA; [4]Institute of Inherited Metabolic Disorders, Prague, Czech Republic; [5]Mayo Clinic, Rochester, MN; [6]University College London, London, United Kingdom; [7]University of Cyprus, Nicosia, Cyprus; [8]Wake Forest University School of Medicine, Winston-Salem, NC; [9]Trinity Health Kidney Centre, Dublin, Ireland.*

Background: Autosomal dominant tubulo-interstitial kidney disease (ADTKD) due to MUC1 mutations is caused most commonly by a single cytosine insertion within the variable number of tandem repeat (VNTR) region of the MUC1 gene. ~ 30 families have been reported with this condition to date, with considerable variation in the observed age of onset of end stage renal disease (ESRD). We have reevaluated these clinical findings in a larger cohort of families.

Methods: MUC1 mutational analysis was carried out through an assay designed by and offered at no cost to patients or providers at Broad Institute of MIT and Harvard on families with a history of ADTKD. Family histories and pedigrees were clinically characterized. We also included historic data for patients with presumed ADTKD-MUC1 (defined as deceased family members who reached ESRD, and from whom DNA samples were unavailable for mutational analysis).

Results: We identified a *MUC1* mutation in 129 families. The mean age of ESRD among individuals was 44.0 ± 13.7 years, with substantial inter- and intrafamilial variation. The mean age of ESRD onset for all families was 41.5 ± 11.5, with a range from 25 to 73.5 years. The mean age of ESRD for families with more than 20 affected members was 50.9 ± 13.0, vs a mean age of ESRD of 41.4 ± 13.1 for families with fewer than 20 affecteds ($p < 0.0001$). Figure 1 shows the mean age of ESRD onset for 23 largest families, with significant variation in age of ESRD within families.

Conclusions: The mean age of ESRD varies substantially within and among families with ADTKD-MUC1. Larger families have a later mean age of onset of ESRD, likely reflecting milder kidney disease resulting in larger ascertained family size. Further work will aim to identify risk factors for disease severity.

SA-PO601

Kidney Outcome in Primary Hyperoxaluria Type 3 Mary I. McIntosh,[1] Peter C. Harris,[1] Ramila A. Mehta,[2] Julie B. Olson,[1] Barbara M. Seide,[1] Felicity T. Enders,[1] David J. Sas,[1] John C. Lieske,[1] Dawn S. Milliner.[1] *[1]Mayo Clinic, Rochester, MN; [2]Mayo Clinic, Rochester, MN, Rochester, MN. Group/Team: Rare Kidney Stone Consortium.*

Background: Primary hyperoxaluria type 3 (PH3) is caused by *HOGA1* gene mutations. Little is known of the mechanism of hyperoxaluria, long term outcome, or genotype effects.

Methods: PH3 patients were identified (n=47) from the Rare Kidney Stone Consortium (RKSC) PH Registry and categorized by *HOGA1* mutations. In addition to demographics and baseline laboratory data, eGFR and urine oxalate (Uox) were compared at diagnosis (dx) and last followup (f/u). Comparisons between groups were by Chi-square test for categorical variables and Kruskal-Wallis test for continuous variables.

Results: Most frequent mutations were the splicing change p.Leu233_Gly234ins17, n=10 homozygotes (Leu233), and the inframe deletion p.Glu315del, n=9 homozygotes (Glu315). Comparisons were made between these and all other combinations (n = 28). Among PH3 overall, eGFR declined with age (r^2=.30, p= .0001). Among patients < 20 yrs of age, median eGFR at dx for Leu233 was 125.3 ml/min/1.73m^2 vs. 115.7 in Glu315 and 86.3 among all others (p=0.057). There were no significant differences among genotype groups for age at dx or f/u yrs [median 4.5(1.1,11.7)]. There was a trend toward lower Uox and higher eGFR in the Leu233 group at dx and at f/u, though statistically significant only for Uox at f/u (p=0.02) and eGFR at dx (p=0.047). Urine HOG did not correlate with urine glycerate in PH3 overall (r=.39, p=0.12).

Conclusions: PH3 patients show decreasing eGFR over time. Lower Uox and higher eGFR trends were seen in Leu233 homozygotes, though patient numbers were small. HOG suppression of GRHPR as a mechanism for the hyperoxaluria, predicted to elevate d-glycerate, is not supported by this data. Further study is needed to understand genotype effects and outcome of PH3.

Funding: NIDDK Support, Other NIH Support - NCATS, Private Foundation Support

KEOPS Complex Dysfunction Causes Nephrotic Syndrome by Impairing Protein Biosynthesis and by Inducing ER Stress Daniela A. Braun,[1] Jia Rao,[1] Geraldine Mollet,[3] David Schapiro,[1] Weizhen Tan,[1] Jennifer Hu,[4] Peter Dedon,[5] Herman Van tilbeurgh,[7] Martin Zenker,[6] Corinne Antignac,[2] Friedhelm Hildebrandt.[1] *[1]Boston Children's Hospital, HMS, Boston, MA; [2]Imagine Institute, Paris, France; [3]Inserm U1163, Paris, France; [4]MIT, Cambridge, MA; [5]Massachusetts Institute of Technology, Cambridge, MA; [6]University Hospital Magdeburg, Magdeburg, Germany; [7]Université Paris Sud CNRS UMR9198, Orsay, France.*

Background: Steroid resistant nephrotic syndrome (SRNS), a disease of glomerular podocytes, is a frequent cause of end-stage renal disease in children and young adults. Identification of single-gene causes of SRNS has contributed to a better understanding of podocyte biology. In 32 unrelated families, we recently identified mutations in genes encoding the evolutionarily highly conserved KEOPS complex (*LAGE3, OSGEP, TP53RK,* and *TPRKB)* as novel monogenic cause of SRNS and microcephaly. The KEOPS complex catalyzes an essential posttranscriptional modification of tRNA.

Methods: To characterize the pathogenesis of the four newly recognized human disease genes, we measured tRNA modifications by mass-spectrometry, assessed protein biosynthesis *in vitro*, and performed immunoblotting of ER stress marker proteins.

Results: We show that shRNA knockdown of *OSGEP* or *TPRKB* in human podocytes reduced the cellular content of t6A, a specific posttranscriptional modification of tRNA. Using a yeast system, we demonstrate that human mutations of *OSGEP,* identified in patients with SRNS, alter the t6A-related catalytic activity of the encoded protein. We furthermore found that knockdown of *OSGEP, TP53RK,* or *TPRKB* inhibited *de novo* protein biosynthesis and activated the unfolded protein response in human podocytes, thus indicating the presence of ER stress. Knockdown of either of the three genes induced apoptosis in human podocytes, suggesting a central role in the pathogenesis of SRNS in patients with mutations in KEOPS complex genes.

Conclusions: Studying the pathogenesis of four newly recognized monogenic causes of SRNS, we generate evidence that altered function of the KEOPS complex results in podocyte damage by impairing the rate and the accuracy of *de novo* protein biosynthesis.

SA-PO603

Analysis of 24 Genes Reveals a Monogenic Cause in 11% of Cases with Steroid Resistant Nephrotic Syndrome at a Single Center Weizhen Tan,[1] Svjetlana Lovric,[1,2] Shazia Ashraf,[1] Jia Rao,[1] David Schapiro,[1] Merlin Airik,[1,3] Shirlee Shril,[1] Heon Yung Gee,[1] Michelle A. Baum,[1] Ghaleb H. Daouk,[1] Michael A. Ferguson,[1] Nancy M. Rodig,[1] Michael J. Somers,[1] Deborah R. Stein,[1] Asaf Vivante,[1] Jillian K. Warejko,[1] Eugen Widmeier,[1] Friedhelm Hildebrandt.[1] *[1]Boston Children's Hospital, Boston, MA; [2]Hannover Medical School, Hannover, Germany; [3]University of Pittsburgh, Pittsburgh, PA.*

Background: Background: Steroid resistant nephrotic syndrome (SRNS) is the second most frequent cause of end stage renal disease (ESRD) among patients manifesting <25 years of age. We performed mutation analysis using a high-throughput PCR-based microfluidic technology in 24 single-gene causes of SRNS in a cohort of 72 families, who manifested with steroid resistant nephrotic syndrome before the age of 25 years.

Methods: Methods: Within an 18 month interval, we obtained DNA samples, pedigree information, and clinical information from 77 consecutive children with SRNS from 72 different families seen at Boston Children's Hospital (BCH). Mutation analysis was completed by combining high-throughput multiplex PCR with next-generation exon sequencing. We analyzed the sequences of 18 recessive and 6 dominant genes of SRNS in all 72 families for disease causing variants.

Results: Results: We identified the disease causing mutation in 8 of 72 (11.1%) families. Mutations were detected in the 6 genes: *NPHS1* (2/72), *WT1* (2/72), and in *NPHS2, MYO1E, TRPC6,* and *INF2.* Median age of onset was 4.1 years in patients without a mutation (range 0.5-18.8), and 3.2 years in those where the causative mutation was detected (range 0.1-14.3). Mutations in dominant genes presented with a median onset of 4.5 years (range 3.2-14.3). Mutations in recessive genes presented with a median onset of 0.5 years (range 0.1-3.2).

Conclusions: Conclusion: Our molecular genetic diagnostic study identified the underlying monogenic cause of steroid-resistant nephrotic syndrome in ~11% of patients with SRNS using a cost effective technique. We delineated some of the therapeutic, diagnostic, or prognostic implications. Our study confirms that genetic testing is indicated in pediatric patients with SRNS.

SA-PO604

Clinical and Molecular Analysis of 17 Families with a Heterozygous Mutation in COL4A3 or COL4A4 Ilse M. Rood, Sander Groen in 't Woud, Jeroen Schoots, Jack F. Wetzels, Dorien Lugtenberg, Jeroen Deegens, Ernie M. Bongers. *Radboudumc, Nijmegen, Netherlands.*

Background: Heterozygous mutations in *COL4A3* and *COL4A4 (COL4A3/4)* have been described as a cause of Alport syndrome and benign familial hematuria. Recently, these mutations were associated with focal segmental glomerulosclerosis (FSGS) and renal function deterioration as well. The aims of this study are 1) further delineation of the phenotypic spectrum of heterozygous *COL4A3/4* variants, and 2) to investigate whether variants in *NPHS2* (R229Q/ R138Q) and *NEPH3* (V353M) modify the phenotypic expression of *COL4A3/4* mutations.

Methods: Patients with a heterozygous mutation in *COL4A3/4,* detected by diagnostic exome sequencing (ES) using a renal gene panel between 2013 and 2016, were included.

Results: Of 72 patients analyzed because of a familial glomerular disease, a heterozygous mutation in *COL4A3/4* was found in 17 (24%). All patients had microscopic hematuria at clinical presentation and 14 had (micro)albuminuria, including two patients within nephrotic range (3,7 and 6gr/24h). Median age at clinical presentation was 43 years (range 4-55). Renal biopsy in ten index patients showed FSGS (n=3), TBMN (n=1) and MCN (n=1), and in one patient electron microscopy (EM) was compatible with Alport syndrome. In four patients, LM and IF was inconclusive, and EM showed segmental thinning of the GBM. No correlation was found between renal biopsy and clinical status. Segregation analyses in 13 families revealed 24 additional patients with a heterozygous *COL4A3/4* variant. At end of follow up (median age 53 years, range 13-81), 14/41 patients (35%) had renal function deterioration (MDRD4 < 60ml/min), of whom six had ESRD (mean age at ESRD 51 years). Hearing loss and visual impairment was present in 1/41 patients. The R229Q / R138Q variants in *NPHS2* were not detected. Variant V353M in *NEPH3* was found homozygous in one patient and heterozygous in another patient.

Conclusions: This study broadens the phenotypic spectrum: 1) clinical presentation and course of disease is highly variable and not limited to benign hematuria, 2) renal pathology is not limited to FSGS or TBMN. The heterogeneity could not fully be explained by modifier variants in *NPHS2* and *NEPH3.*

SA-PO605

APOL1 Glomerular Transcriptional Networks in Non-Black FSGS Patients D Fermin, K Yasutake, Matt G. Sampson. *University of Michigan, Ann Arbor, MI. Group/Team: NEPTUNE.*

Background: The "G1" & "G2" alleles of *APOL1* are common in African-Americans and confer greatly increased risk for the development of FSGS. While these risk variants are essentially absent in non-blacks, *APOL1* is substantially expressed in kidney tissue across races. Furthermore, experimental models have shown that increased expression of wild-type *APOL1* is also associated with renal toxicity. Thus, we hypothesized that even when not harboring G1 & G2, glomerular *APOL1* may have a role in NS pathogenesis. To pursue this, we contextualized *APOL1* expression within glomerular transcriptional networks derived from whites with FSGS enrolled in the Nephrotic Syndrome Study Network (NEPTUNE).

Methods: Transcriptomic data was available from microdissected glomeruli of 18 white NEPTUNE participants with FSGS (100% wild-type *APOL1*). We measured *APOL1* expression & then used "**W**eighted **G**ene **C**o-expression **N**etwork **A**nalysis" (WCGNA) to identify genesets significantly correlated with its expression. To identify biologic processes associated with these genesets, we use gene-ontology term based enrichment analysis. To idenity key genes in these biologic processes, we constructed interaction networks.

Results: *APOL1* was in the top 15th percentile of expression of the 18,000 glomerular genes analyzed. There were 5 co-expression networks significantly correlated with *APOL1*. The most significant (r=-0.65, p=0.004) was enriched for GO terms related to anion transmembrane transport & metabolic processes. The 2nd most correlated network (r=0.64, p=0.004) was enriched for development processes, particularly vascular & epithelial development. Viral responses & Type 1 Interferon signaling pathways, previously implicated in intrarenal transcriptomic studies of black NS patients with a HR *APOL1* genotype, were enriched in the 5th most correlated network (r=0.50, p=0.04). *CD4* was a central hub in this network.

Conclusions: Our study of *APOL1* in the glomeruli of white FSGS patients identified similarities to black patients with *APOL1*-attributed NS, both in expression level & co-regulated networks. But we also discovered highly correlated glomerular networks enriched for non-immune related biology. Some of these processes have been implicated in previous studies of *APOL1*, while others are novel. Further study of *APOL1* glomerular transcriptional networks across races may help us discover the biologic mechanisms driving *APOL1*-attributed NS.

SA-PO606

Clinical Gout Separates ADTKD-UMOD from ADTKD-MUC1 in a Large International Registry Eric G. Olinger,[3] Kendrah O. Kidd,[4] Anna Greka,[1] Stanislav Kmoch,[2] Anthony J. Bleyer,[4] Olivier Devuyst.[3] *[1]Harvard Medical School, Boston, MA; [2]Institute of Inherited Metabolic Disorders, Prague, Czech Republic; [3]University of Zurich, Zurich, Switzerland; [4]Wake Forest University School of Medicine, Winston-Salem, NC.*

Background: Autosomal dominant tubulointerstitial kidney diseases (ADTKD) comprise a group of rare disorders characterized by progressive CKD with interstitial fibrosis and tubular atrophy. ADTKD is genetically heterogeneous: mutations in *UMO*D are mainly involved but *MUC1*, *HNF1B* and *REN* have also been associated. Despite a recent gene-based disease ontology, clinical characteristics and diagnostic criteria of various ADTKD subgroups remain to be defined.

Methods: In an international effort, 463 families diagnosed with ADTKD were included in a comprehensive registry. Index cases were screened for *UMOD* mutations, followed by *MUC1*, *HNF1B* and *REN* mutations in *UMOD*-negative families.

Results: We detected mutations in *UMOD* in 181 families (39.1%). Among the *UMOD*-negative families, 20.3% screened positive for *MUC1*, 12.5% positive for *HNF1B* and 1.8% positive for *REN* mutations. 107 mutations were detected in *UMOD,* all missense except 7 small indels, with 90% clustering in exon 3 and 56% involving cysteine residues. All *MUC1* families displayed cytosine insertion in the VNTR region. Point mutations, small indels and large genomic rearrangements were reported in *HNF1B*. Clinical gout was more prevalent in ADTKD-*UMOD* cases compared *to* ADTKD-*MUC1* (58% vs. 17% of cases respectively, p<0.0001; PPV: 0.86) with an earlier age of onset (29.0±12.7 vs. 43.3±14.2 years; p<0.0001). A family history (FH) of CKD and gout was reported in 66% of ADTKD-*UMOD* cases contrasting with a predominant FH of isolated CKD in 84% of ADTKD-*MUC1*. FH of CKD with gout separates ADTKD-*UMOD* from ADTKD-*MUC1* (p<0.0001; PPV: 0.92) in this cohort.

Conclusions: Mutations in *UMOD* and *MUC1* are the leading genetic causes for ADTKD. Personal or familial history of clinical gout and early age of gout onset are specifically associated with ADTKD-*UMOD* inside this group of disorders. This international registry will help to identify modifying genes and biomarkers in ADTKD subgroups and to test future interventions.

SA-PO607

Identification of a New Mutation Mapping in the Renin Mature Protein Associated with Autosomal Dominant Tubulo-Interstitial Kidney Disease Celine Schaeffer,[1] Claudia Izzi,[2] Gianfranco Savoldi,[2] Elena Pasqualetto,[1] Gianluca Caridi,[3] Antonio Amoroso,[4] Luca Rampoldi,[1] Francesco Scolari.[2] *[1]San Raffaele Scientific Institute, MILAN, Italy; [2]Montichiari Hospital, ASST, Montichiari (Brescia), Italy; [3]Gaslini Institute, Genova, Italy; [4]University of Torino, Torino, Italy.*

Background: Autosomal dominant tubulo-interstitial kidney diseases (ADTKD) is a renal disorder characterised by interstitial fibrosis, tubular atrophy and dilation, and thickening and lamellation of tubular basal membranes. Known responsible genes are *UMOD* (uromodulin), *MUC1* (mucin 1), *HNF1B* (HNF1beta), *REN* (renin) and *SEC61A1* (Sec 61 translocon alpha 1 subunit). ADTKD-*REN* is usually characterised by early onset, anaemia during childhood, hyperkaelemia and mild hypotension. All ADTKD mutations in renin so far reported are localised in the leader peptide of the protein (aa 1-23; exon 1), affecting its co-translational insertion in the endoplasmic reticulum (ER).

Methods: Whole exome sequencing was performed on 3 sibs (2 affected and 1 healthy) of a pedigree with suspected ADTKD of unknown origin that tested negative for

UMOD, *HNF1B* and *REN* (exon1). A variant was found in *REN* (exon 10) and confirmed by Sanger sequencing. The effect of such variant was studied by expression in cell lines.

Results: We identified a unique *REN* mutation (p.L381P) that is associated with ADTKD. This variant co-segregates with renal disease following an autosomal dominant way on inheritance. It was found in all tested affected individuals (3) and absent in healthy subject (1). The p.L381P variant is not found in sequence databases from disease-specific and population genetic studies (ExAC, gnomAD). Interestingly this variant maps in mature renin and is predicted to be damaging (Polyphen, SIFT, SDM). Functional studies in HEK293 and AtT20 cell lines showed that L381P renin is fully retained in the ER and it is absent from the culturing medium. This effect is likely due to mutant protein misfolding. ER retention induces ER stress. Co-expression of mutant protein with wild type renin does not interfere with wild type protein trafficking and secretion.

Conclusions: These results suggest that the spectrum of *REN* mutations associated with ADTKD is broader and that screening of the *REN* gene in patients compatible with ADTKD diagnosis should not be limited to exon 1. Interestingly, the possible mechanism of pathogenesis associated with the p.L381P mutation, i.e. ER stress and reduced secretion, is likely similar to the one proposed for already described mutations in the leader peptide.

SA-PO608

Diet-Dependent Development of CKD in a Mouse Model of Cystinuria Type I Lauren E. Woodard,[1,3] Rick C. Welch,[3] Ruth A. Veach,[2] Thomas M. Beckermann,[3] Feng Sha,[3] Talat Alp Ikizler,[1,3] Jay A. Tischfield,[4] Amrik Sahota,[4] Matthew H. Wilson.[1,3] *[1]Veterans Affairs, Tennessee Valley Healthcare System, Nashville, TN; [2]Vanderbilt University Medical Center, Nashville, TN; [3]Medicine, Division of Nephrology, Vanderbilt University Medical Center, Nashville, TN; [4]Genetics, Rutgers University, Piscataway, NJ.*

Background: Cystinuria type I results from mutation of *SLC3A1* and is a disorder of renal amino acid transport, resulting in recurrent nephrolithiasis and significant morbidity. It is one of the most common autosomal recessive genetic disorders in humans with an incidence in the United States of 1 in 15000. Using two diets, we compared the rate of stone and chronic kidney development in *Slc3a1* knockout mice.

Methods: In a mouse model of cystinuria type I, mice lacking the gene had increased basic amino acids in their urine and developed cystine stones. Mice were supplied with either a normal or breeder chow diet and allowed to age for approximately one year. Blood and tissue samples were obtained to assess development of chronic kidney disease in each group. We also evaluated cystine levels in the blood and glutathione (GSH) levels in the liver.

Results: When placed on a normal diet, aged *Slc3a1* knockout mice had an elevated blood urea nitrogen (BUN) and normal serum creatinine. *Slc3a1* knockout mice that were aged on a breeder diet containing higher levels of cystine had more severe chronic kidney disease as indicated by both elevated BUN and serum creatinine. Histologic analysis also revealed a greater degree of kidney and bladder injury in aged mice maintained on a breeder diet than in those maintained on a normal diet. Additionally, we observed lower levels of cystine in the blood of knockout animals. The availability of cysteine, which forms cystine when two molecules are joined together, is a major determinant of the regulation of GSH synthesis. We found that glutathione levels in the liver were reduced in the *Slc3a1* knockout animals.

Conclusions: These results suggest that diet can modulate the severity of kidney disease that developed over time in an animal model of cystinuria and may have implications for the potential to modulate disease severity in cystinuric patients. Additionally, lack of *Slc3a1* function results in lower blood cystine and tissue glutathione levels indicating a metabolic phenotype beyond just kidney stone formation in cystinuria.

Macrophage Enzyme Chitotriosidase Reflects Long-Term Cystine Accumulation in Cystinosis Mohamed A. Elmonem,[2,5] Koenraad Veys,[3] Maria Van dyck,[4] Mirian C. Janssen,[6] Elisabeth A. Cornelissen,[1] Elena N. Levtchenko.[3] *[1]Radboud University Medical Centre, Nijmegen, Netherlands; [2]Laboratory of Pediatric nephrology, University Hospital Leuven, KU Leuven, Leuven, Belgium; [3]University Hospitals Leuven, Leuven, Belgium; [4]university hospitals Leuven, Leuven, Belgium; [5]Clinical and Chemical Pathology, Faculty of Medicine, Cairo University, Cairo, Egypt; [6]Radboudumc university Medical centre, NIJMEGEN, Netherlands.*

Background: Cystinosis is an autosomal recessive lysosomal storage disorder characterized by early renal damage. Strict compliance to the cystine depleting agent cysteamine is necessary for more efficient treatment. Leucocyte cystine is the current therapeutic monitor. Although highly specific, its use is hindered by many technical difficulties and its availability in only few laboratories. Recent evidence suggests that inflammatory cells play a major role in the pathogenesis of cystinosis and its rapid progression to ESRD. Macrophage activation markers, such as chitotriosidase and several cytokines have been linked to disease severity and response to cysteamine therapy in cross-sectional studies. We aim to assess the longitudinal clinical value of these markers as potential therapeutic monitors in a large cohort of cystinosis patients.

Methods: Fifty four patients (19 children and 35 adults) were recruited from the cystinosis clinics in Leuven (Belgium), Nijmegen (Netherlands) and Traunstein (Germany). Patients were followed-up for two years during which, clinical and laboratory data were regularly collected from hospital records. Every three months, plasma samples were obtained to analyze chitotriosidase and other cytokines. These markers were correlated with leucocyte cystine concentration and with other parameters of renal disease such as, serum creatinine and urinary albumin/creatinine ratio.

Results: Cystinosis patients showed large variation in compliance/response to cysteamine therapy. Average leucocyte cystine concentrations over two years ranged from 0.65 to 5.8 nmol ½ cystine/mg protein. During the first year of the study, plasma chitotriosidase activities ranged from 2 to 834 nmol/ml plasma/h in cystinosis patients (reference range <55 nmol/ml plasma/h). Chitotriosidase activities correlated with individual cystine measurements ($r=0.432$, $P=0.002$). More importantly, the correlation was stronger with the average cystine values ($r=0.582$, $P<0.001$).

Conclusions: Chitotriosidase activity correlates with long-term cystine concentrations and can be used for the therapeutic monitoring of cysteamine therapy in nephropathic cystinosis.

Cell Non-Autonomous Origin of Renal Fibroblasts in Autosomal Dominant Tubulointerstitial Kidney Disease (ADTKD) Annie Shao, Siu Chiu Chan, Alan Mickelson, Peter Igarashi. *University of Minnesota, Minneapolis, MN.*

Background: Autosomal dominant tubulointerstitial kidney disease (ADTKD) is an uncommon disorder that is characterized by slowly progressive CKD and autosomal dominant inheritance. Renal histology shows tubular cysts and interstitial fibrosis. ADTKD is genetically heterogeneous and can arise from mutations in at least four different genes. ADTKD-HNF1B is caused by mutations of the transcription factor hepatocyte nuclear factor-1β (HNF-1β). The mechanism whereby mutations of HNF-1β, an epithelial-specific protein, produce renal interstitial fibrosis is not known. Here, we performed lineage analysis to determine whether renal fibroblasts originate from HNF-1β-deficient tubular epithelial cells or via a cell non-autonomous process.

Methods: Ksp/Cre;$Hnf1b^{F/F}$ mice were generated to specifically ablate HNF-1β in renal tubular cells. These mice were crossed with RYFP mice to introduce an EYFP reporter gene that is permanently activated upon Cre/loxP recombination, thereby enabling us to follow the fate of HNF-1β mutant cells. Kidneys were harvested from Ksp/Cre;$Hnf1b^{F/F}$;RYFP (HNF-1β KO) mice at P16 and P28. $Hnf1b^{F/+}$;RYFP littermates were used as negative controls.

Results: Histological staining with trichrome, PAS, and H&E showed that HNF-1β KO kidneys developed cysts and had increased extracellular matrix compared to control kidneys at P16. Costaining of HNF-1β KO kidney sections with antibodies against HNF-1β and EYFP showed that HNF-1β was absent in EYFP-positive cyst epithelial cells, confirming that expression of EYFP marks HNF-1β mutant cells. Costaining of HNF-1β KO kidney sections at P28 with antibodies against EYFP and entactin revealed that HNF-1β mutant cells remained on the luminal side of the tubular basement membrane. Costaining of HNF-1β KO kidney sections with antibodies against EYFP and smooth muscle α-actin revealed that myofibroblasts accumulated in the renal interstitium but did not express EYFP.

Conclusions: We conclude that HNF-1β-deficient kidneys develop fibrosis as early as P16. Lineage tracing demonstrates that HNF-1β mutant epithelial cells do not migrate out of renal tubules. Fibroblasts in the interstitium are not of tubular origin, indicating that fibrosis in ADTKD-HNF1B is due to a cell non-autonomous mechanism.

Leveraging Statistical Natural Language Processing (NLP) to Surface Clinically Relevant Biomarkers in Pediatric Nephrotic Syndrome Friedhelm Hildebrandt,[1] Svjetlana Lovric,[1] Shirlee Shril,[1] Patrick Mcneillie,[3] Irene Dankwa-Mullan,[3] Evan Leibovitz,[2] Kevin J. Scanlan.[3] *[1]Boston Children's Hospital, Boston, MA; [2]IBM, Cambridge, MA; [3]IBM Watson Health, Bethesda, MD.*

Background: The majority of pediatric idiopathic nephrotic syndrome (NS) have minimal change disease, which is generally responsive to steroid therapy. Patients with genetic forms of steroid-resistant nephrotic syndrome (SRNS) are unresponsive to steroid therapy. Thus, therapeutic decisions are based on the underlying etiology, renal histology and genetic screening. While mechanisms of NS are not well understood, recent advances in molecular genetics have shown that single gene defects are responsible for a 25-33% of all cases of isolated and syndromic SRNS. Biomarkers represent significant value to the clinical domain, offering information on disease diagnosis, prognosis, risk-assessment, and treatment efficacy. However, the process of extracting biomarkers from unstructured literature is time consuming and requires domain expertise. This study evaluates the potential for NLP and cognitive analytics to facilitate a review of SRNS to accelerate discovery of potential biomarkers.

Methods: Boston Children's Hospital (BCH) and IBM collaborated to train a machine learning model to identify appropriate entities and relationships across literature articles focused on SRNS. The team identified and labeled 11 entity types and 50 relationship types across 180 literature articles. The trained model was tested against the unstructured text of articles and outputs were analyzed for accuracy and precision.

Results: Comparing the expert output and the trained model showed 100% precision (23/23) and 92.0% sensitivity (23/25). One false-negatives was due to lack of co-reference, which links the lexical subject across multiple sentences. The other false-negative was due to the gene not being identified as relevant. The model took less than 30 seconds to identify the relevant biomarkers and provided passage level references to enable seamless follow up by the researcher.

Conclusions: The machine learning model provided rapid and accurate extraction of potential molecular biomarkers for NS. With additional training this model could

be expanded to other rare diseases, accelerating mutational analysis for therapeutic interventions.

SA-PO612

Pharmacologic Chaperone Responsiveness in Canadian Patients with Fabry Disease Michael L. West,[1] Daniel G. Bichet,[2] Sandra Sirrs.[3] *[1]Dalhousie University, Halifax, NS, Canada; [2]University of Montreal, Montreal, QC, Canada; [3]Vancouver General Hospital, Vancouver, AB, Canada. Group/Team: Canadian Fabry Disease Initiative Research Group.*

Background: Fabry disease (FD) is an X-linked lysosomal storage disease due to deficiency of the enzyme α-galactosidase. This results in premature death from renal failure, hypertrophic cardiomyopathy and strokes. Treatment with intravenous enzyme replacement therapy (ERT) is expensive and not curative. Pharmacologic chaperone therapy (PCT) with Migalastat, an oral iminosugar, increases residual enzyme activity by stabilizing the molecule and delivering more enzyme to the lysosome. Recent data suggests that some patients on ERT may derive additional benefit from PCT. We report the prevalence of chaperone responsiveness in Canadian Fabry disease patients as a guide to planning future therapy.

Methods: The Canadian Fabry Disease Initiative (CFDI) is a registry of 466 FD patients followed for up to 10 years. All known GLA gene mutations in CFDI patients were evaluated using a published library of chaperone responsive mutations based on a good laboratory practice-validated HEK cell assay (Benjamin et al Genetics in Medicine 2017;19:430-8).

Results: The majority of Canadian patients with FD are enrolled in the CFDI with ascertainment of 92%. Over 95% have been genotyped. We evaluated 404 FD patients with 143 males, 261 females, mean age 45.0±17.8 (sd), range 8-86 years. ERT use under Canadian Fabry Treatment Guidelines was 50%. Chaperone responsiveness mutations (n=23) were noted in 86 patients (21.3%); missense 95.6%; half were receiving ERT. Non-responsive mutations (n=67) were found in 318 patients (78.7%); missense 53%, deletion/insertion 26%, stop codon 13%, duplication 3%, intronic 3%, frame shift 2%. Patients with chaperone responsive mutations had classic FD phenotype in 72.1%, vs. variant (24.4%) or indeterminate (3.5%) phenotypes. Chaperone responsive mutations varied by region with a maximum prevalence of 48.1% in Alberta (n=25) vs. a low of 2.2% in Nova Scotia (n=2). This is explained in part by the presence of a large Nova Scotia kindred with a chaperone non-responsive A143P mutation.

Conclusions: Oral PCT could be currently used in about one fifth of the Canadian FD population. Only half of those patients meet the current Canadian FD treatment guidelines for ERT suggesting that introduction of chaperone therapy would potentially only offer a change of treatment in a maximum of 40 (10%) FD patients in Canada. These data will help plan future therapy.

SA-PO613

We Propose a Single Heterozygous Mutation in ATP6V0A4 as a Novel Genetic Cause of dRTA Takayasu Mori,[1] Motoko Chiga,[1] Takuya Fujimaru,[1] Shintaro Mandai,[1] Shota Watanabe,[2] Yasuhisa Nakamura,[2] Takehiro Morishita,[2] Osamu Uemura,[4] Eri Imai,[3] Shuzo Kaneko,[3] Yusuke Tsukamoto,[3] Eisei Sohara,[1] Tatemitsu Rai,[1] Shinichi Uchida.[1] *[1]Department of Nephrology, Graduate School of Medical and Dental Sciences, Tokyo Medical and Dental University, Bunkyo-ku, Tokyo, Japan; [2]Ichinomiya Municipal Hospital, Ichinomiya, Japan; [3]Itabashi Chuo Medical Center, Itabashi-Ku, Japan; [4]Aichi Children's Health and Medical Center, Obu, Aichi, Japan.*

Background: We have recently reported the development of a comprehensive diagnostic panel using next-generation sequencing (NGS) for 166 genes responsible for various inherited kidney diseases such as Gitelman syndrome, nephrogenic diabetes insipidus, Alport syndrome, renal tubular acidosis (RTA), etc., named SPEEDI-KID. Of the 137 families with inherited kidney diseases analyzed so far, three distal RTA (dRTA) families carrying only a single heterozygous variant in the known pathogenic gene, *ATP6V0A4*, were included. All the cases showed hypokalemic metabolic acidosis with nephrocalcinosis and high urine pH (>6.5). Interestingly, two cases showed late-onset of the disease (40 and 12 y.o., respectively), indicating that the phenotypes of the individuals are relatively milder than the previously reported cases. Genetic diagnosis revealed that each of the three families carried a single heterozygous missense variant in *ATP6V0A4* (p.P393L, p.S544L, and p.G822S, respectively), even though autosomal recessive is the known inheritance mode. In all the cases, no other variants in known genes for RTA were detected. Relatively large genomic rearrangement in the alternative allele was excluded by using the NGS data. One family had two affected siblings carrying the same variant. In the other family, possibly affected father and an affected child had the same variant. The variants are extremely rare in general populations (ExAC, 1000G, and ToMMo2K) and *in silico* prediction scores (SIFT, PolyPhen2, and CADD) are consistent with the concept that these variants are disease-causative. Considering that heterozygous knockout mouse of *ATP6V0A4* was reported to present metabolic acidosis under the condition of acid administration, these heterozygous variants could be responsible for the disease.

Methods:

Results:

Conclusions: We propose single heterozygous mutations in ATP6V0A4 can be responsible for dRTA. dRTA with late-onset and mild phenotype caused by heterozygous variants in *ATP6V0A4* may be more commonly present.

SA-PO614

Whole Exome Sequencing Frequently Detects a Monogenic Cause in Early Onset Nephrolithiasis and Nephrocalcinosis Ankana Daga,[7] Amar J. Majmundar,[2] Jennifer A. Lawson,[6] Shirlee Shril,[5] Daniela A. Braun,[4] Michelle A. Baum,[1] Friedhelm Hildebrandt.[3] *[1]Boston Children Hospital, Boston, MA; [2]Boston Children's Hospital, Somerville, MA; [3]Boston Children's Hospital, Boston, MA; [4]Boston Children's Hospital, HMS, Boston, MA; [5]Boston Childrens Hospital, Boston, MA; [6]University of Connecticut School of Medicine, Farmington, CT; [7]Nephrology, Boston Children's Hospital, Boston, MA.*

Background: The incidence of Nephrolithiasis (NL) continues to rise. We previously detected a monogenic cause of NL in 20% of patients manifesting before the age of 25 years, and recently confirmed this high rate of monogenic causation (17%) in a pediatric cohort of patients by using a gene panel sequencing approach containing 30 known NL genes. We here employ whole exome sequencing (WES) rather than panel sequencing to identify monogenic causes of NL and/or nephrocalcinosis (NC).

Methods: Patients who had a history or renal ultrasound finding of at least one renal stone (NL) or NC before age 25 years were enrolled between 1/2014 to 12/2015. WES was performed on 51 families (65 affected individuals), and evaluated for causative mutations in 30 NL/NC genes. Deleteriousness of mutations was evaluated by pathogenicity prediction scores, evolutionary conservation, and prior reporting status of mutations.

Results: 63% were males, and the median age at presentation was 6 years (Range: 1 mo – 24 years). Of the 65 individuals, 32 had isolated NL, 22 had isolated NC, and 11 had both NL and NC. We detected a causative mutation in 15 out of 51 (29.4%) families. We detected a mutation in 7 recessive genes (*AGXT, ATP6V1B1, CLDN16, CLDN19, GRHPR, SLC3A1, SLC12A1*), in 1 dominant gene (*SLC9A3R1*), and in 1 gene (*SLC34A1*) with both recessive and dominant inheritance. 7 of the 19 different mutations were not previously described as disease causing. Median age of onset was significantly lower in patients in whom we detected a monogenic cause of NL/NC (3 yrs) vs. those without mutation detection (7 yrs) ($p < 0.05$). In one family we detected a causative mutation in one of 117 genes (*CTNS*) that represent phenocopies of NL-causing genes. Several factors that correlated with higher detection rate were younger age of onset of NL/NC (58%), presence of multiple affected in a family (41%), and presence of consanguinity (75%). In 9 of 15 families the genetic diagnosis led to specific implications for future clinical management and prevention of stone recurrence.

Conclusions: Thus, we established WES as an efficient approach towards a molecular genetic diagnosis in individuals with NL/NC who manifest before 25 years. Specific genetic diagnosis holds potential for personalization of the treatment plan.

SA-PO615

Mutational Burden in Monogenic Glomerular Kidney Disease Genes in Adult CKD Patients Matthias Wuttke,[2] Anselm Hoppmann,[2] Ulla T. Schultheiss,[2] Kai-Uwe Eckardt,[4] Beata S. Lipska-Zietkiewicz,[1] Franz S. Schaefer,[3] Anna Kottgen.[2] *[1]University of Gdansk, Gdansk, Poland; [2]University of Freiburg, Freiburg, Germany; [3]University of Heidelberg, Heidelberg, Germany; [4]Charité University Medicine Berlin, Berlin, Germany.*

Background: Monogenic kidney diseases often show severe manifestations in childhood (recessive) or mid-age (dominant traits). Conversely, moderate chronic kidney disease (CKD) in adults is often regarded a complex disease with a genetic predisposition. The contribution of mutations in monogenic kidney disease genes in adult CKD patients and the combined effects of rare variants and common susceptibility alleles are understudied.

Methods: 341 participants of the German Chronic Kidney Disease study (inclusion criteria CKD stages G1-G3 or A3 with biopsy-proven primary glomerular disease) underwent next-generation gene panel sequencing (Illumina MiSeq) of 37 glomerulopathy-associated monogenic traits. Read alignment and variant calling followed GATK best practices and incorporated consensus calling. Variants were annotated using VEP/SNPeff and filtered using GEMINI based on frequency, predicted impact and presence in clinical mutation databases to obtain putative deleterious mutations.

Results: At present, data are available for 202 patients. Definite pathogenic mutations were identified for 12 patients (median age 44 yr, eGFR 49 ml/min/1.73m2, UACR 357 mg/g, 67% FSGS) in genes with dominant inheritance mode (4 in *COL4A5*, 2 in *PAX2*, and 1 each in *GLA, INF2* and *WT1*) and 3 compound heterozygotes in *NPHS2*. In addition, 21 individuals carried plausible pathogenic variants (in *ACTN4, ANLN, ARHGAP24, COL4A5, CRB2, GLA, LMX1B, PAX2, TRPC6, TTC21B* and *WT1*). Within the next weeks, sequencing and evaluation of atypical presentations and extra-renal manifestations as well as integration with common susceptibility alleles from GWAS will be completed.

Conclusions: About 5% of adult patients selected for CKD stages G1-G3 or A3 and with presumed primary glomerular etiology carry pathogenic mutations in monogenic glomerular disease genes. Another 10% carry plausible pathogenic variants. Evaluating rare mutations together with common CKD susceptibility variants may provide further insights into their combined impact and contribution to atypical presentations and a mild disease course.

SA-PO616

The Comprehensive Gene Screening for Congenital, Infantile, and Steroid Resistant Nephrotic Syndrome in Japan Keita Nakanishi,[4] Kandai Nozu,[3] Junya Fujimura,[4] Shogo Minamikawa,[4] Tomohiko Yamamura,[4] Hiroshi Kaito,[5] Yuko Shima,[6] Koichi Nakanishi,[2] Kazumoto Iijima.[1] *[1]Dept. of Pediatrics, Kobe Univ. Graduate School of Medicine, Kobe, Japan; [2]Graduate School of Medicine, University of the Ryukyus, Nishihara-cho, Japan; [3]Kobe University, Kobe, Japan; [4]Kobe University Graduate School of Medicine, Kobe, Japan; [5]None, Kobe, Japan; [6]Wakayama Medical University, Wakayama City, Japan.*

Background: Cases with congenital nephrotic syndrome (CNS), infantile nephrotic syndrome (INS) or steroid-resistant nephrotic syndrome (SRNS) frequently progress to end stage renal disease (ESRD). It has been reported that about thirty percent of CNS/INS/SRNS patients possessed single causative gene variants in podocyte related genes that were detected by next generation sequencing. It has been revealed CNS/INS/SRNS patients with gene defects show severe renal prognosis; however, those patients seldom show recurrence of nephrotic syndrome after kidney transplantation. Thus, we established a gene screening system for CNS/INS/SRNS patients in their early stages, to suggest their clinical courses.

Methods: The gene screening system by targeted sequencing for 45 podocyte related genes that have been reported as causative genes for CNS/INS/SRNS was established. Newly diagnosed patients as CNS/INS/SRNS were recruited between January in 2016 and May in 2017.

Results: In total, 84 patients from 42 hospitals in Japan were screened. We detected causative genes in 25 patients (30%). The most frequent gene was WT1 (4 patients), and other genes were LAMB2 (3 patients), ADCK4, TRPC6, LMX1B, INF2, NUP107 (2 patients each), and so on. None of our cases possessed NPHS2 gene variants, which is most common causative gene in European countries. Seven out of 25 patients progressed to ESRD, and only one patient who had TRPC6 variant had kidney transplantation and showed no recurrence of nephrotic syndrome. The cost of gene screening for one sample was about 250.00 (USD).

Conclusions: We have established a comprehensive gene screening system for CNS/INS/SRNS cases in their early disease stages in Japan and detected a single causative gene in 30% in our cohort. The variation of causative genes in Japan was different from those in other countries. The screening results will be used in deciding treatment and thereby help to improve the quality of life for patients.

SA-PO617

Quantifying Mendelian Genetic Disease in the Pediatric Renal Clinic Yadhavan Upendran,[2] Fiona Mackie,[1] Rebecca A. Spicer,[1] Siah Kim,[1] Sean E. Kennedy,[1,2] Hugh J. Mccarthy.[1,2] *[1]Sydney Children's Hospital, Randwick, NSW, Australia; [2]University of New South Wales, Sydney, NSW, Australia.*

Background: With the advent of new sequencing technology, gene tests are more readily available to the nephrologist and increasingly cost effective. Planning is required to provide the same level of counseling for those now undergoing testing in the renal clinic compared to the clinical genetic clinic. The aim of this study was to determine the prevalence of disease with a likely genetic aetiology within the paediatric renal clinic.

Methods: An algorithm was configured to determine those with a possible Mendelian genetic aetiology to disease who could be offered gene testing. A retrospective review was then undertaken of new referrals to the renal clinic at a tertiary children's hospital from 2012-2015 to determine the number of patients who would have then required genetic counseling.

Results: The algorithm identified risk as Inherited Glomerular (including steroid resistant or congenital nephrotic syndrome and Alport's syndrome); Tubular or Metabolic disorders; Complement mediated disorders, Nephrocalcinosis/lithiasis; Cystic Kidney Disease; Syndromic Congenital Anomalies of Kidney and Urinary Tract (CAKUT); other including familial not otherwise specified. Simple CAKUT was excluded due to low rate of identifiable genetic aetiology. In the total cohort, the mean age at presentation was 5.25 years and male to female ratio was 1.52. 173/751 (23%) patients so far analysed have a possible genetic aetiology to their renal disease and could have been offered genetic counseling +/- testing.

Conclusions: Gene testing is becoming a routine component of clinical practice within nephrology either to direct management; aid diagnostic dilemmas; inform for family planning or living donation. The number of patients who would benefit justifies establishing a separate renal genetic service to run concurrently with the routine service in order to ensure optimal counseling for patients and their families.

Sub-category split of genetic at risk cohort

	Number n=173 (%)
Glomerular	39 (22.5)
CAKUT	58 (33.5)
Cystic	17 (9.8)
Tubular/Metabolic	10 (5.8)
Nephrocalcinosis/Lithiasis	23 (13.3)
Complement Mediated	4 (2.3)
Other	22 (12.7)

Integrative Analysis of Genome-Wide Transcriptome Data Sets Reveals Shared Biology Between Lupus and its Co-Morbidities Thomas Oates, Alan D. Salama. *University College London, London, United Kingdom.*

Background: The autoimmune disease Systemic Lupus Erythematosus (SLE) is frequently complicated by co-morbidities such as cardiovascular disease and stroke. The biology of these disease associations are largely unknown but increased understanding may result from transcriptomic analysis of SLE and its co-morbidities.

Methods: 7 major co-morbidities of SLE were identified for analysis: chronic kidney disease, stroke, cardiovascular disease, osteoporosis, lung cancer, Hodgkin lymphoma, and viral infections. Transcriptomic datasets for these diseases available via the Gene Expression Omnibus were screened and those with over 30 subjects in a case-control design were retained for analysis. Previously described methods were used to explore SLE and the chosen co-morbidities at gene, pathway and disease level (PMID: 27842596). The methods used are statistically robust to the multiple-test corrections required in genome-wide experiments and the combination of results from several independent tests.

Results: 36 microarray datasets passed the filter criteria above. These contained expression data from 4,776 individuals (3,320 cases, 1,456 controls). Differentially expressed genes (DEGs) between cases and controls were calculated for each dataset and combined for all datasets per disease (see Figure row A). Next, enrichment of the DEGs per disease was examined in multiple reference pathways including the Kyoto Encyclopedia of Genes and Genomes (KEGG) (Figure row B). Combining P-values across the 8 studied diseases (Figure row C) delineated pathways that retained statistical significance for dysregulation in SLE and all co-morbidities (Figure Heatmap & blue text).

Conclusions: The significant enrichment of pathway gene sets across SLE and its co-morbidities suggest that these diseases may share an underlying molecular architecture. Further analysis of these data may be able to guide treatment decisions when SLE is complicated by co-morbidities, or delineate gene expression signatures that could prompt focused screening of patients with SLE for relevant co-morbidities.

Genetic Alterations in DMBT Confer Urinary Tract Infection Risk in Children and Mice Andrew L. Schwaderer,[2] David S. Hains,[4] John Ketz,[1] Ed Hollox.[3] *[1]Nationwide Children's Hospital, Columbus, OH; [2]The Ohio State University, Westerville, OH; [3]University of Leicester, Leicester, United Kingdom; [4]Riley Children's Hospital, Indianapolis, IN.*

Background: The deleted in malignant brain tumor 1 (DMBT1) gene is prone to copy number variation (CNV) that alters the number of bacteria-binding domains in 2 distinct gene regions (CNV1 and CNV2). DMBT1's role in urinary tract functions (UTI) has not been previously evaluated

Methods: RIVUR study children with UTI and vesicoureteral reflux treated with antibiotics vs. placebo were studied. Copy number estimates for CNV1 and CNV2 were determined using a paralogue ratio test (PRT). Experimental UTI was induced by transurethral inoculation of uropathogenic E.coli (UPEC) into *Dmbt1*$^{-/-}$ vs wild-type mice. DMBT1-UPEC aggregation was evaluated by evaluating differential GFP expressing UPEC aggregation in the bottom of wells coated with DMBT versus control.

Results: DNA samples from 314 Caucasian children (159 in antibiotic prophylaxis group and 155 in the placebo group) were typed for DMBT1 CNV1 and CNV2. Higher copy number of CNV2 (but not CNV1) was associated with fewer infections (p=.007), particularly in the prophylaxis group (Figure). Compared to wild type mice, *Dmbt1*$^{-/-}$ mice had 5-fold higher bladder bacterial burdens (cfu/bladder) at 6 hrs following following low (10^7UPEC) inoculum and a 2.4-fold higher UPEC bladder burden at 6 hrs following a high (10^8 UPEC) inoculum; p values were 0.04 and 0.01 respectively. Kidney UPEC burdens were not different between *Dmbt1*$^{-/-}$ and wild-type mice. Additionally, DMBT protein, but not control resulted in bacterial clumping in our bacterial agglutination assay.

Conclusions: Our results indicate that children with low copy number of DMBT1 CNV2 would benefit from antibiotic prophylaxis. Increased murine bladder bacterial burdens in *Dmbt1*$^{-/-}$ mice compared to wild type and increased UPEC agglutination with DMBT demonstrates it's functional relevance in the innate immune defense against UTI.

SA-PO620

Congenic Substitution to Uncover the Genetic Pathway of Hypertensive Renal Injury Peter A. Doris,[2] Michael C. Braun,[1] John Hicks,[4] Isha Dhande.[3] *[1]TCH/ BCM, Houston, TX; [2]UNIVERSITY OF TEXAS HOUSTON, Houston, TX; [3]University of Texas Health Science Center at Houston, Houston, TX; [4]Pathology, Texas Children's Hospital, Houston, TX.*

Background: The SHR-A3 line of the spontaneously hypertensive rat experienes progressive renal injury (RI). Susceptibility arises from natural gnetic variaiton and contrasts with injury resistant SHR-B2. These two lines are 87% genetically identical. SHR-A3 has higher blood pressure (BP) than SHR-B2. We have mapped a locus responsible to an 8MB block on chr17. Here we assess whether a congenic line (CL) in which this block is transferred from SHR-B2 into SHR-A3 experiences different levels of BP and RI than SHR-A3. The SHR-A3 and SHR-B2 genomes are most divergent in the immunoglobulin heavy chain (IgH). We created a CL substituting the SHR-B2 IgH locus into SHR-A3 and assesssed the effect on BP and RI. Finally we have created a bicongenic (2CL) line containing both these SHR-B2 loci within the SHR-A3 background.

Methods: CLs were created by backcrossing using genetic markers to identify those regions of the genome at which SHR-A3 and SHR-B2 differ. Blood pressure was measured by telemetry. Renal injury was assessed histologically in paraffin-embedded tissue stained with Periodic acid-Schiffs stain.

Results: Congenic substitution of the chr17 locus was associated with a reduction in blood pressure to a level that was significantly below SHR-A3, but not different from SHR-B2. At 40wks of age, glomerular injury (GI) was indistinguishable in this CL from SHR-B2. Tubulointerstital injury (TI) in the CL was intermediate, but significantly below SHR-A3. Congenic substituion of the IgH locus from SHR-B2 into the SHR-A3 background had no effect on BP. At 40wks, this CL also had GI indistinguishable from SHR-B2 and TI intermediate between SHR-A3 and SHR-B2. In the 2CL, GI and TI were both reduced to the SHR-B2 level.

Conclusions: RI in SHR-A3 appears to result from at least two genetic loci. One is an 8Mbase block on chromosome 17 that results in hgiher blood pressure in SHR-A3 than SHR-B2. The other is the immunoglobulin heavy chain, indicating that genetic variation in germ-line antibody sequences may contribue to the pathogenesis of renal injury in this model. The combined effect of these loci eliminates histologically assessed RI, resulting in animals that are 99.5% geneticall identical to SHR-A3, but resistant to renal injury.

COL4A3 Gene Variants Exacerbate Diabetic Kidney Disease: Genetic Investigation from Nine MODY Families Yiting Wang,[1] Junlin Zhang,[2] Fang Liu.[2] *[1]Division of Nephrology, West China Hospital of Sichuan University, Chengdu, China; [2]West China Hospital of Sichuan University, Chengdu, China.*

Background: Despite the advances in the identification of genetic factors of diabetic kidney disease (DKD), much of the heritability for the clinical heterogeneity of DKD remains unexplained. In the study, DKD of nine probands who were suspected maturity-onset diabetes of the young (MODY) were proven by renal biopasy. Notably, three of the probands has processed to ESRD and other four with overt proteinuria or albuminuria, however, their parents remained almost normal renal function or denied any discomforts or clinical symptoms of DKD, despite they have suffered longer duration of DM. The present study aimed to explore the genetic factor in clinical heterogeneity of DKD.

Methods: The whole-exome sequencing (WES) was performed for the nine probands and their families. The susceptibility genes of DKD were reviewed and analyzed with Gene Ontology enrichment. The variants which have been reported to be associated with DKD, or MAF<0.05 and predicted to be pathogenic by software in susceptibility genes of DKD were selected.

Results: HNF1B-MODY, CEL-MODY, PAX4-MODY, and WFS1-MODY were diagnosed among nine families. There were 174 selected variants of 25 susceptibility genes among all participants, quantity of selected variants in genes related to DKD were identified more in offspring, moreover, pathogenic variants in COL4A3 genes were only identified in four probands but their MODY parents. Combined with analysis of gene function and Protein-Protein interaction network, we speculated the cumulative effect of susceptibility genes on the severity of DKD and indentified the potential pathogenesis of COL4A3 gene variants in aggravating the progression of DKD.

Conclusions: Pathogenic variants of COL4A3 gene and cumulative effect of susceptibility genes exacerbate DKD.

Collagen VI Associates with Basement Membrane Defects in Alport Syndrome Michael J. Randles,[1] Franziska Lausecker,[1] Paul K. Potter,[2] Sara Falcone,[2] Hani Suleiman,[3] Jeffrey H. Miner,[4] Rachel Lennon.[1] *[1]University of Manchester, Manchester, United Kingdom; [2]Medical Research Council, Harwell, United Kingdom; [3]Washington University, Saint Louis, MO; [4]Washington University School of Medicine, St. Louis, MO.*

Background: Alport Syndrome is caused by genetic defects in *COL4A3, COL4A4* or *COL4A5*, leading to inadequate assembly of the type IV collagen α3, α4, α5 network in basement membranes. In the glomerulus this causes irregularities in glomerular basement membrane (GBM) width and a characteristic basket weave appearance. We aimed to build our basic understanding about the glomerular extracellular matrix (ECM) in Alport syndrome and performed global analysis of composition and ultrastructural imaging in the both the *Col4a3-/-* and *Col4a5-/-* Alport mouse models.

Methods: Cellular and ECM fractions from wild type and Alport glomeruli at 6-8 and 16-18 weeks of age were analysed by mass spectrometry (MS)- based proteomics. Imaging included serial block face-scanning electron microscopy (SBF-SEM) and stochastic optical reconstruction microscopy (STORM).

Results: MS analysis revealed moderate changes in the composition of glomerular ECM at 6-8 weeks, even prior to the onset of glomerular barrier dysfunction. These changes included complete absence of type IV collagen α3, α4, α5 in both mouse models and an upregulation of type IV collagen α1, α2, α6 and the interstitial type VI collagen. At 16-18 weeks more dramatic changes were detected including elevated type IV collagen α1, α2, fibronectin, type I collagen, laminin α2 and fibrinogen chains. Global and pathway analysis of cellular fractions indicated changes in actin regulating proteins at 6 weeks and mitochondrial dysfunction at 16 weeks. SBFSEM demonstrated thickened and irregular GBM with evidence of invading podocyte protrusions. Interestingly, STORM localised type VI collagen to GBM defects in Alport mice whereas collagen VI was absent from wild type controls.

Conclusions: Our data demonstrate that Alport syndrome progresses with distinct early changes in ECM followed by more profound ECM accumulation, disruption and a marked increase in type VI collagen in the GBM. Enhanced understanding about the pathways that control matrix deposition in glomerular disease may ultimately inform targeted strategies to correct or repair glomerular barrier dysfunction.

SA-PO623

Impact of High-Risk APOL1 Variants in Kidney Disease in South America Cristian Riella,[1] Tobias A. Siemens,[3] Rodrigo P. Campos,[5] Thyago P. Moraes,[4] David J. Friedman,[1] Miguel C. Riella,[3] Martin R. Pollak.[2] *[1]Beth Israel Deaconess Medical Center, Boston, MA; [2]Beth Israel Deaconess Medical Center/Harvard Medical School, Boston, MA; [3]Hospital Universitário Evangélico de Curitiba, Curitiba, Brazil; [4]Pontificia Universidade Catolica do Parana, Curitiba, Brazil; [5]Nephrology, Federal University of Alagoas, Maceio, Brazil.*

Background: The presence of apolipoprotein L-1 (APOL1) mutations is associated with increased risk of end-stage renal disease (ESRD) in African Americans. This effect has not been investigated in South Americans of African descent. In this study we analyzed APOL1 variants in dialysis patients and healthy controls with African descent in Brazil.

Methods: Inclusion criteria: dialysis patients 18 years of age or older who reportedly had African ancestry, first degree relatives were selected as controls. **Exclusion criteria**: individuals below the age of 18, history of obstructive uropathy, polycystic kidney disease, and known SLE or other vasculitic etiologies. After informed consent was obtained, clinical data along with blood samples for DNA extraction were collected. Genotyping was performed with a TaqMan RT-PCR assay for the wild type allele G0, and G1 and G2 risk alleles.

Results: 440 individuals were included in the study (271 patients and 169 controls). The frequency of high risk variants (G1,G2) was higher in dialysis patients than controls: one risk variant frequency was **17.7%(48) vs. 10.6%(18);** two risk variants: **12.2%(33) vs. 1.2%(2),** respectively. In a multivariate logistic regression model, the presence of one risk variant was associated with a 4-fold increase in risk of ESRD (OR=3.95, p=0.002, CI=1.68-9.27); while carriers of **two risk variants had a 21-fold increase in risk of ESRD** (OR=21.66, p<0.0001, 95% CI= 4.13-113.51). After adjusting for comorbidities and other variables, patients with two risk alleles started dialysis 7.5 years earlier (Coef.=-7.53856, p=0.007) in a multivariate linear regression model. The analyses were adjusted for gender, comorbidities, smoking status, income and education level.

Conclusions: APOL1 mutations are a significant risk factor for the development of ESRD in South American individuals of African descent. The presence of two APOL1 risk alleles conferred up to 21-fold higher risk of ESRD and was associated with younger age at the start of dialysis.

SA-PO624

APOL1 Nephropathy Risk Variants and Incident Cardiovascular Disease Events in Community-Dwelling Black Adults Orlando M. Gutierrez,[9] Marguerite Irvin,[8] Ninad S. Chaudhary,[10] Mary Cushman,[11] Neil A. Zakai,[11] Sophie Limou,[5] Nathalie Pamir,[6] Alex Reiner,[14] Rakhi Naik,[2] Michele Sale,[12] George W. Nelson,[7] Monika M. Safford,[13] Hyacinth I. Hacinth,[1] Suzanne E. Judd,[8] Jeffrey B. Kopp,[4] Cheryl A. Winkler.[3] *[1]Aflac Cancer and Blood Disorder Center, of Children?s Healthcare of Atlanta, Atlanta, GA; [2]Johns Hopkins, Baltimore, MD; [3]NCI, NIH, Frederick National Laboratory, Frederick, MD; [4]NIDDK, NIH, Bethesda, MD; [5]NIH, Leidos Biomedical Research Inc, Nantes, France; [6]Oregon Health and Science University, Portland, OR; [7]SAIC-Frederick/FNLCR, Frederick, MD; [8]UAB, Birmingham, AL; [9]UAB School of Medicine, Birmingham, AL; [10]University of Alabama at Birmingham, Birimingham, AL; [11]University of Vermont, Colchester, VT; [12]University of Virginia, Charlottesville, VA; [13]Weill Cornell Medicine, New York, NY; [14]University of Washington, Seattle, WA.*

Background: *APOL1* nephropathy risk variants are strongly associated with chronic kidney disease progression in Black adults, but associations with incident cardiovascular disease (CVD) are uncertain.

Methods: We examined associations of *APOL1* risk variants with incident coronary heart disease (CHD,n=323), stroke (n=331), and a combined CVD end point (n=500) in 10,605 Black participants of the Reasons for Geographic and Racial Differences in Stroke (REGARDS) study. Main analyses compared those with *APOL1* high-risk nephropathy genotypes (2 risk variants) to *APOL1* low-risk genotypes (0/1 risk variant) in Cox models adjusted for CVD risk factors and ancestry principle components.

Results: *APOL1 h*igh-risk participants were younger and more likely to have albuminuria than *APOL1* low-risk participants. The risk of incident stroke, CHD or the composite CVD endpoint did not significantly differ by *APOL1* genotype in multivariable models. However, the association of *APOL1* genotype with the composite CVD outcome differed by diabetes status (P<0.01). In those without diabetes, high-risk genotypes were associated with higher risk of incident composite CVD than low-risk genotypes in fully adjusted models [table]. This association appeared to be driven by incident stroke risk. In contrast, the *APOL1* high-risk genotype was associated with a trend towards lower risk of CVD in diabetics.

Conclusions: *APOL1* high-risk genotypes are associated with higher incidence of CVD events in individuals without diabetes, whereas the association appeared to be opposite among individuals with diabetes.

Funding: NIDDK Support, Other NIH Support - NINDS

SA-PO625

Clinician Attitudes Toward Use of APOL1 Genetic Testing in Clinical Practice Ebele Umeukeje,[1] Wylie Burke,[2] Kerri L. Cavanaugh,[1] Stephanie M. Fullerton,[2] James G. Wilson,[3] Bessie A. Young.[4] *[1]Nephrology, Vanderbilt University Medical Center, Vanderbilt Center for Kidney Disease, Nashville, TN; [2]Bioethics and Humanities, University of Washington, Seattle, WA; [3]Physiology & Biophysics and Medicine, University of Mississippi Medical Center, Jackson, MS; [4]Nephrology, University of Washington, VA Puget Sound Health Care System, Kidney Research Institute, Seattle, WA.*

Background: Apolipoprotein L1 (*APOL1*) high-risk variants are common among African Americans (AA) and are associated with a 7-10 fold higher risk of non-diabetic endstage renal disease (ESRD). However, there are gaps in knowledge regarding the clinical implication of *APOL1* variants in part because associated effects on risk in combination with co-morbidities or environmental exposures are not fully established. The objective of this study is to describe clinicians' views of *APOL1* genetic testing in clinical practice.

Methods: As part of an ongoing study of stakeholder views regarding *APOL1* genetic testing in AA, we conducted key informant interviews with primary care (N=13) and nephrology (N=14) clinicians in Seattle WA, Nashville TN, and Jackson MS. Interviews assessed clinicians' views about the use of *APOL1* genetic testing in clinical care.

Results: Clinicians were recruited from different practice settings (63% in Academic centers; 26% in private practice; and 11% in the VA and other settings), and 78% of them provide care to a significant proportion of AA patients (≥ 25%). Dominant themes included possible increased monitoring and motivation of patients with risk factors (e.g. hypertension, family history) vs. possible over or under treatment, increased cost, stigmatization and increased psychological stress. Exemplar quotes: "In terms of getting people to change their lifestyles, for some people, having this risk might help that. It might just freak them out. I don't really know. I think those are all – I think we're in uncharted territory clinically, actually"; "We want to make sure we're following the data and not jumping to conclusions about when to apply something that may still be in the phase of further interpretation in the science."

Conclusions: Our results suggest that clinicians hold uncertain views on the use of *APOL1* testing to guide clinical practice. Further research is needed to determine the impact of testing on clinical outcomes especially in patients with ESRD risk factors.

SA-PO626

Nephrologists Treating C3 Glomerulopathy Patients Report Highest Clinical Utility by Using Gene Sequencing to Confirm a Diagnosis of C3G in Departure from C3G Consensus Report Bjorn Stromsness. *Machaon Diagnostics, Oakland, CA.*

Background: C3 glomerulopathy (C3G) is a recent renaming of a group of diseases and applies to MPGN Type II and III as well as C3 Glomerulonephritis [2]. In 2013, a C3 glomerulopathy consensus report was published with testing guidelines [1, 3]. We were curious about the degree to which physicians followed these guidelines and their impressions of the tests recommended in that report.

Methods: An anonymous survey titled "C3 glomerulopathy testing: A questionnaire for nephrologists" was sent via email to approximately 4,000 nephrologists.

Results: The C3 glomerulopathy consensus report recommended all suspected C3G patients receive testing for C3 Levels, C4 Levels, C3 Nephritic Factor, CFH Level, Serum paraprotein detection and screening for a CFHR5 mutation. Of the physicians who complete the first detailed section of the survey, 97% reported ordering C3 Levels, 93% had ordered C4 Levels, 69% had ordered CFH Levels and 76% had ordered C3 Nephritic Factor testing. For the self-identified experts, there were five tests seen as having "High Utility in C3G." Those tests were C3 Level (67%), C4 Level (67%), C3 Nephritic Factor (67%), CFH Antibody (67%) and Genetic Sequencing (83%).

Conclusions: The clinical value of genetic sequencing (CFH, CFI, CD46, C3, CFB, DGKE, CFHR5), C3 Nephritic Factor and CFH antibody testing appears greater than the consensus report indicated. The importance of serum paraprotein detection (Serum Protein Electrophoresis, or SPEP) and the CFHR5 mutation screen may need to be further demonstrated to the field. Additionally, in a search for performing laboratories, we could not find a test which explicitly targeted the CFHR5 duplication referenced in the consensus report and so physician may not actually be screening for that specific mutation.

Attitudes towards Biosample Collection and Genetic Testing in a Racially Diverse CKD Population in Cleveland, OH Jessica N. Cooke Bailey,[2] Dana C. Crawford,[1] Julie A. Pencak,[3] Marleen Schachere,[1] William S. Bush,[1] John R. Sedor,[3] John F. O'Toole.[1] *[1]Case Western Reserve University, Cleveland, OH; [2]Case Western Reserve University, Cleveland, OH; [3]MetroHealth Medical Center, Cleveland, OH.*

Background: The NIH All of Us Research Program (AURP) is an ambitious national effort to longitudinally collect health data and biospecimens from a million Americans for storage, processing, and analysis in a government-funded data repository. Previous studies have suggested minority populations would be reluctant to share personal data and samples with the Federal government. We tested this premise in a population of chronic kidney disease (CKD) patients in Cleveland, OH.

Methods: Patients in a CKD clinic were approached prior to standard of care visit, asked to complete a structured 5 question bioethics and IRB-approved survey, and to provide blood sample for future genetic analysis.

Results: Most (86%) participants in the genetic study took the survey; 50% African American, 54% female, average age 61.5. Responses from 111 individuals indicate the majority would participate in the AURP and were willing to send biosamples to a national repository and share de-identified data, but <50% of respondents were willing to install a phone app to track personal data. Most wanted results returned and 96% of those who did wanted personal (health or genetic) data returned; 41% wanted *at least* summary data about the PMI-CP cohort, 4% *only* summary data about the overall group, 76% *at least* personal health data, and 4% *only* personal health data. Genetic data was priority; 89% wanted *at least* personal genetic data while 19% wanted *only* personal genetic data. 10% did not want any results returned. We found no significant difference between responses when comparing African American and White individuals.

Conclusions: Attitudes of CKD patients in a diverse health care environment towards the AURP are varied but, in contrast to published data, did not differ across self-reported race (African Americans and Whites) in this sample. Willingness to participate in some aspect of a AURP-like project was high. Of those agreeing to the survey, almost all wanted return of genetic results. Given this demand, efficient processes should be developed to provide subjects with appropriate education and context for results return. Other chronic disease populations and healthy subjects need to be studied to determine if health status, race or ethnicity modifies willingness to join the AURP.

SA-PO628

Renal Biopsy Findings Precede Clinical Evidence of Renal Disease in Female Patients with Fabry Disease Luiz A. Moura,[3] Maria Eugenia F. Canziani,[2] Hugo Abensur,[6] Valeria Veloso,[7] Simone M. Lima,[8] Marlene A. Reis,[9] Nayze L. Aldeman,[1] David G. Warnock,[4] Agnes B. Fogo.[5] *[1]FEDERAL UNIVERSITY OF PIAUI, TERESINA, Brazil; [2]Federal University of Sao Paulo, Sao Paulo, Brazil; [3]Hospital do Rim e Hipertensao, Sao Paulo, Brazil; [4]UAB, Birmingham, AL; [5]Vanderbilt University Medical Center, Nashville, TN; [6]Universidade de Sao Paulo, Sao Paulo, Brazil; [7]universidade Federal de Goias, Goiania, Brazil; [8]Medical Affairs, Sanofi Genzyme, São Paulo, Brazil; [9]Federal University of Triangulo Mineiro - UFTM, Uberaba, Brazil.*

Background: Fabry nephropathy results from mutations in the GLA gene causing a deficiency in alpha-galactosidase and the accumulation of glycosphingolipids in kidney cells, proteinuria and progressive loss of kidney function. The aim of this study was to describe renal biopsy findings in a Brazilian cohort of Fabry patients according to the ISGFN Fabry renal pathology scoring system and correlate these findings to clinical and laboratory data.

Methods: Kidney biopsies, indicated based upon a family screening program, were analyzed by light microscopy from paraffin embedded sections stained by PAS and semi-thin sections from plastic embedded sections stained by toluidine blue. Clinical data were retrieved from patient medical records.

Results: A total of 27 (14 male and 13 female) kidney biopsies from Fabry patients were analyzed. None of the patients had previously initiated enzyme replacement therapy. Males and females were the same age (34.7±10.8 vs. 36.8±18.4 yo) and predominantly in CKD stage 1 (59%) and 2 (22%). Proteinuria was significantly more pronounced in males compared to females ($p<0.05$). Renal biopsies in female patients showed histological alterations, particularly podocyte inclusions, even with proteinuria less than 200mg/24h and GFR greater than 60 ml/min/1.73 m2. There was no difference males vs females in vacuolization or inclusions in podocytes. More women had biopsies without glomerular sclerosis ($p<0.05$) while men had 5 times more scarring than age-matched women. Males had significantly more interstitial fibrosis than females (26.1±30.9% vs. 5.0±2.89; $p=0.007$). Interstitial fibrosis correlated with eGFR ($p<0.001$) in males but not in females ($p=0.501$). Interstitial inflammation was present in 93% of biopsies from males vs. 23% of females ($p<0.001$).

Conclusions: Males with Fabry disease, even in early stage of CKD, showed substantially more interstitial fibrosis and inflammation than females. Females had better preserved renal function than males, but still histological lesions, mainly podocyte inclusions, even though renal function was nearly normal. Renal histologic findings may be important factors to be considered when making therapeutic decisions for patients with Fabry disease.

Fabry Disease Prevalence in Kidney Transplant Patients: A Multicenter Study S. F. Yalin,[8] N Eren,[15] A. Sinangil,[14] A. Ucar,[9] V. T. Yilmaz,[2] O Can,[17] A Gurkan,[5] D TAYMEZ,[10] S. Ecder,[12] S. Gulcicek,[6] M. Mese,[11] K. Turkmen,[3] N. Arik,[1] Z Bicik,[7] M. B. Ogutmen,[16] H. Kocak,[4] Y. Caliskan,[8] T. Ecder,[13] N. Seyahi.[8] *[1]Ondokuz Mayis Univ., Samsun, Turkey; [2]Akdeniz Univ., Antalya, Turkey; [3]Necmettin Erbakan Univ., Konya, Turkey; [4]Akdeniz Univ., Antalya, Turkey; [5]Medicana C. Hosp., Istanbul, Turkey; [6]Istanbul T.R.Hosp., Istanbul, Turkey; [7]Kartal T.R.Hosp., Istanbul, Turkey; [8]Istanbul Univ., Istanbul, Turkey; [9]Istanbul Univ., Istanbul, Turkey; [10]Kocaeli S. Hosp., Kocaeli, Turkey; [11]Kartal T.R.Hosp., Istanbul, Turkey; [12]Istanbul Medeniyet Univ., Istanbul, Turkey; [13]Istanbul Bilim Univ., Istanbul, Turkey; [14]Istanbul Bilim Univ., Istanbul, Turkey; [15]Kocaeli Univ., Kocaeli, Turkey; [16]Haydarpasa Numune Hosp., Istanbul, Turkey; [17]Haydarpasa Numune Hosp., Istanbul, Turkey.*

Background: Higher prevalence of Fabry disease was reported in specific patient populations. To the best of knowledge, a formal prevalence study was not conducted in kidney transplant (TX) recipients. We aimed to investigate the prevalence of Fabry disease in transplant recipients.

Methods: We performed a multicenter cross-sectional study in transplant centers. We also screened dialysis (D) patients to have comparative data. All adult patients were screened regardless of primary disease. Blood was collected for the measurement of alpha-galactosidase enzyme activity in males and for the screening of genetic mutations in females. Additionally, a genetic screening was performed in males with low alpha-galactosidase enzyme activity.

Results: We screened 2206 TX and 1442 D patients for a total of 3648 cases (mean age 48,9±15,7; 63,1%male). Data regarding study population are shown in Table 1. In the whole population, a total of 12 unique mutation were detected in 23 patients (0,63%) (15 with TX, 8 with D).

Conclusions: Our results have important implication regarding TX activity. First, in countries where living donation is common, donors are generally relatives of the patients. Therefore in those cases, screening for the genetic diseases that can lead to kidney failure is important. Second, recurrence can be prevented with timely initiation of enzyme replacement therapy and patients might have better survival.

	Tx	Dialysis	P

Fabry's Disease within Dialysis Patients in Madeira Island: An Unexpected Surprise Maria N. Pestana, José M. Durães, Ana F. Gomes da silva, Miguel Goncalves, Pedro M. Vieira, Luís Resende, Jose N. Guimaraes Rosa, José Teixeira, Gil Silva. *Nephrology, Hospital Central do Funchal, Funchal, Portugal.*

Background: Fabry's Anderson disease (FAD) is a rare disorder that is highly undiagnosed worldwide. This entity is caused by alpha-galactosidase A gene (GLA) mutations. FAD, being a rare cause of end-stage renal disease (ESRD), accounts for less than 0,02% of all causes. The prevalence of FAD in Portugal is expected to be 1 in 833,000. Considering Madeira Island's (MI) population of about 250.000, one would not ponder more than one case, but little is known about FAD. Nevertheless, preliminary studies taking course point out to an increased genetic pool.

Methods: Screening of FAD is being performed among dialysis patients in MI. Alpha galactosidase A (AGAL) activity is obtained by a blood spot test. Male patients with decreased AGAL activity are tested for genetic mutations. Female patients are tested for genetic mutations regardless of AGAL activity. The diagnosis is confirmed by the presence of the mutations in the GLA gene. These patients also have lyso-Gb3 measurements. The pathogenicity is determined according to Annual Clinical Meeting Genetics (ACMG).

Results: Among 72 patients tested, we found 4 different mutations in 4 different families, all with distinctive pathogenicity. Following studies in those families revealed 10 additional cases and we are still testing other members. Two of these families have

a previously described pathogenic mutation, c.937G>T (pAsp313Tyr) in family 1 with 2 affected females and c.870G>C (pMet290Ile) in family 2 with 1 affected male and 5 affected females. Family 3 has a c.352C>T (pArg118Cys) mutation labelled as pathogenic although with conflicting reports in several studies. Curiously, we discovered a novel mutation in family 4 never reported before, referring to exon 4 of GLA gene, c.580A>G (p.Thr194Ala). Further evaluations of clinical findings suggest this mutation to be pathogenic.

Conclusions: Testing in dialysis patients and other members of identified families in MI will probably result in higher prevalence of FAD. These results are clearly above what would be expected from published previous studies. The reasons are unknown and further prompt investigation is required. Additional evaluation of affected patients will help understand the pathogenic implications.

SA-PO631

A Potential Novel Mutation of CYP24A1 Leading to Hypercalcemia and Hypercalciuria Pace Romney,[3] Robert H. Yenchek,[1] Josephine Abraham.[2] *[1]Salt Lake City, UT; [2]University of Utah, Holladay, UT; [3]University of Utah Medical Center, Salt Lake City, UT.*

Background: Mutations of CYP24A1 can lead to a deficiency of vitamin D 24-hydroxylase and can lead to hypercalcemia due to dysregulation of vitamin D 1,25-OH. New mutations are continuing to be discovered.

Methods: A 29 year old man with history of prior nephrolithiasis sustained a traumatic pelvic fracture and he was incidentally discovered to have CT findings consistent with severe bilateral medullary nephrocalcinosis, hypercalcemia, and elevated creatinine. Prior to the trauma, the patient was well and had no complaints. He had 24 hour urine collections done and was found to have hypercacliuria. Parathyroid hormone was low, vitamin D 25-OH and vitamin D 1,25-OH levels were both within normal limits. Given his long history of nephrocalcinosis and nephrolithiasis at a young age, a genetic mutation of CYP24A1 was suspected and so he was started on empiric low dose of fluconazole to control his hypercalcemia. He subsequently underwent genetic sequencing for nephrocalcinosis. The results of the genetic test were positive for three mutations; heterozygous for a c.62del (p.Pro21Argfs*8) in CYP24A1, homozygous for c.1219T>A (p.Tyr407Asn) in CYP24A1, and heterozygous for c.374C>G (p.Thr125Arg) in SLC2A9. The heterozygous mutation for CYP24A1 is reported as a recessive mutation for idiopathic infantile hypercalcemia. The heterozygous mutation of SLC2A9 was felt not to fit his clinical picture. The homozygous mutation of CYP24A1 has not been previously reported in literature and modeling predicted this mutation to have probable deleterious effects. Since starting fluconazole, the patient's calcium level has normalized.

Results:

Conclusions: Idiopathic hypercalcemia is often caused by genetic mutations of CYP24A1 which encodes for the enzyme 24-hydroxylase. This enzyme promotes the conversion of 25-OHD to 24,25-(OH)2D instead of 1,25-(OH)2D and also promotes the conversion of 1,25-$(OH)_2$D to 1. With a deficiency of this enzyme, various phenotypes of hypercalcemia and nephrocalcinosis have been described. This patient has been found to have a newly discovered mutation of the CYP24A1 gene which is suspected to be causing hypercalcemia and nephrocalcinosis.

Undiagnosed Genomic Disorders in Adult with CKD Miguel Verbitsky,[1] Priya Krithivasan,[1] Maddalena Marasa,[1] Junying Zhang,[1] Yifu Li,[1] Wei Yang,[2] Simone Sanna-Cherchi,[1] Krzysztof Kiryluk,[1] Harold I. Feldman,[2] Ali G. Gharavi.[1] *[1]Columbia University, New York, NY; [2]University of Pennsylvania, Philadelphia, PA.*

Background: Genomic Disorders (GDs) are caused by pathogenic deletions or duplications of large genomic regions of the genome. GDs are associated with many multiorgan developmental disorders and are enriched in children with chronic kidney disease (CKD), associating with poorer neurocognitive scores.

Methods: We studied the prevalence of GDs in adults with all-cause CKD enrolled in the Chronic Renal Insufficiency Cohort (CRIC, N= 3,375) and in the Columbia University CKD cohort (CU-CKD, N= 1,146) and compared them to 21,498 population controls. All samples were genotyped on Illumina microarrays and screened for deletions and duplications that are diagnostic of 131 known GDs.

Results: We detected GDs in 58/4,521 (1.3%) renal patients compared to 134/21,498 (0.6%) population controls (OR = 2.1, p = 1.3 x 10^{-5}). Known GDs in the CKD cohorts included 1q21.1 and 4p16.3 deletions and the 15q13.3, 16p13.11, 17p12, 17q12, 22q11.2 deletions/duplications. These GDs were all undiagnosed in the CU-CKD cohort, while diagnosis data were not available in CRIC. Analysis of available baseline clinical data in CRIC participants demonstrated that GDs are associated with significantly lower serum Mg (p = $7x10^{-4}$) and lower educational achievement (p = $8x10^{-3}$). We also detected known phenotypic associations for specific syndromes. For example, the 17q12 deletion/duplication syndrome (renal cyst and diabetes syndrome) was detected in 9 CRIC participants and was associated with diabetes (8/9 carriers) and insulin therapy (7/9 carriers) despite normal BMI, as well as hypomagnesemia (7/9 carriers).

Conclusions: GDs are undiagnosed and significantly enriched in adults with CKD, providing a molecular explanation for poorer neurocognition and specific metabolic defects in mutation carriers. Systematic detection of GDs can enable a precise genetic diagnosis and reconcile seemingly disparate clinical findings in patients. Risk stratification with GDs can also remove confounders in ongoing clinical studies, offering an opportunity to better explore causal relationships between CKD and outcomes.

Plasma Biomarkers and Renal Outcome in African Americans with High-Risk APOL1 Variants and Preserved Renal Function Girish N. Nadkarni,[1] Kinsuk Chauhan,[1] Divya A. Verghese,[1] Chirag R. Parikh,[2] Ron Do,[1] Carol Horowitz,[1] Erwin P. Bottinger,[1] Steven G. Coca.[1] *[1]Icahn School of Medicine at Mount Sinai, New York, NY; [2]Yale University and VAMC, New Haven, CT.*

Background: Variants in Apolipoprotein L1 (*APOL1*) gene are associated with end stage renal disease (ESRD) in African Americans (AAs). However, risk stratification in AA's with high risk *APOL1* genotype (G1/G1; G2/G2 or G1/G2) is poor. We assessed the association between plasma biomarkers and renal outcomes in AAs with high-risk *APOL1* genotype.

Methods: We genotyped AA Bio*Me* Biobank participants for high-risk *APOL1* genotype. We measured soluble tumor necrosis factor receptor 1/2 (sTNFR1/2) and kidney injury molecule-1 (KIM1) in plasma specimens *via* MesoScale Discovery multiplex assay and determined their association with a composite renal outcome of ESRD or 40% sustained decline in eGFR. We assessed improvement in area under curve (AUC) with addition of biomarkers from a baseline model using kidney failure risk equation (KFRE) with age, sex and eGFR.

Results: Among 498 *APOL1* high-risk participants, median age was 56 years, 68% were female and baseline eGFR was 83 ml/min. 80 (16%) experienced the composite renal outcome over median of 6.9 years. After adjusting for age, sex and baseline eGFR, sTNFR1, sTNFR2, and KIM1 were independently associated with the renal outcome when expressed continuously or in tertiles, and in sensitivity analyses adjusting for baseline proteinuria in those with available measurements (n=209). (**Table**) AUC improved from 0.57 with the KFRE model to 0.74 with a biomarker-enhanced model. The event rate for participants with all 3 biomarkers in the top tertile was 40%, compared to 7% and 19% with 0 or 1 biomarker elevated, respectively (p < 0.001).

Conclusions: sTNFR1/2 and KIM1 are independently associated with renal outcome in AA's with high-risk *APOL1* genotype and improve risk discrimination. These markers can be valuable for risk stratification in AA's with *APOL1* high risk.

African and European Ancestry Proportions Are Associated with eGFR Measures in Over 270,000 Participants from the Million Veterans Program (MVP) Digna R. Velez edwards,[4] Ayush Giri,[4] Eric S. Torstenson,[4] Jacklyn N. Hellwege,[4] Csaba P. Kovesdy,[3] Christopher J. O'Donnell,[1] Todd L. Edwards,[2] Adriana Hung.[4,5] *[1]Boston Veterans Administration, Boston, MA; [2]Vanderbilt University Medical Center, Nashville, TN; [3]University of Tennessee Health Science Center, Memphis, TN; [4]Vanderbilt University, Nashville, TN; [5]VA TVHS, Nashville, TN. Group/Team: On behalf of VA Million Veteran Program.*

Background: Current methods estimate glomerular filtration rate (eGFR) using a creatinine based equation. Because African Americans have higher muscle mass and creatinine generation, current eGFR equations incorporate a dichotomous indicator for race (black/not black). It is unclear if this measure appropriately accounts for eGFR variability due to genetic ancestry.

Methods: To determine whether ancestry proportions influence eGFR, we evaluated associations between genetically inferred proportions of ancestry relative to 5 reference populations (GBR, PEL, YRI, CHB, and LWK) and eGFR in 56,237 self-reported blacks and 216,528 self-reported whites from the MVP. Traits were modeled using linear regression against each ancestry proportion variable adjusted for important covariates to report estimates per 10% increase for a given inferred ancestry percentage in whites and blacks separately.

Results: In self-reported blacks, every 10% increase in GBR ancestry was associated with 1.1 unit increase in eGFR levels (p-value = $5x10^{-76}$), while 10% increase in Yoruban ancestry was inversely associated with eGFR (beta: -1.1; p-value = $1x10^{-88}$). The virtually identical magnitude of effect estimates is consistent with the known two-way European/African admixture observed in blacks from the United States. Interestingly, despite the small contribution of Native American (estimated using Peruvian (PEL)) admixture to this group, PEL ancestry was positively associated with eGFR (beta: 2.16; p-value = $1.2x10^{-9}$); with the largest effect estimates observed in non-diabetic blacks. Neither CHB nor LWK ancestry was associated with eGFR in blacks (p-values >0.05). In Whites, PEL ancestry was positively associated with eGFR (beta = 0.63; p-value = $2.5x10^{-21}$), while both African ancestry proportions were inversely associated (YRI beta = -0.86, p-value = $8x10^{-29}$; LWK beta = -3.10, p-value = $8x10^{-39}$).

Conclusions: Overall, Yoruban ancestry strongly associates with decreased eGFR in both whites and blacks, after accounting for dichotomous race in the eGFR equation. Since

eGFR is a strong predictor of end stage renal disease, our results suggest incorporating ancestry proportion information into eGFR calculations may provide a better predictor for future disease risk.

Sparsentan Pharmacokinetics and Pharmacodynamics as the Basis of Dose Selection for Primary Focal Segmental Glomerular Sclerosis (FSGS) Michael Karol, Xin-Ru Pan-Zhou, Sarah E. Tuller, Radko Komers. *Retrophin, Inc., Cambridge, MA.*

Background: Sparsentan's dual action is being studied for potential use in the treatment of primary FSGS. This analysis was performed to assess the dose/pharmacokinetic (PK)/pharmacodynamic (PD) relationship of sparsentan in FSGS patients enrolled in the DUET trial, to guide future dose selection.

Methods: The DUET trial determined the sparsentan-induced changes in urine protein/creatinine ratio (Up/C), (baseline to Week 8) in patients assigned to 200 (n=13), 400 (n=21), or 800 (n=30) mg/day. The relationship between sparsentan dose or area under the curve (AUC), and change in Up/C was assessed. PK/PD analyses were based on actual doses received, accounting for dose reductions resulting in PK/PD sample sizes of 17, 23, and 22 for 200, 400, and 800 mg/day, respectively.

Results: Due to small sample sizes, antiproteinuric effects across sparsentan doses were not statistically distinguishable; however, likelihood of a patient having drug exposures resulting in a decrease in Up/C was greater for the 800 mg dose. For the three dose groups, the percentages of patients with a decrease in Up/C were 76%, 74%, and 91%, respectively, as shown in the Figure. Of the 30 patients assigned to the 800 mg dose, 18% experienced hypotension. In general, sparsentan was safe and well tolerated with no clinically significant changes in vital signs or major clinically significant abnormalities in laboratory tests.

Conclusions: Initial daily dosing at 400 mg, followed by escalation to 800 mg for those that tolerate 400 mg, increases the likelihood of antiproteinuric effect while maximizing safety. Both the therapeutic effect vs dose or AUC and AUC distribution analyses each led to the same conclusion.

Exploring population Pharmacokinetics of Vancomycin While Using Different Anticoagulant Modalities during Continuous Venovenous Haemodiafiltration (CVVHDF) Hannah M. O'Keeffe,[3] Reema M. Munshi,[2] Mary Coyle,[1] Evelyn Deasy,[1] Maria B. Donnelly,[1] Gerard J. Fitzpatrick,[1] Peter J. Lavin,[3] Deirdre M. D'Arcy.[2] *[1]Tallaght Hospital, Dublin, Ireland; [2]Trinity College Dublin, Dublin, Ireland; [3]Trinity Health Kidney Centre, Tallaght Hospital, Dublin, Ireland.*

Background: Uncertainty remains concerning pharmacokinetics (PK) of antimicrobials in critically ill patients due to the scarcity of data and the heterogeneity of the patient cohort. Our aim was to describe the population PK estimates and the influence of patient covariates and anticoagulant modality on PK of vancomycin, following intermittent infusion in intensive care patients receiving CVVHDF.

Methods: Vancomycin dose and concentration data (peak, trough) were collected retrospectively from the electronic health records of 31 critically ill patients (n = 280 levels). A one-compartment model was used to describe the vancomycin concentration-time profiles using Pmetrics software. For brevity, only R^2 values are presented here, from observed vs. population predicted concentration plots. Dosing intervals were classified according to the dialysis modality for the majority of the dosing interval i.e. 1) dialysis with citrate anticoagulation (60 levels) 2) dialysis with non-citrate anticoagulation (120 levels) or 3) not on dialysis (44 levels). Continuous covariates were: cumulative fluid balance, effluent flow rate, blood flow rate, body weight, albumin concentration and age.

Results: An acceptable base model was produced using the Elimination Rate Constant (Ke) and Volume of Distribution (V) (R 2 0.51). The mean ± SD of vancomycin PK estimates were: V 80.65 ± 22.65 L; Ke 0.03 ± 0.01 h -1. The best population predicted models included cumulative fluid balance and albumin concentration as covariates (R^2 = 0.59 for both). The concentrations in the citrate group correlated best with the population predicted models as compared to the non-citrate dialysis and not on dialysis cohorts, with R^2 of 0.86, 0.58 and 0.28, respectively.

Conclusions: Cumulative fluid balance and albumin concentration data along with citrate anticoagulation status are suggested as covariates for further analysis with richer data, to optimise covariate PK modelling of vancomycin in ICU patients on CVVHDF, and support dose optimisation. Interestingly, the less variable PK estimates in the citrate group model suggest that the anticoagulant modality used might be associated with observed PK variability

Pharmacokinetics and Intra-Renal Accumulation of the Drug Delivery Biopolymer Elastin-Like Polypeptide Is Dependent on its Molecular Weight Marija Kuna,[1] Jeremy W. Mcgowan,[2] Fakhri Mahdi,[2] Gene L. Bidwell.[2,1] *[1]Biochemistry, University of Mississippi Medical Center, Jackson, MS; [2]Neurology, University of Mississippi Medical Center, Jackson, MS.*

Background: The number of patients suffering from chronic kidney disease (CKD) and end-stage renal disease (ESRD) is rising, highlighting the need to identify novel therapies to slow down, stop or possibly reverse progression of the disease. Our lab focuses on the development of a drug delivery system based on a bioengineered protein polymer called elastin-like polypeptide (ELP) and on development of ELP-fusion proteins for renal therapy. Considering our interest in the development of ELP for kidney-targeted drug delivery, the aim of this study is to investigate how the physical characteristics of ELP, particularly its molecular weight (MW), affect its plasma clearance, biodistribution, kidney accumulation, and intra-renal distribution.

Methods: ELP proteins were synthesized, purified and characterized by SDS-PAGE, DLS and turbidity assays. Fluorescently labeled ELPs were used to assess *in vitro* degradation and in chronic and acute mice studies to define the pharmacokinetics and biodistribution.

Results: Our data show that increasing the ELP MW from 25 kDa to 86 kDa resulted in an increase of the hydrodynamic radius from 4 to almost 7 nm. Degradation studies demonstrated that the proteins are stable for 10 days with negligible degradation at 4°C in both plasma and PBS. The proteins were also stable at 37°C in PBS, but showed time-dependent degradation in plasma at 37°C. After 24 hours, 12-15% degradation was present, and these levels increased to 50% for ELPb-63 (25 kDa) and 24% for ELPb-191 (74 kDa) over the 10-day experiment. However, these degradation rates were slow compared to the plasma clearance rate. ELP plasma half-life increased from 0.84 to 7.05 h with an increase in MW from 25 to 74 kDa. As expected, ELPs accumulated predominantly in the kidneys, with ELPb-63 levels significantly different from the larger proteins. ELPb-63 accumulated mostly in the cortex, while increasing MW resulted in more ELP deposition in the medulla.

Conclusions:

Funding: Other NIH Support - NIH NHLBI Grant R01HL121527 (GLB)

SA-PO639

Safety, Tolerability, and Pharmacokinetics of the Selective Mineralocorticoid Receptor Antagonist KBP-5074 in Hemodialysis and Non-Hemodialysis Patients with Severe CKD Jeffrey J. Connaire,[1,2] Mark A. Bush,[5,2] Vincent Benn,[3] Y. Fred Yang,[2] Jon L. Ruckle,[4,2] Xiaojuan Tan.[2] *[1]Davita Clinical Research, Minneapolis, MN; [2]KBP Biosciences Co., Ltd., Princeton, NJ; [3]KBP Biosciences USA Inc, Princeton, NJ; [4]Pacific Pharma Group, LLC, Tacoma, WA; [5]Wingate University School of Pharmacy, Wingate, NC.*

Background: Background: Chronic kidney disease (CKD) is a leading cause of morbidity/mortality in the US. Mineralocorticoid receptor antagonism (MRA) has been shown to benefit in heart failure/hypertension but not in advanced CKD patients due to safety concerns, e.g., hyperkalemia. KBP-5074 is a novel, non-steroidal, highly-selective MRA being developed for patients with hypertension and advanced CKD.

Methods: Methods: This was a Phase 1, open-label study to evaluate the safety, tolerability, and pharmacokinetics (PK) of KBP-5074 following single oral administration to subjects with severe CKD, comparing Stage 5 subjects receiving hemodialysis (HD) with Stage 4 subjects not receiving hemodialysis (non-HD). Eleven subjects (6 HD and 5 non-HD) were enrolled and received a single 0.5 mg dose of KBP-5074. HD subjects were dosed immediately following a dialysis session. All subjects were followed for 13 days post-dose. In HD subjects, PK samples were collected before, during, and after the first HD session.

Results: Results: The mean age of the study subjects was 53.5 years; 54.5% were male. KBP-5074 was well tolerated: 6 TEAEs (mostly mild) were reported in 4/11 subjects. Plasma exposure of KBP-5074 in HD subjects was statistically significantly lower than in non-HD subjects: C_{max} (7.34 ng/ml vs 10.6 ng/ml)/AUC (669 hr*ng/ml

vs. 1310 hr*ng/ml), and $T_{1/2}$ was shorter in HD subjects (64.2 hrs vs. 87.9 hrs). HD was associated with minimal alterations in KBP-5074 plasma concentrations and outflow dialysate concentrations of KBP-5074 were undetectable, indicating negligible clearance of KBP-5074 via HD. Plasma aldosterone and serum potassium values were generally comparable between HD and non-HD subjects.

Conclusions: Conclusions: KBP-5074 at a dose of 0.5 mg was safe and well tolerated in all study subjects. Plasma exposures of KBP-5074 in HD subjects were significantly lower than in non-HD subjects. Hemodialysis had a negligible effect on plasma concentrations of KBP-5074. These data support further evaluation of KBP-5074 in patients with advanced CKD.

Funding: Commercial Support - KBP Biosciences

SA-PO640

The Effect of Tacrolimus Exposure on CYP3A5 and P-gp Expression in a Model of Human Proximal Tubule Cells for Studying the Role of Pharmacogenetic Variation in Renal Drug Metabolism and Toxicity

Noel Knops,[2] Yasaman Ramazani,[1] Elena N. Levtchenko,[2] Dirk R. Kuypers.[2] *[1]KU Leuven, Leuven, Belgium; [2]University Hospitals Leuven, Leuven, Belgium.*

Background: Tacrolimus (Tac) constitutes the mainstay of immunosuppressive therapy and is metabolized through the interplay between CYP3A enzymes and the P-gp transporter (*ABCB1*). Clinical and fundamental studies have demonstrated the importance of genetic variation for the expression of corresponding proteins in relation to drug metabolism and toxicity. The effect of Tac on their expression in renal cells with a variable pharmacogenetic background common in the general population is unknown.

Methods: Human immortalized proximal tubule cells (PTC) with 4 combinations of *CYP3A5(rs776746)* and *ABCB1(rs1045642)* were selected. Tac exposure during experiments was based on WST-1 assay and *in vivo* data on tissue levels in allograft recipients, i.e. vehicle, 50 ng/ml and 300 ng/ml for 24 and 72hrs. Quantitative and functional expression was assessed by RT-PCR, WB, midazolam (MDZ) hydroxylation (for CYP3A5) and calcein efflux (P-gp).

Results: Only very high Tac concentrations (45,000ng/ml) resulted in cell death. Baseline *mRNA*, protein and functional expression of CYP3A5 was higher in ciPTC with the **1* versus **3/*3 allele.* Increasing Tac conc. within the range of tissue levels had no effect on CYP3A5 mRNA or protein expression but resulted in decreasing 1'OH MDZ hydroxylation ($p<0.001$). Quantitative expression of ABCB1mRNA and Pgp was similar between variants of *ABCB1 3435C>T,* but calcein-AM efflux was higher in *TT* vs. *CC/CT* (delta fluorescence: 45.3% vs. 27.1%; $p= 0.001$). Tac conc. did not affect quantitative ABCB1/P-gp expression but resulted in decreasing calcein efflux ($p<0.001$) in both variants.

Conclusions: Tacrolimus exposure associated with in vivo tissue levels are not lethal and have no direct effect on the regulation of gene/protein expression for CYP3A5 and P-gp in PTC with a variable pharmacogenetic background. However, these concentrations do result in decreasing functional expression of both actors involved in Tac metabolism on top of the differences associated with the genetic background. The potential nephrotoxic effect ascribed to Tac might therefore be the result of basal variation in functional expression due to underlying genotype for *CYP3A5* or *ABCB1,* and/or in combination with the inhibitory effect of tacrolimus on the enzyme and pump function.

SA-PO641

Age Influences on Tacrolimus Pharmacokinetics Post-Transplant

Kathleen M. Tornatore,[1,2] Kris Attwood,[4] Rocco C. Venuto.[3,5] *[1]Pharmacy Practice, School of Pharmacy and Pharmaceutical Sciences; Erie County Medical Center, Buffalo, NY; [2]SUNY; NYS Center for Bioinformatics and Life Sciences, Buffalo, NY; [3]Erie County Medical Center, Buffalo, NY; [4]Biostatistics, School of Public Health, Buffalo, NY; [5]Medicine, School of Medicine; University at Buffalo, Buffalo, NY.*

Background: Minimal data is available describing the influence of age on tacrolimus (TAC) pharmacokinetics (PK) in African American (AA) and Caucasian (C) renal transplant recipients (RTR) in spite of increased renal transplantation in the elderly. This sub-study investigated the impact of age on TAC PK in stable AA and C RTR.

Methods: The 12-hour PK study of TAC was investigated in 35 AA and 32 C RTR receiving enteric coated MPA and tacrolimus. Cumulative adverse effects (CAE) were assessed including gastrointestinal, neurologic and aesthetic manifestations. Patents were categorized by age as follows: Young: >21 & ≤ 40 years; Middle Age: >40 &≤ 60 years and Elderly>60 years. Apparent clearance (CL), BMI normalized CL (CL/BMI), Area Under the Concentration-time curve 0-12h (AUC12), dose-normalized AUC12 (AUC*), 12 hour troughs (C-12h) and dose normalized C-12hr(C-12h/Dose) with CAE were determined and analyzed with univariate ANOVA.

Results: Table summarizes the results. All group means were within the therapeutic AUC12 guide of 120-200 mg.hr/ml for TAC. The elderly received the lowest TAC dose and achieved comparable, therapeutic C-12h troughs and AUC12 to other groups. The elderly had a higher dose normalized trough and AUC* with slower CL and more CAE compared to younger patients.

Conclusions: These findings suggest that TAC dosing regimens need be individualized based upon adult ages and time post transplant. Further investigations into age-related changes in TAC exposure and relation to clinical responses(i.e. adverse effects) remain important for safe and efficacious immunosuppression.

Antibiotics: A Novel Factor Associated with Tacrolimus Trough Variability in Kidney Transplantation

John R. Lee,[2] Yuanpu Zheng,[1] Michael P. Wagner,[1] Darshana Dadhania,[2] Thangamani Muthukumar,[2] Manikkam Suthanthiran.[2] *[1]New York Presbyterian Hospital, New York, NY; [2]Weill Cornell Medicine-, New York, NY.*

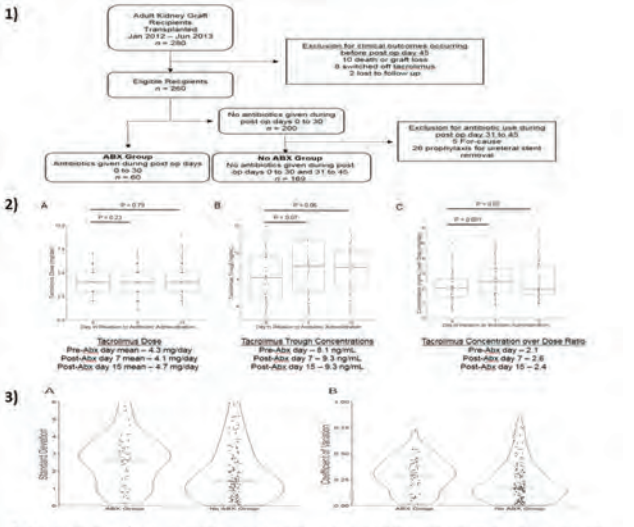
Background: We previously reported a relationship of the gut microbiota to tacrolimus dosing requirements. Based upon this data, we hypothesize that antibiotics, which are known to alter the gut microbiota, is associated with tacrolimus trough variability.

Methods: We performed a retrospective chart review of subjects who received a kidney transplantation at our institution from 2012 to 2013. We divided the population into subjects who received antibiotics during the first month of transplantation (Abx Group, N=60) and subjects who did not (No Abx Group, N=169) (Fig A). We evaluated whether antibiotics increase tacrolimus trough levels and tacrolimus trough level over dosing (C/D) in the Abx Group and whether antibiotics increase tacrolimus trough variability as measured by standard deviation (SD) and coefficient of variation (CV) between post op days 31 to 45.

Results: In the Abx Group, 48 subjects had a tacrolimus trough level measured prior to antibiotic administration and these subjects had increased tacrolimus trough levels and increased tacrolimus C/D, 7 and 15 days after antibiotic administration (Fig 2B, 2C). Subgroup analysis of type of antibiotics suggested increasing C/D after 7 days after antibiotic administration in penicillin type antibiotics and cephalosporin type antibiotics (P=0.08, 0.09, respectively). Tacrolimus trough variability as measured by SD and CV between post op days 31 to 45 was significantly different between the Abx Group and the No Abx Group (SD median 2.6 vs 1.6, P=0.03; CV median 0.29 vs. 0.18, P=0.02, Wilcoxon rank sum test) (Fig 3).

Conclusions: Our identification of antibiotics' association with tacrolimus trough variability highlights the need to measure tacrolimus trough levels after antibiotic administration.

Funding: Other NIH Support - NIAID K23 AI 124464



1) Cohort selection. **2)** Box and whisker plots with days after antibiotic administration on the x axis and tacrolimus dose (A), tacrolimus trough (B), and tacrolimus C/D (C) on the y axis. Tacrolimus trough and tacrolimus C/D increases after antibiotic administration (P values calculated using one-way anova with repeated measures using contrasts and are above each group comparison). **3)** Violin plots analyzing tacrolimus trough levels between post op day 31 to 45. On the x axis is the ABX Group and the No ABX Group and on the y axis is the standard deviation of tacrolimus trough levels for each subject (Left) and the coefficient of variation of tacrolimus trough levels for each subject (right). The line represents the median value in each group.

SA-PO643

Intrapatient Tacrolimus Variability Has Similar Outcomes on Kidney Allograft Function between UK Transplant Centers Ryan Ghita. *NHS Greater Glasgow and Clyde, Glasgow, United Kingdom. Group/Team: UK Transplant Audit Collaborative.*

Background: Tacrolimus based immunosuppression regimes are the mainstay of treatment for transplant patients in the United Kingdom. High intrapatient variability (IPV) of tacrolimus levels has been associated with poorer kidney allograft function. A retrospective study looked at the effects of high IPV on eGFR in five transplant centers across the UK (Glasgow, Oxford, King's London, Liverpool, Manchester).

Methods: Data was collected from patients who received a kidney transplant between 2009 and 2014 in one of the 5 UK centers. Tacrolimus trough levels were recorded at two time points - 6-12 months post transplant (T1) and most recent 12 months (T2). Exclusion criteria included patients that received dual-organ transplants or if death or graft loss occurred within two years of transplantation, or if their immunosuppression regimens included modified release tacrolimus. For each transplant center, patients that fell into the highest and lowest IPV quartiles were identified and their MDRD eGFR were compared using a Mann-Whitney U-test. The results are in table1.

Results: Three of the comparisons between the high and low variability groups had a U-value lower than the critical value suggesting a significant difference in MDRD eGFR. In all other groups the median eGFR was lower in the high IPV group however this was not found to be statistically significant.

Conclusions: The results suggest a correlation between high IPV and worse allograft function, as determined by eGFR, throughout the UK transplant centers. However the small patient cohort in each center limits analysis. Further analysis will be performed merging the data from all centers which to the best of our knowledge will be the largest study looking at IPV with over 1000 patients.

Table 1: eGFR comparison between patients with high and low tacrolimus variability in UK Transplant Centers

	Glasgow (n=168)	Oxford (n=284)	Liverpool (n=171)	Manchester (n=313)	King's London (n=134)
T1 MEDIAN (IQR) eGFR of low IPV patients	62 (49-77)	54 (45-64)	51.5 (38-57.3)	49 (38.5-61)	56 (48.3-73.3)
T1 MEDIAN (IQR) eGFR of high IPV patients	46 (34.3-58.6)	50 (35.5-58)	44 (36-52)	48.5 (39.3-59.3)	55 (43-67)
P – value	0.001	0.02	0.19	0.59	0.52

SA-PO644

Drug Dosing During AKI Michael E. Brier,[2] George Aronoff,[1] Adam E. Gaweda.[2] *[1]DaVita, Inc., Naples, FL; [2]University of Louisville, Louisville, KY.*

Background: When renal function is rapidly changing during acute kidney injury (AKI), determining the proper dosage for drugs that are renally eliminated becomes difficult. We tested the hypothesis that estimating the creatinine production rate (CPR) combined with measured serum creatinine (Scr) allows us to determine the level of renal function as the estimated glomerular filtration rate (eGFR) to guide in drug dosing.

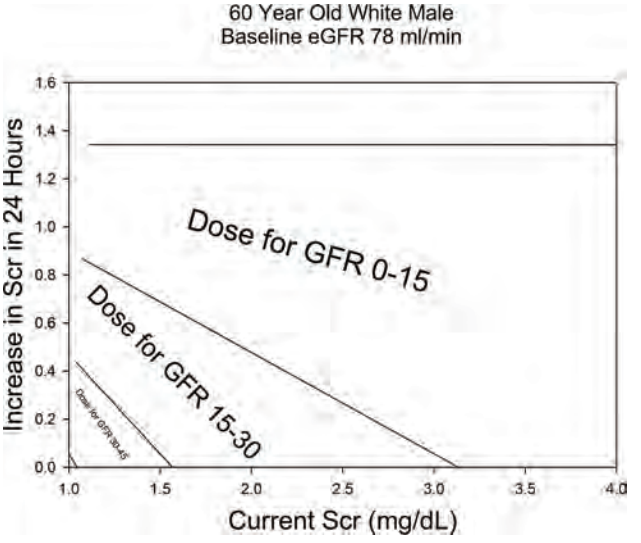
Methods: Baseline creatinine production was determined by rearrainging the CKD-EPI equation and solving for creatinine generation using the principle that at steady-state the rate of elimination = rate of production. We calculated creatinine production over a range of baseline serum creatinine concentrations for white males, white females, black males, and black females at different ages. Using the change in Scr in 24 hours we are able to determine the integrated eGFR. We then simulated the hourly change in Scr using the estimated CPR and actual GFR to determine delta Scr/24 hours and developed a graphical representation.

Results: The results are shown in the table for CPR (mg/hr) for a 60 year old white male. Dosing information for this patient is shown in the figure with recommendations to dose at a GFR of 0-15, 15-30, and 30-45. Maximum increase in Scr for this patient at no renal function is 1.34 mg/dL/day.

Conclusions: Complex processes occur during AKI that complicate drug dosing. However, estimation of renal function can still occur using routinely obtained Scr measurements that can help in determining drug dosage adjustments. CKD-EPI shows that CPR is decreased in the population as baseline Scr increases.

Creatinine Production Rate (mg/hr)

Baseline Scr	White/Male	White/Female	Black/Male	Black/Female
1.0	47	32	54	37
2.0	30	21	35	24
3.0	24	16	27	19
4.0	20	13	23	16
5.0	17	12	20	14



Example dosing nomogram.

Proteinuric Renal Disease Alters the Biodistribution of Antisense Oligonucleotides Allowing Reduction in Dose for Kidney Targets Anna Granqvist,[1] Lena William-Olsson,[1] Barbro Basta,[1] Thomas Bell,[3] Patrik Andersson,[2] Magnus Soderberg,[2] Mark J. Anderton,[2] Christine Ahlström.[1] *[1]Innovative Medicines & Early Development Cardiovascular & Metabolic Disease, AstraZeneca R&D, Gothenburg, Sweden; [2]Drug Safety & Metabolism, AstraZeneca R&D, Gothenburg, Sweden; [3]Ionis Pharmaceuticals, Carlsbad, CA.*

Background: An increasing number of oligonucleotide therapeutics are used in clinical trials today. Antisense oligonucleotides (ASOs) are predominantly taken up by the liver and kidneys, which makes them a desirable modality for the treatment of renal disease. However, there is a concern regarding potential clinical safety risks such as thrombocytopenia, injection site reactions and renal/liver toxicity at higher doses. The biodistribution of ASOs to different tissues is assisted by plasma protein binding that delays urinary excretion and it was therefore hypothesized that distribution of ASOs with phosphorothioate backbone is altered in proteinuric renal disease.

Methods: We investigated the tissue exposure and distribution of a phosphorothioate cEt gapmer ASO in the obese diabetic BTBR ob/ob mouse. This is a suitable model as it mimics key features of human diabetic nephropathy, including progressive proteinuria and glomerulopathy. Mice were subcutaneously administered weekly doses of 3, 10, 30 or 100 mg/kg ASO in saline and followed for 2-12 weeks.

Results: In all animals tissue exposure and significant knock down of the target gene in kidney was achieved (between 45-75% decreased expression, $p \leq 0.001$). In the diabetic BTBR ob/ob mice a shift in the distribution of ASO towards the kidney was observed in comparison to healthy mice, leading to a lower exposure in liver. Similar exposure and knock down in the kidney was achieved in the diseased animals with a 30 mg/kg dose compared with a 100 mg/kg dose in healthy animals. There were no nephrotoxic effects of the ASO treatment (determined by biomarker analysis and histology).

Conclusions: These results suggest that in a model of proteinuric renal disease similar level of kidney mRNA knockdown is observed at lower ASO dose levels compared to healthy mice. If such observations translate to patients with kidney disease, this may reduce the risk of toxicities in other organs and tissues.

SA-PO646

Targeted C4 Inhibition by Affinity Purified Immunoglobulins Elena Volokhina,[3] Thea J. Van der velden,[1] Marloes Michels,[4] Nicole Van De Kar,[2] Marcin Okroj,[5] Bert Van den heuvel.[4] *[1]Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands; [2]UMC St. Radboud Nymegen, Nijmegen, Netherlands; [3]Radboud university medical center, Nijmegen, Netherlands; [4]Radboudumc, Nijmegen, Netherlands; [5]Medical University Gdansk, Gdansk, Poland.*

Background: Immunoglobulins (Igs) can activate complement when bound to their antigens. Moreover, they may inhibit complement activation and in clinical practice intravenous Igs are widely used to treat immunodeficiencies as well as inflammatory conditions. Complement inhibitory properties of Igs are poorly understood, which limits their use for targeted complement modulation in renal disorders. In this study we describe immunoglobulin preparations with specific complement inhibiting properties.

Methods: Igs from healthy donors were purified using Protein L or Protein A/G affinity chromatography. Classical (CP) and alternative pathway (AP) activation was assessed using hemolytic assays. Activation of C1q, C4b, C3b and C5b-9 in CP was assessed by ELISA. Purified fractions were analyzed by SDS-PAGE and silver staining.

Results: Igs purified from serum using Protein L, but not Protein A/G inhibited CP in normal human serum (NHS) to below 10% of normal activity when added at 13 mg/mL. Igs from lepirudin, citrate and heparin plasma showed similar inhibiting results, while those isolated from EDTA plasma had no effect. None of the fractions had effect on AP. CP ELISA revealed normal deposition of C1q, and strongly decreased deposition of C4b, C3b and C5b-9. All fractions showed same band pattern in SDS-PAGE. All purified Igs retained ability to activate CP when heat-aggregated. Moreover, Igs isolated from serum spiked with 100 μg/mL eculizumab were still able to fully block AP when added to NHS.

Conclusions: Thus, Igs purified using Protein L chromatography block complement in NHS at the stage of C4. These findings have important therapeutic potential for the inhibition of classical complement pathway in the future in such conditions as antibody-mediated renal graft rejection, lupus nephritis and antiphospholipid syndrome.

SA-PO647

Effect of the Microbiota-Derived Uremic Toxin Indoxyl Sulfate on FMO Expression and TMAO Formation: A Pilot Study Alexander J. Prokopienko, Anand Joshi, Raman Venkataramanan, Thomas D. Nolin. *School of Pharmacy, Center for Clinical Pharmaceutical Sciences, University of Pittsburgh, Pittsburgh, PA.*

Background: Cardiovascular disease (CVD) is the leading cause of death in kidney disease. Microbiota-derived uremic toxins likely contribute to CVD progression and may be modifiable risk factors. The microbiota-derived uremic toxins indoxyl sulfate and trimethylamine-N-oxide (TMAO) are associated with poor CVD outcomes. Indoxyl sulfate activates the aryl hydrocarbon receptor (AhR) transcription factor, which partially regulates flavin-containing monooxygenase (FMO) expression. FMOs are an important class of hepatic enzymes that oxidize trimethylamine to TMAO. We hypothesize that indoxyl sulfate induces hepatic FMO expression and activity, thereby increasing TMAO formation. The aim of this pilot study was to assess the effect of indoxyl sulfate on the expression and activity of FMO.

Methods: Primary cultures of human hepatocytes (n=1 donor) were pre-treated with 0.1% dimethylsulfoxide (vehicle control), rifampin (induction control), PCB-77 (AhR agonist) and indoxyl sulfate (1, 25, 100 and 250 μM) for 72 hours. All treatments were run in duplicate. Hepatocytes were then incubated for 3 hours with trimethylamine and formation rate of TMAO was used as an indicator of hepatic FMO activity. TMAO was measured via LC-MS. Gene expression was determined by RT-qPCR using specific Taqman® probes and master mix. All data was analyzed using one-way ANOVA.

Results: FMO3 mRNA expression increased by 2.4-fold, 2.1-fold, 2.9-fold and 5.1-fold compared to vehicle control with indoxyl sulfate 1, 25, 100 and 250 μM, respectively ($p<0.0055$). CYP1A2 mRNA expression increased by 2.7-fold, 16-fold, 96-fold and 254-fold compared to vehicle control with indoxyl sulfate 1, 25, 100 and 250 μM, respectively ($p<0.0003$). AhR mRNA expression was not significantly changed compared to control. Indoxyl sulfate 1, 25, 100 and 250 μM increased TMAO formation by 1.2-fold, 1.6-fold, 1-fold, and 3-fold compared to vehicle control, respectively ($p<0.0049$).

Conclusions: These results suggest that indoxyl sulfate induces FMO3 mRNA expression and activity, leading to increased FMO-mediated TMAO formation. This novel metabolic interaction may contribute to dramatically increased systemic exposure of TMAO and CVD progression in kidney disease patients.

Genetics of Serum Urate Concentrations and Gout in a High-Risk Population, Patients with CKD Ulla T. Schultheiss,[4] Jiaojiao Jing,[9] Arif Ekici,[8] Thomas Sitter,[5] Kai-Uwe Eckardt,[7] Elke Schaeffner,[1] Yong Li,[3] Florian Kronenberg,[2] Anna Kottgen.[6] *[1]Charite, Berlin, Germany; [2]Innsbruck Medical University, Innsbruck, Austria; [3]University Hospital Freiburg, Freiburg, Germany; [4]University Hospital Freiburg, Freiburg, Germany; [5]Medizinische Klinik, Munich, Germany; [6]University Hospital Freiburg, Freiburg, Germany; [7]University of Erlangen-Nuremberg, Erlangen, Germany; [8]University of Erlangen-Nuremberg, Erlangen, Germany; [9]University of Freiburg, Freiburg, Germany.*

Background: Gout is the most common inflammatory arthritis in many countries with a strong genetic component. Individuals with chronic kidney disease (CKD) represent a high-risk population for gout. Genetic risk factors for gout and their interactions with clinical factors in CKD are understudied.

Methods: Genome-wide association studies of serum urate and gout were performed in 4941 CKD patients (1217 with gout) in the German Chronic Kidney Disease study. Effect sizes of 26 known serum urate-associated SNPs from population-based studies were examined. Interactions of urate-associated variants with serum urate-altering medications and clinical characteristics of gout were evaluated.

Results: Genome-wide significant associations ($p<5E-08$) with serum urate and gout were identified for the known loci *SLC2A9* and *ABCG2*, encoding urate transporters. Effects of 26 known SNPs were of similar magnitude in CKD patients and population-based studies (**Figure 1**). Gene-medication interactions implicated interactions (e.g. *ABCG2* rs2231142 and loop diuretics) but were not significant when accounting for multiple testing. Effects of *ABCG2* rs2231142 on serum urate were higher in those with lower eGFR, consistent with the transporters role in urate excretion. Associations with gout in specific joints were strongest for *SLC2A9* rs12498742 in elbows and wrists, and *ABCG2* rs2231142 in knees and ankle joints.

Conclusions: Known genetic variants in *SLC2A9* and *ABCG2* were associated with serum urate and gout in a CKD cohort with effect sizes similar to population-based studies. Studying pharmacogenomic interactions is challenging in the setting of polypharmacy in CKD. CKD patients are at high risk of gout due to reduced kidney function, diuretics intake and genetic predisposition.

Funding: Commercial Support - Astra Zeneca, Grünenthal, Private Foundation Support, Government Support - Non-U.S.

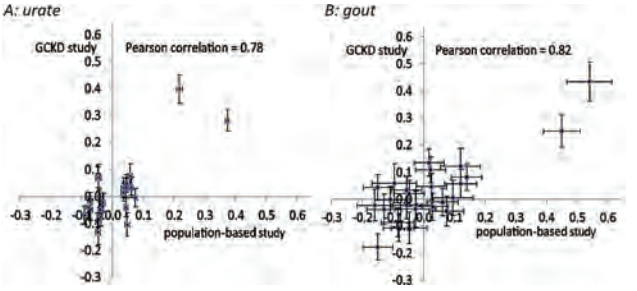

Figure 1: Effect size comparison of SNPs on serum urate in population-based studies (X) vs. CKD patients (Y) for urate (panel A) and gout (panel B, log odds ratio).

SA-PO649

Targeting Stat3 Activity Blocks Muscle Wasting in CKD Liping Zhang,[2] William E. Mitch.[1] *[1]Baylor College of Medicine, Houston, TX; [2]Nephrology, Baylor College of Medicine, Houston, TX.*

Background: Muscle wasting with morbidity and mortality is common in patients with chronic kidney disease (CKD) but there are no regularly effective treatments. We find there is activation of a p-Stat3/CEBPδ/myostatin signaling pathway in muscles of patients or mice with CKD and inhibition of myostatin or p-Stat3 blocked muscle loss in mice with CKD. We also find that C188-9, a small-molecule inhibitor of Stat3 increases muscle mass and improves muscle function despite CKD. To extend these results, we examined optimal dosing, frequency and route of administration of C188-9 to rats with CKD

Methods: CKD (subtotal nephrectomy) was created in male Sprague-Dawley rats. C188-9 was administered by gavage feeding or i.p. injection; plasma levels of C188-9 were measured by LC/MS

Results: For pharmacokinetics, we administered C188-9 (doses 0, 10, 30, 100 mg/kg) once to 2 groups of rats: A) sham-operated, control rats; and B) rats with CKD, pair fed with control rats. Plasma was collected at 0, 0.25, 0.5 1, 2, 4, 8 and 24 hr following C188-9 treatment. We found: 1) plasma C188-9 concentrations were linear with the administered dose in control and CKD rats. 2) C188-9 plasma concentrations in mg/ml were similar in CKD vs. control rats at different doses: 10 (CKD, 2.5 vs control, 2.4); 30 (8.4 vs. 8.3) and 100 mg/kg, (13 vs. 9.8). 3). Time to maximal C188-9 blood level was 1h for all doses of control and CKD rats. 4) In CKD rats, the C188-9 half-life was greater vs. results in control rats. 5) At 3 days after C188-9 dosing, we measured C188-9 in muscle lysates; levels of C188-9 in muscle were similar in sham and CKD rats. 6) Notably, C188-9 suppressed muscle p-Stat3 levels in CKD rats vs. controls (no C188-9) and the p-Stat3 level was inversely correlated with the C188-9 in muscle. 7). C188-9 was tolerated in CKD rats even at 100 mg C188-9/kg/day for 7 days

Conclusions: 1) the optimal C188-9 dose is 30mg/kg which blocks p-Stat3 effectively in muscle of rats with CKD and it has a half-life similar to that of 100 mg/kg. 2) From this half-life, C188-9 could be dosed every 4 hrs to CKD rats. 3) C188-9 has a potential for developing oral dosing as results with gavage feeding were similar to those of i.p. injection. 4) The drug remains in muscles, inhibiting p-Stat3 effectively. 5) C188-9 exhibits minimal short-term toxicity. Thus, C188-9 has a potential for combating muscle wasting in patients with CKD.

SA-PO650

Apabetalone (RVX-208) Impacts Key Markers and Pathways Associated with CKD in Patients with Severe Renal Impairment Ewelina Kulikowski,[3] Sylwia Wasiak,[3] Laura Tsujikawa,[3] Christopher Halliday,[3] Stephanie Stotz,[3] Dean Gilham,[2] Ravi Jahagirdar,[3] Kamyar Kalantar-Zadeh,[5] Richard A. Robson,[1] Michael Sweeney,[6] Jan O. Johansson,[4] Norman C. Wong.[4] *[1]CHristchurch Clinical Studies Trust, Christchurch, New Zealand; [2]Resverlogix, Calgary, AB, Canada; [3]Resverlogix Corp, Calgary, AB, Canada; [4]Resverlogix Corp., San Francisco, CA; [5]University of California Irvine, School of Medicine, Orange, CA; [6]Resverlogix Inc, San Francisco, CA.*

Background: Chronic kidney disease (CKD) is associated with a progressive loss of renal function and a high risk of cardiovascular disease (CVD). Apabetalone is an orally active BET protein inhibitor that decreased major adverse cardiac events (MACE) in CVD patients in phase 2 clinical trials. Thus, a phase 1, open-label, parallel group study of patients with impaired kidney function was conducted to determine the effect of apabetalone on plasma proteins associated with CVD complications in CKD.

Methods: 8 subjects with stage 4 CKD not on dialysis (mean eGFR=20 ml/min/1.73m²) and 8 matched controls (mean eGFR=78.5 ml/min/1.73m²) received a single 100 mg dose of apabetalone. Plasma was collected over 48h for PK analysis and at 12h post dose for proteomics analysis using the SOMAscan® platform (1305 proteins). Data

were analysed with Ingenuity® Pathway Analysis (IPA®) to identify pathways regulated by apabetalone.

Results: PK parameters were similar in CKD patients and controls. Plasma proteomics in CKD patients showed that after 12h apabetalone altered levels of 261 proteins by 10-58% ($p<0.05$), versus baseline. 257/261 proteins were downregulated, consistent with inhibition of BET sensitive genes. IPA® revealed a robust effect of apabetalone on pathways involved in immunity and inflammation, acute phase response, diabetes, endothelial dysfunction, vascular calcification, fibrosis, and hypertension. Apabetalone also reduced circulating CKD and CVD markers, including IL-6, TNFα, IL-1, ICAM-1, VCAM-1, CRP, PAI-1, L-selectin, E-selectin, MMP-3, MMP-10, fibronectin and SPP1 ($p<0.05$).

Conclusions: In stage 4 CKD patients, apabetalone rapidly downregulates plasma markers and molecular pathways linked to renal disease and CVD complications. The long term impact of apabetalone is currently being studied in a subpopulation with impaired kidney function of the phase 3 BETonMACE CVD outcomes trial.

SA-PO651

Personalized Levetiracetam Dosing Adjustments for Patients Undergoing Continuous Venovenous Hemofiltration Shamir Kalaria,[2] Paul J. Mccarthy,[2] Miguel Franquiz,[2] Michael Armahizer,[3] Mathangi Gopalakrishnan.[1] *[1]School of Pharmacy, University of Maryland, Baltimore, Baltimore, MD; [2]University of Maryland, Baltimore, MD; [3]University of Maryland Medical Center, Baltiomre, MD.*

Background: Few clinical data exist on the effect of continuous renal replacement therapy (CRRT) methods on medication pharmacokinetics (PK). Appropriately designed PK studies could potentially optimize dosing recommendations in patients undergoing CRRT. This clinical study in critically ill patients receiving levetiracetam aims to understand the (1) methodology of conducting an appropriate CRRT study to characterize PK, (2) potential barriers that exist with an observational CRRT study, and (3) derivation of individualized dosing recommendations.

Methods: Five patients receiving oral or intravenous levetiracetam and continuous venovenous hemofiltration (CVVH) in a neurocritical care unit were sampled to investigate the need for dosing adjustments. Pre-filter, post-filter, and ultrafiltrate samples were taken before dosing, after the completion of a 15 minute infusion, and at 4-5 additional time points post-infusion. Plasma concentrations were determined using a validated HPLC-UV bioanalytical method. Blood and effluent flow rates and laboratory parameters were also collected at the time of sampling. Non-compartmental analysis was conducted using Phoenix WinNonlin® 7.1 (Pharsight Corporation).

Results: The average sieving coefficient (ratio of ultrafiltrate concentrations to prefilter plasma concentrations) was 0.90 ± 0.1 and the average volume of distribution was 52.7 ± 7.6 liters. Three out of the five patients experienced concentrations outside the reported therapeutic range (12-46 mg/L) of levetiracetam. Average total drug clearance for patients taking 750 mg, 1000 mg, and 2000 mg were 3.10, 5.14, and 3.46 L/hr respectively, indicating that differences in clearance can be attributed to differences in ultrafiltration flow rates.

Conclusions: Preset ultrafiltrate rates were different amongst patients and need to be taken into consideration when determining an appropriate dose. Patients with higher ultrafiltrate rates will have increased drug clearance and therefore will require higher doses in order to match exposures seen in patients with normal renal function. Therefore, individualized dosing recommendations should be based on CRRT flow parameters and drug specific sieving coefficients.

SA-PO652

Effect of CKD on Expression of Cyp3a11, Cyp2c37, Cyp2d22, and Oatp1b2 in C57BL/6 Mice Nicholas Tonial,[3] Emily D. Hartjes,[3] Jean-Francois Thibodeau,[2] Chet E. Holterman,[1] Eldjonai Kamto,[1] Lyne Gagnon,[2] Brad Urquhart.[3] *[1]Ottawa Hospital Research Institute, Ottawa, ON, Canada; [2]ProMetic BioSciences Inc., Laval, QC, Canada; [3]Western University, London, ON, Canada.*

Background: Drug disposition can be severely altered in patients with chronic kidney disease (CKD) due to the multitude of physiological changes that occur. Cytochrome P450s and membrane transporters are major contributors to overall drug disposition, and have been extensively studied in rodent models of CKD. Induction of CKD in rat models by 5/6 nephrectomy or dietary treatment with adenine have shown decreased expression of CYPs such as CYP3A2 and CYP2C11. CKD mouse models using 3/4 nephrectomy have also shown a reduced expression of Cyp3a11. However, the use of adenine to induce CKD in mice for the purpose of evaluating drug response has not been studied. This study investigated the effects of adenine-induced CKD in C57BL/6 mice on the expression of Cyp3a11, Cyp2c37, Cyp2d22, and Oatp1b2. It was hypothesized that CKD would decrease the expression of these genes.

Methods: C57BL/6 mice were fed standard chow (n=4) or standard chow supplemented with 0.25% adenine (n=6) for 4 weeks. Mice were sacrificed, organs collected and RNA was isolated and analyzed by RT-qPCR for Cyp3a11, Cyp2c37, Cyp2d22, and Oatp1b2 with expression levels normalized to beta actin using the $\Delta\Delta C_T$ method.

Results: Plasma urea and creatinine were significantly elevated ($p<0.05$, $p<0.01$ respectively), and creatinine clearance was significantly reduced ($p<0.01$) in adenine-fed mice compared to controls. No differences were found between the two groups for the four genes analyzed ($p>0.05$), however a trend was observed for increased Cyp2c37 expression in CKD mice compared to control mice (143.5% increase; $p=0.0967$).

Conclusions: CKD did not alter expression levels of Cyp3a11, Cyp2c37, Cyp2d22, and Oatp1b2 in C57BL/6 mice. Although not a statistically significant increase, Cyp2c37 expression remains of interest for future studies to better elucidate this change. Analysis of protein expression and functional activity remain to be determined to better understand the impact of CKD on drug metabolism and distribution in this mouse model.

SA-PO653

Comparative Effectiveness of Allopurinol, Febuxostat, and Benzbromarone on Renal Function in CKD Patients with Hyperuricemia: A 13 Year Cohort Study Ching-Wei Tsai,[1,2] Chin-Chi Kuo.[1,2] *[1]Internal Medicine and Big Data Center, China Medical University Hospital, Taichung, Taiwan; [2]China Medical University, Taichung, Taiwan.*

Background: Direct comparisons of the effectiveness of allopurinol with that of other urate-lowering agents in chronic kidney disease (CKD) populations, as well as guideline recommendations for clinical practice, are lacking.

Methods: We constructed a pharmacoepidemiology cohort study by using patients from Taiwan's long-term integrated CKD care program to compare the effectiveness among allopurinol, febuxostat, and benzbromarone in reducing the risk of progression to dialysis. A total of 874 patients with hyperuricemia who were newly treated with allopurinol, febuxostat, or benzbromarone were included. The primary and secondary outcomes were incident ESRD and the serum uric acid (SUA) changes from baseline, respectively. The results were analyzed using multiple Cox proportional models adjusted for multinomial propensity scores.

Results: Compared with allopurinol, benzbromarone therapy was associated with a reduced risk of progression to dialysis, the adjusted hazard ratio (aHR) was 0.50 (95% CI, 0.25–0.99). Patients who received allopurinol or febuxostat exhibited a comparable risk of end-stage renal disease [aHR, 0.99 (0.40–2.44)]. Febuxostat was significantly more potent than was allopurinol or benzbromarone in lowering SUA levels in the fully adjusted model. Among patients who reached the therapeutic target, those with febuxostat and benzbromarone initiation had a significantly lower risk of ESRD.

Conclusions: In conclusion, compared with conventional allopurinol, febuxostat and benzbromarone are more effective in reducing the risk of progression to dialysis and in lowering SUA levels in CKD populations.

Effect of serum uric acid and eGFR associated with allopurinol, febuxostat, and benzbromarone

Study drugs	N	Change from baseline (mg/dL)	Percentage change from baseline (%)
		Adjusted†	Adjusted†
		LSM (95% CI)	LSM (95% CI)
Serum uric acid			
Allopurinol	308	-1.49 (-1.82, -1.16)	-13.70 (-16.90, -10.60)
Febuxostat	133	-3.71 (-4.18, -3.23)	-36.70 (-41.30, -32.20)

Single Ascending Dose Study of Intraperitoneal Triferic® (Ferric Pyrophosphate Citrate) in Patients on Chronic Peritoneal Dialysis Raymond D. Pratt,[2] Sarah L. Grimberg,[1] Ajay Gupta.[2] *[1]Rockwell Medical, Inc., Mission Viejo, CA; [2]Rockwell Medical Inc, Wixom, MI.*

Background: The inconvenience of giving intravenous (IV) iron as an outpatient has limited its use in peritoneal dialysis patients (PD). Ferric pyrophosphate citrate (FPC) is a complex, water soluble iron salt approved to maintain iron balance and hemoglobin in patients receiving chronic hemodialysis. FPC donates iron to transferrin, bypassing the reticuloendothelial block to iron metabolism in patients with chronic kidney disease. We postulated that FPC could be administered in peritoneal dialysis fluid (PDF) to replace and/or maintain iron stores.

Methods: Thirty (30) PD patients were enrolled in an open-label, randomized, two-period, single ascending dose study of FPC administered in PDF in 5 cohorts. All patients received FPC in either Dianeal® (1.5% or 2.5% dextrose) 2 L or Extraneal® (Icodextrin 7.5%) 1.5 L for a 12 hour dwell. FPC was added to the PDF at iron concentrations of 2.5, 5.0 (2 cohorts), 7.5, or 12.5 mg Fe/L. At another session, 6.6 mg FPC was administered IV over 4 hours. A serum iron profile (sFe) was obtained at defined time points to characterize the PK of absorbed iron.

Results: Iron absorption from PDF was dose dependent with peak sFe values at approximately 6 hours. Clearance of PD administered iron followed the time course of IV FPC administration. Serum iron levels exhibited an initial rapid rise followed by a slower increase. Estimates of iron absorption ranged from 0.8 mg with the 2.5 mg Fe/L dose to 7.3 mg Fe with the 12.5 mg Fe/L dose. Triferic was generally well tolerated. Two patients (7%) experienced moderate abdominal discomfort and cramping upon infusion of the 12.5 and 7.5 mg dose. One subject in the 12.5 mg dose group withdrew due to the event the other event resolved. Transient nausea and vomiting were experienced by 2 patients (7%) upon infusion of PDF. No changes in PDF cell counts or differential were observed at any dose level.

Conclusions: Ferric pyrophosphate citrate (Triferic®) iron is bioavailable via peritoneal dialysis. The adverse effects were mild to moderate in severity and appeared to be dose dependent. Iron absorbed from PDF to the systemic circulation was rapidly cleared with a time course similar to IV FPC. FPC added to PDF may be an effective and simple iron replacement therapy for PD patients.

Parathyroid Hormone Contributes to the Down-Regulation of Cytochrome P450 3A through the cAMP/PI3K/Akt Signaling Pathway in Secondary Hyperparathyroidism Hiroshi Watanabe,[1] Ryusei Sugimoto,[1] Masafumi Fukagawa,[2] Toru Maruyama.[1] *[1]Department of Biopharmaceutics, School of Pharmacy, Kumamoto University, Kumamoto, Japan; [2]Tokai University School of Medicine, Isehara, Japan.*

Background: Although it is reported that humoral factors, such as uremic toxins, may contribute to the change of extra-renal drug clearance observed in CKD, the details have not been clarified. We investigated the role of parathyroid hormone (PTH) in the change of extra-renal clearance.

Methods: Secondary hyperparathyroidism (SHPT) model rats were created by feeding a high phosphorus diet to the 5/6 renal nephrectomy rats. In vitro experiments were performed using rat primary hepatocyte and Caco-2 cells.

Results: In rats with SHPT, hepatic and intestinal expression of CYP3A was down-regulated. Pharmacokinetic study using midazolam, a probe of CYP3A metabolism, showed that area under the curve (AUC) after oral administration increased about 8 times in the SHPT group compared to the sham group. These changes were suppressed by the administration of cinacalcet, a calcimimetic PTH suppressor, suggesting PTH contributes to the down-regulation of CYP3A. Using rat primary hepatocytes and Caco-2 cells, PTH (1-34) treatment decreased the expression of CYP3A proteins. The data supported the results obtained from SHPT rats. In Caco-2 cells, PTH (1-34) down-regulated mRNA expression of CYP3A but inactive PTH derivative (13-34) did not, suggesting that the action of PTH (1-34) occurs via PTH receptor. In addition, 8-Br-cAMP significantly reduced mRNA expression of CYP3A. Inhibitors of PI3K, NF-κB, PKC and PKA reversed the PTH-induced CYP3A down-regulation.

Conclusions: PTH down-regulates hepatic and intestinal CYP3A expression through cAMP/PI3K/Akt pathways, following the elevation of intracellular cAMP via PTH receptor. Such effects of PTH can be prevented by a cinacalcet treatment.

SA-PO656

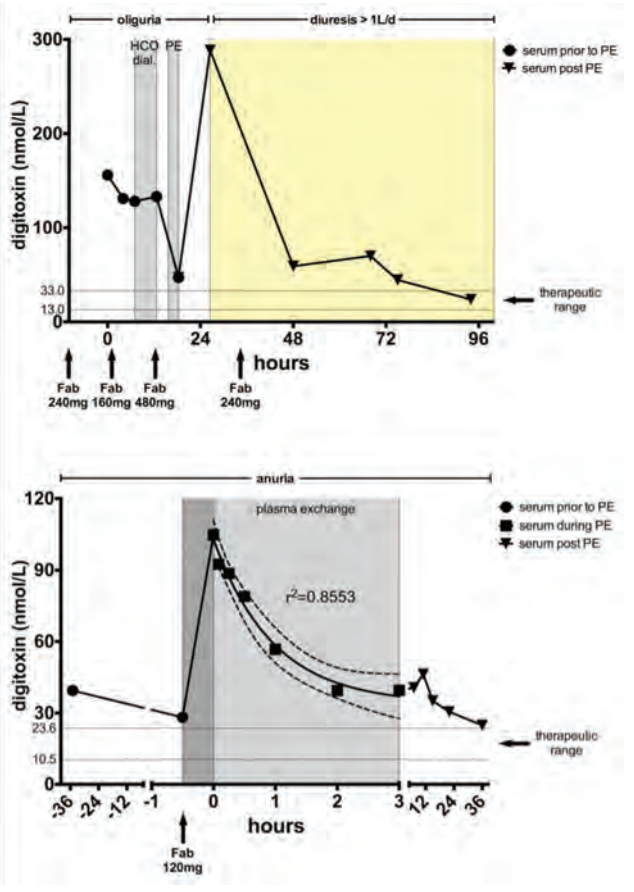
Time for a(n Ex)Change: Treatment of Acute Cardiac Glycoside Intoxication with Extracorporeal Fab-Glycoside Removal in the Setting of Oliguria or Anuria: Experience from Two Cases Treated with TPE Michael S. Balzer, Klaus Stahl, Susanne V. Fleig, Sascha David, Hermann G. Haller. *Hannover Medical School, Hannover, Germany.*

Background: Anti-cardiac glycoside-antibody-fragments (Fab) (46kDa) are the only approved treatment for severe digitoxin intoxication. Simplified binding of the Fab to the glycoside inhibits its therapeutic effects and facilitates its renal excretion. Therefore, sustaining effectiveness of this detoxification strategy requires a certain glomerular filtration rate. It becomes obvious that in acute kidney injury (AKI) or chronic kidney disease (CKD) scenarios this elimination efficacy might be negatively affected. Removal of the Fab-glycoside complex by conventional hemodialysis is not efficient.

Methods: We here report 1 case of a patient with oliguric AKI and 1 case of an anuric patient with CKD stage 5D, both with symptomatic digitoxin intoxication. Treatment with Fab was complemented by subsequent elimination of the Fab-glycoside complex using either therapeutic plasma exchange (TPE) alone or a combination of TPE and high cut-off (HCO) dialysis. Digitoxin serum levels prior to, during and after the different treatment regimens are presented in Figure 1 and include a kinetic time course during TPE for the anuric patient.

Results:

Conclusions: TPE appeared to be much more efficient in reducing digitoxin serum levels than HCO dialysis. This was most likely due to the high extent of plasma protein binding of digitoxin. As demonstrated by these 2 cases, we suggest to consider extracorporal Fab-glycoside removal to prevent rebound toxicity following Fab treatment in severe cardiac glycoside intoxication in oliguric or anuric patients. While it has still to be demonstrated that HCO dialysis is efficient in digoxin intoxication, TPE might be the preferred treatment modality in digitoxin intoxication.



SA-PO657

Mortality after Continuous Renal Replacement Therapy (CRRT) in Maintenance Hemodialysis Patients: A Scoring System of Short-Term Mortality Risk after CRRT Toma Hamada, Masahide Mizobuchi, Yasuto Shikida, Takanori Shibata. *Division of Nephrology, Department of Medicine, Showa University School of Medicine, Tokyo, Japan.*

Background: Critically ill patients, suffering from serious diseases such as acute heart failure, acute kidney injury, septic shock, and so on, often require continuous renal replacement therapy (CRRT). Little is known about the outcome of CRRT in maintenance hemodialysis (MHD) patients, and what clinical parameters are risk factors of short-term mortality after CRRT. The objective was to investigate whether MHD patients are at high risk of the short term mortality after CRRT and to determine a scoring system relating to the mortality.

Methods: In this study, 308 patients who required CRRT in our facility from April 2013 to March 2015 were retrospectively analyzed. We excluded patients who were indicated HD within 7 days before CRRT, transferred to other hospital, and lost to follow. Patients were stratified by two groups, MHD group and Non-MHD (control) group. Analyses were performed using JMP.

Results: Two hundred fifty eight patients are included in the study. Sixty five % of them were male, mean age was 71 years. Cumulative incidence of death for MHD group versus control group was 60.4 % versus 46.0 % at 30 days (p=0.09), respectively. Kaplan-Meier analysis revealed that MHD group (log-rank test: p=0.02), intubated patients (log-rank test: $p < 0.0001$) had significant lower cumulative survival rate at 30-days after CRRT. Logistic regression analysis revealed that MHD patients were likely to die within 30-days after CRRT but did not reach statistically significance (unadjusted odds ratio 1.79; 95 % CI 0.92 – 3.54). After adjustment for elderly (age over 65 years), catecholamine administration, intubation, and MHD, MHD was an independent risk factor for 30-days mortality after CRRT (adjusted odds ratio 2.75; 95 % CI 1.31 – 5.94; p = 0.0067). We formulated a scoring system. The scoring system, MEIC score, was derived as follows: (MHD×5) +(Elderly(Age>65 y)×3)+(Intubation×7) + (Catecholamine×5). The area under the ROC curve was 0.73 for the MEIC score.

Conclusions: These results suggested that MHD, intubation, elderly, catecholamine administration were independent risk factors of 30-days mortality after CRRT. The MEIC score could be a useful scoring system for the short-term mortality.

SA-PO658

Impact of Early Initiation of Continuous Renal Replacement Therapy in Critically Ill Patients with AKI Jihyun Yang,[1] Taeyeon Hwang,[1] Sung Yoon Lim,[1] Woori C. Cho,[1] Yoon kyung Choi,[1] Myung-gyu Kim,[2] Sang-Kyung Jo,[1] Won-Yong Cho.[1] *[1]Korea University Medical Center, Sungbuk-Gu, Seoul, Republic of Korea; [2]National Institutes of Health, North Bethesda, MD.*

Background: The overall incidence of acute kidney injury (AKI) in ICU patients range from 20% to 50% and AKI represents a significant risk factor for mortality ICU patients with AKI ≥ 50%. CRRT (Continuous renal replacement therapy) widely used in ICU because of slower solute clearance and removal of fluid (better hemodynamic tolerance). However the optimal timing for initiation of CRRT in critically ill patients with AKI remains controversial. The purpose of this study is to investigate the outcomes of patients who received CRRT without any of these indications (Non-classic) with patients with one or more of these indications (Classic).

Methods: This is a retrospective single center cohort study enrolling patients who underwent CRRT in Korea University Anam Hospital. CRRT is run by the specialized CRRT team composed of two specialized nephrologists, an Intensivist, and two CRRT specialized nurses. The primary clinical outcome variables were 90-day Mortality and Renal recovery. Renal recovery was defined by creatinine clearance (≥15 mL/minute) with no need of renal replacement therapy at 90 days.

Results: At 90 days after CRRT, the mortality rate in the Classic group was 79.4% and that in the Non-classic group was 57.1%. Delayed initiation of CRRT was independently associated with greater odds of 90 day mortality. The classic group had lower renal recovery than the non-classic group. Delayed initiation of CRRT was independently associated with greater odds of non renal recovery.

Conclusions: In conclusion, initiating CRRT in critically ill patients with AKI should not be delayed until fulfillment of classic indications.

SA-PO659

Females Receive Continuous Dialysis Modalities Less Often Than Their Male ICU Counterparts Neelja D. Kumar, Ladan Golestaneh. *Albert Einstein College of Medicine; Montefiore Medical Center, Bronx, NY.*

Background: Acute kidney injury (AKI) carries significant mortality with rates as high as 50-70% reported in the Intensive Care Unit (ICU). Standard clinical parameters for hemodialysis (HD) in AKI include azotemia, hyperkalemia, acidosis, and volume overload. Continuous renal replacement therapy (CRRT) is used in hemodynamically unstable patients or those with massive volume overload requiring prolonged ultrafiltration. Initiation of CRRT involves dedicated ICU nursing and is generally more expensive than HD. Race and initiation of dialysis has been evaluated though data remains conflicted. Gender also influences delivery of care as some studies suggest that males with AKI receive initiation of dialysis less often, while others suggest that women receive less aggressive critical care and dialysis. We hypothesize that certain non-clinical factors like race, socioeconomic status (SES), gender, or location affect the decision to pursue CRRT versus HD.

Methods: We used a clinical database "Clinical Looking Glass" (CLG) to retrospectively analyze 1,519 patients in the ICU between 2012-2015. AKI was defined as creatinine >3.0 mg /dL with pre-admission creatinine < 2.0 mg/dL. Endpoints included: CRRT, HD, Palliative Care or no intervention. Variables evaluated included age, gender, SES, race, vasopressor use, laboratory parameters before RRT initiation, and the type of ICU. We did bivariate analyses examining demographic and clinical variables with treatment assignment. We then built a logistic regression model to test our hypothesis.

Results: A total of 370 subjects (24.4%) received CRRT, 307(20.2%) received HD, 264(17.4%) received palliative care and 578(38%) received no intervention. In the cohort, 46.7% were female, 32.8% were black and 18.3% were white; with a mean age of 63.3 years. Our logistic regression model included 408 subjects and showed a significant association between gender and type of RRT received, with females having a significantly lower odds of receiving CRRT(odds ratio: 0.58, CI(0.37-0.89), as compared to HD, after adjusting for other variables. Other variables significantly associated with use of CRRT were vasopressor use, lower pH, lower creatinine, type of ICU, and hospital location.

Conclusions: Female patients were less likely to receive CRRT than males. Other factors including race and SES did not significantly affect the decision to start CRRT versus HD.

SA-PO660

Thrombocytopenia among Critically Ill Patients Receiving CRRT in the Medical ICU: Is it AKI or CRRT? Ghassan Bandak,[1] Ankit Sakhuja,[1] Kianoush Banaei-Kashani.[1,2] *[1]Pulmonary and Critical Care, Mayo Clinic, Rochester, MN; [2]Nephrology and Hypertension, Mayo Clinic, Rochester, MN.*

Background: Thrombocytopenia has been reported as a side effect of hemodialysis in ESRD patients. It has also been reported in critically ill patients receiving CRRT. CRRT is commonly used in patients requiring RRT who are hemodynamically unstable in the ICU for both patients with AKI and ESRD. However, these populations are different in multiple aspects. There are various patient and treatment-related factors that are proposed to be contributing to thrombocytopenia. Furthermore, thrombocytopenia has been linked to increased mortality among patients receiving CRRT. We hypothesized that the rates of thrombocytopenia will be higher among patients with AKI in comparison with ESRD patients given their severe inflammatory state, new exposure to extracorporeal membranes and uremic milieu.

Methods: We performed a retrospective analysis of all patients receiving CRRT in our institution between Jan 1, 2007, to Oct 31, 2015. Data was electronically abstracted from the electronic medical chart. We included patients in medical ICUs and excluded patients in surgical and cardiovascular ICUs. We identified ESRD patients using ICD 9 and 10 codes. New thrombocytopenia was defined as a 50% drop in platelets count after CRRT initiation. We performed a chi-square test to compare rates of decline in platelets among ESRD and AKI patients. A P-value of 0.05 was considered to be statistically significant. Data analysis was done using STATA 14.0. We provide a standard CVVH prescription with regional citrate anticoagulation for all patients in our ICUs

Results: We identified a total of 673 unique patients who received CRRT in medical ICUs. A total of 94 patients (13.9%) had a diagnosis of ESRD. 54.4% were males. Median (IQR) age was 60 years (51-68). The rate of new thrombocytopenia after CRRT initiation was 55.4%. Median platelet count prior to CRRT was 107 and median lowest platelet count after CRRT initiation was 45. The incidence of drop of platelets amongst patients with ESRD was 53.8% vs. 55.6% amongst those without ESRD (P=0.7)

Conclusions: Both ESRD patients and AKI patients requiring CRRT are at significant risk of developing thrombocytopenia. The risk is not different between the two patient populations and is possibly influenced by CRRT treatment-related factors in the setting of critical illness.

SA-PO661

Propofol Induced CRRT Failure Mohammad Y. Alsawah, David B. Butcher, Lamia Aljundi, Rachel E. Wilson. *Nephrology, St John Hospital and Medical Center, Detroit, MI.*

Background: Severe hypertriglyceridemia (TG level >1000 mg/dL) is a known complication of prolonged (>48 hours) propofol infusion Serial monitoring of serum triglycerides (TG) level is recommended in these cases. Continuous renal replacement therapy (CRRT) is the hemodialysis modality of choice in hemodynamically unstable patients. The CRRT machine cartridge can clot during the dialysis procedure. Anticoagulation with citrate or heparin can decrease clotting. There are a few case reports describing CRRT cartridge clotting in association with hypertriglyceridemia in patients treated with TPN. We describe a case of severe hypertriglyceridemia associated with propofol infusion resulting in clotting of the CRRT cartridge.

Methods: .**Case report** A 42 year old African American male with newly diagnosed stage 4 Hodgkin's lymphoma was admitted to the intensive care unit with septic shock and respiratory failure that developed after receiving the first cycle of chemotherapy. Sedation was provided with propofol infusion at a rate of 5 mcg/kg/min. He developed acute renal failure and was started on continuous renal replacement therapy (CRRT). Local circuit anticoagulation was not used due to severe thrombocytopenia and liver disease. CRRT was interrupted 48 hours after initiation due to cartridge failure. This was associated with a yellow discoloration of the blood in the dialyzer tubing. The serum triglyceride (TG) level was elevated at 1,552 mg/dL (reference range 30-149 mg/dL). Propofol was discontinued and follow up serum TG decreased to less than 500 mg/dL. CRRT was successfully restarted within 48 hours of stopping propofol infusion

Results:

Conclusions: Critically ill patients receiving propofol sedation are at risk of developing hypertriglyceridemia. Elevated triglyceride (TG) levels can promote a procoagulant state, potentially inducing cartridge clotting. CRRT cartridge failure due to hypertriglyceridemia was previously described in association with TPN infusion. Our case illustrates the important of frequent monitoring of triglyceride levels with prolonged propofol use.

SA-PO662

A Mystery Case of Blood Leak Alarm Triggering Rhyan Maditz. *Beaumont Health - Royal Oak, Royal Oak, MI.*

Background: The mandatory blood leak detector (BLD) in a hemodialysis machine protects patients from harm by automatically shutting down the instrument if a leak is detected. Mechanical issues such as air bubbles or grease depositis may falsely activate the BLD alarm. Hemolysis has also been shown to activate the BLD. Hydroxocobalmin is known to interfere with the blood leak detector, causing a false alarm, which leads to the inability to perform dialysis.

Methods: A 68-year-old male with end stage renal disease on intermittent hemodialysis was admitted to the hospital after presenting with weakness and fatigue. He was previously scheduled to have outpatient coronary artery bypass grafting due to severe coronary artery disease. Patient was found to have aortic valve infective endocarditis and underwent urgent aortic valve replacement along with coronary artery bypass grafting. His postoperative course was complicated by hypotension, resulting in acute kidney injury requiring hemodialysis. He initially received intermittent hemodialysis with a 2008K Fresenius dialyzer instruments with adequate tolerance. On post-operative day 10, BLD interrupted dialysis as the dialysate effluent became read in color. Work up for hemolysis returned negative. Hemoglobin remained stable. Hemodialysis was attempted twice again using different 2008K Fresenius dialyzer instruments and the BLD alarm interrupted dialysis on each occasion. We bypassed the BLD alarms by testing the dialysate fluid for leaks every 15 minutes and by continuously resetting the alarm. Review of administered medications revealed that the patient received 5 mg of hydroxocobalmin (Vitamin B12A) intravenously on the day preceding the first blood leak alarm for vasoplegia syndrome. Rifampin was included in the patient's antibiotic regimen for infective endocarditis and is known to cause reddish discoloration of bodily fluids. Rifampin was discontinued but did not resolve the issue. The BLD no longer alarmed two days following discontinuation of hydroxocobalmin. Rifampin was restarted without any additional blood leak alarms.

Results:

Conclusions: This case highlights the importance of recognizing other etiologies of BLD alarms, especially when mechanical issues and hemolysis have been ruled out. It is important to recognize hydroxocobalmin as a cause for BLD false alarms. Fleishman issued a black box warning several months after our case.

SA-PO663

Efficacy and Safety of a Citrate Anticoagulation Protocol for Slow Extended Dialysis in AKI Cancer Patients Using Path Batch Hemodialysis: A Case Control Study Antonio A. Portela Neto,[3] Renato A. Caires,[2] Marcella M. Frediani,[3] Elerson Costalonga,[2] Fernanda O. Coelho,[3] Emmanuel A. Burdmann,[3] Etienne Macedo,[1] Veronica T. Costa e Silva.[3] *[1]UCSD, San Diego, CA; [2]University State of São Paulo, São Paulo, Brazil; [3]University of Sao Paulo Medical School, Sao Paulo, Brazil.*

Background: Few reports have addressed citrate anticoagulation (CA) for hybrid dialysis therapies using Path Batch Hemodialysis (PBH).

Methods: Slow extended dialysis (SLED) procedures with a PBH system in adult critically ill AKI cancer patients in the Sao Paulo State Cancer Institute, from January 7 to April 7, 2015, were prospectively followed. Procedures performed with regional CA (4% sodium citrate and dialysate containing calcium at 5 mg/dL) were compared with those using continuous normal saline (NS) as anticoagulation.

Results: Twenty four CA and 27 NS sessions were performed in 11 patients. Baseline patient characteristics were similar, whereas duration, ultrafiltration (UF) and flow prescription were different within CA and NS groups (Table). At the end of CA-SLED, median citrate flow was 310 (280 320) mL/h and systemic ionized calcium (SCai) was 4.20 (3.92 – 4.47) mg/dL. During the SLED procedure, hypocalcemia (SCai < 3.6 mg/dL) and metabolic alkalosis (serum bicarbonate > 30 mEq/L) rates were 8.0% and 4%, respectively (N=96). Interruption of PBH by clotting was recorded in only three (12.5%) of CA-SLED sessions and in six (22.2%) of NS procedures (P=0.363). Filter[V-W1] life was 8.0 (6.0 – 8.0) and 4.0 (2.75 – 5.00)h in the CA and NS groups (P<0.0001), respectively. Hypotension rate (mean blood pressure <70 mmHg) was similar in both groups (12.5% in CA-SLED vs 14.8% in NS group, P=0.811). No major bleeding, arrhythmia or relevant clinical events were observed in neither groups. PBH provided a satisfactory metabolic control in both groups (data not shown)

Conclusions: A CA protocol can be safely and efficiently used in PBH SLED in critically ill cancer patients with AKI. Larger sample size studies including control pcts are needed to establish the benefit of citrate based anticoagulation for PBH SLED procedures.

Characteristics of PBH procedures

	CA-SLED (N=11)	NS (N=11)	P
Blood/Dialysate flow (ml/min)	180 (180 – 195)	250 (200 - 250)	< 0.001
Prescribed dialysis duration (DD)(hrs)	8.0 (6.5 – 8.0)	4.0 (4.0 – 5.0)	< 0.001
Prescribed UF (L)	2.0 (1.5 – 2.5)	1.0 (0 – 1.5)	0.001
Prescribed/Achieved UF (%)	94.3 ± 12.3	85.8 ± 26.2	0.461
Prescribed/Achieved DD (%)	94.7 ± 11.7	89.5 ± 15.9	0.321

SA-PO664

Concurrent Hemoperfusion and Hemodialysis in Patients with Acute Pesticide Intoxication Hyo-Wook Gil. *Soonchunhyang university Cheonan Hospital, Cheonan, ChungcheongNam-do, Republic of Korea.*

Background: Water soluble and insoluble chemicals in the pesticide formulation may be eliminated more effectively in time if hemodialysis (HD) and hemoperfusion (HP) are performed concurrently. This study is aimed at evaluating the efficacy of concurrent HP and HD in patients with acute pesticide intoxication.

Methods: Between January 2011 and December 2012, we used HP and HD consecutively (HP-HD group, 347 cases), and then during the next 2 years (January 2013 to December 2014), we used concurrent HP and HD (HPD group, 383 cases). We compared the clinical outcomes between the 2 groups. For HP, we used an Absroba 300C HP membrane and for HD, we used a Polyflux 170H HD dialyzer (Baxter).

Results: The mortality was higher in the HP-HD group than in the HPD group: (48.1 vs. 20.9%) for the overall mortality and (81.8 vs. 57.9%) for the paraquat (bipyridylium) mortality ($p < 0.001$). In multiple logistic analyses, age ($p = 0.013$), ingested volume ($p < 0.001$), and HP-HD ($p = 0.014$) were significant risk factors for mortality in the paraquat ingested group.

Conclusions: Concurrent HP and HD would be an effective and safe treatment for patients with acute pesticide intoxication, in particular, paraquat intoxication.

Funding: Government Support - Non-U.S.

SA-PO665

Single-Pass Albumin Dialysis with Continuous Renal Replacement Therapy in Patients with Liver Failure Vimal Chadha,[2] Darcy K. Weidemann,[2] Nathan T. Beins,[4] Uttam Garg,[3] Rebecca M. Greene,[1] Brooke English,[1] Marita Thompson.[5] *[1]Children's Mercy Hospital, Kansas City, MO; [2]Children's Mercy Hospital, Kansas City, MO; [3]Children's Mercy Hospitals and Clinics, Knasas City, MO; [4]None, Kansas City, MO; [5]University of Missouri Kansas City, Children's Mercy Hospital, Kansas City, MO.*

Background: Multiple organ dysfunction syndrome is not uncommon in critically ill children. While many of these children receive CRRT for management of AKI, there is no standard approach available for managing liver failure in which several metabolites that are highly protein bound accumulate, and thus are not cleared with conventional CRRT. Molecular Adsorbent Recycling System (MARS) has been successfully used in these situations, but is unavailable in most centers. Modification of CRRT with Single-Pass Albumin Dialysis (SPAD) has been reported previously.

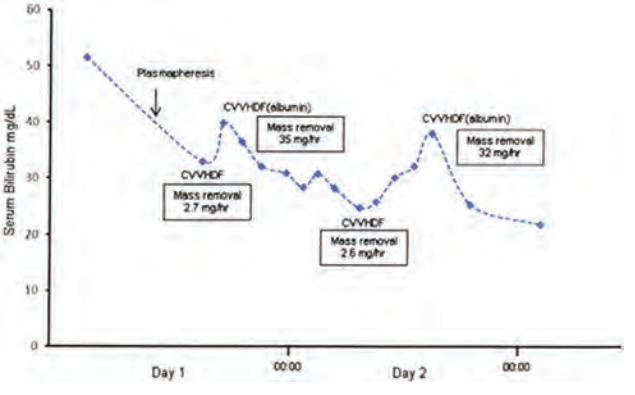
Methods: We report our experience in four children who were treated with SPAD-CRRT. All patients received CRRT (CVVHDF) with a clearance of 2 L/hr/1.73m2. For SPAD, 400 mL of 25% albumin was added to the 5 L dialysate (PrismaSol®) bag to give final albumin concentration of 1.85%. Serum bilirubin was used as a surrogate marker of efficacy of SPAD. Serum and dialysate bilirubin concentrations were monitored to calculate the mass bilirubin removal.

Results: The findings are briefly summarized in the Table.

Conclusions: Our experience shows >10-fold increase in bilirubin clearance with SPAD-CRRT. While SPAD-CRRT is effective in decreasing serum bilirubin and other toxins, its impact on removal of nutrients and medications is currently unknown, Further studies are needed to see if SPAD-CRRT can improve patient outcomes.

Case	Age (yrs)	Sex	Diagnosis	Max. Bilirubin (mg/dL)	SPAD duration (hrs)	% reduction in bilirubin with SPAD	Outcome
1	0.6	M	Hemophagocytic histiolymphocytosis with liver failure.	52	35	56%	Expired
2	7	M	Cystic fibrosis, sepsis, acute on chronic liver failure.	33	96	42%	Recovered, expired 3 weeks later
3	5	M	Fulminant acute liver failure.	24	26	21%	Received liver transplant
4	3	M	Neuroblastoma, post-HCT, VOD, and liver failure.	32	240	73%	Recovered, expired 1.5 yrs later

While severe hyperbilirubinemia was the main reason for using SPAD in patients 1, 2, and 4, it was used as a bridge to liver transplant in patient #3.



SA-PO666

24-Hour Urine Volume May Be a Practical and Convenient Method of Monitoring Change in Native Kidney Function in Patients on In-Center HD Kevin D. Marquez,[2] Andrew I. Chin.[1,3] *[1]University of California Davis, Sacramento, CA; [2]University of California Davis Medical Center, Sacramento, CA; [3]Internal Medicine, VA Health Care Northern California, Mather Field, CA.*

Background: Nephrologists are caring for more in-center HD patients with Acute Kidney Injury on Dialysis (AKI-D). Identifying renal recovery is important. In non-HD patients, change in serum creatinine is commonly used to determine change in renal function. In HD patients, the best indictor of a change in renal function is not known. We examined incident HD patients to determine which factors best correlated to the longitudinal change in residual kidney urea clearance (Kru).

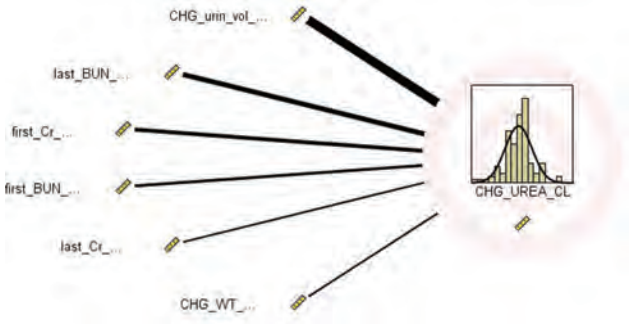
Methods: Retrospective study of incident HD patients with 2 timed, 24-hour urine collections within a 6 month period. Demographic, laboratory, dialysis parameters, and urine data were analyzed to determine the best model to predict change of Kru.

Results: 106 incident HD patients were included, mean age of 57 ± 17 years, 35% female and 40% diabetic. Mean time between paired 24 hour urine collections was 106 ± 34 days. Kru increased in 36% of the patients between urine collections. We modeled the change in Kru using: demographic data; post-HD body weight and fluid gain; change in body weight and fluid gain between the 2 urine collections; pre-dialysis BUN, creatinine and albumin; change in these blood tests between the 2 urine collections. The change in 24

hour urine volume was heavily weighted in best predicting the change in Kru (Figure 1). Increase or decrease of pre-dialysis serum creatinine poorly predicted the change in Kru.

Conclusions: While other factors were included in the model, change in 24 hour urine volume was most important in the correlation with kidney function urea clearance change in patients undergoing in-center HD. Pre-dialysis serum creatinine poorly correlated with change in Kru. Extrapolating these findings to AKI-D patients, formal urine collection and clearance calculation is the best method of gauging renal recovery, but serial measure of timed urine volume may be a convenient and appropriate way for weekly, frequent monitoring.

Funding: Clinical Revenue Support



Urine volume contributes most to predicting change in kidney urea clearance.

SA-PO667

Calculation of Weekly Standard Kt/V by Urea Mass Removed During Hemodialysis Results in a Simple Equation J. Ken Leypoldt, Edward F. Vonesh. *San Clemente, CA.*

Background: Accurate calculation of weekly urea standard Kt/V (stdKt/V) during hemodialysis (HD) requires first calculating sequentially single-pool and equilibrated Kt/V (Daugirdas et al, Kidney Int 2010), but this approach can be intimidating to clinicians. We explored whether an alternative approach to calculating stdKt/V based on urea mass removed would lead to a simple equation with approximately equivalent accuracy for both conventional and more frequent HD.

Methods: Theoretical consideration of urea mass balance during HD treatments derived the following equation for stdKt/V, namely stdKt/V = N * (URR + UFV/V)/(1 - N * t / 10080) where N is number of treatments per week, URR is urea reduction ratio per treatment, UFV is ultrafiltration volume per treatment, V is post-dialysis urea distribution volume and t is treatment time in minutes. The URR requires correction for post-dialysis rebound (Tattersall et al, Kidney Int 1996). The numerator of this equation represents the fractional urea mass removed from V, and the denominator corrects for intradialytic urea generation. We compared the accuracy of this novel equation for calculating stdKt/V with the conventional approach (Daugirdas et al, Kidney Int 2010) by simulations using a two-compartment model of urea kinetics. Model simulations were performed for patients with V of 20-50 L, weekly UFV of 0-14 L, treatment times of 2-8 hours, 5 different dialyzer urea clearances; this generated 350 different treatment conditions for HD performed 3, 4, 5 and 6 times per week.

Results: Results are tabulated as the absolute value of differences between approximation equations and the numerically simulated stdKt/V.

Conclusions: The urea mass removed and Daugirdas et al equations compute values of stdKt/V that are clinically equivalent. This work provides a novel, simple equation for calculating stdKt/V during HD and strengthens the theoretical understanding of stdKt/V.

Treatments per week	Statistic	Daugirdas et al equations	Urea mass removed equation
3	Mean ± SD	0.019 ± 0.016	0.014 ± 0.017
	Median (IQR)	0.017 (0.009-0.023)	0.008 (0.003-0.018)
4	Mean ± SD	0.024 ± 0.022	0.072 ± 0.029
	Median (IQR)	0.020 (0.011-0.030)	0.069 (0.051-0.090)

Volume of Urea Cleared as a Therapy Dosing Guide for More Frequent Hemodialysis J. Ken Leypoldt,[2] Allan J. Collins.[1] [1]*Chronic Disease Research Group, Minneapolis, MN;* [2]*None, San Clemente, CA.*

Background: Prescribing more frequent hemodialysis (HD) based on conventional thrice weekly HD therapy normalized to a weekly dose is challenging. Urea kinetic modeling based on the normalized urea distribution volume (V) has been shown to be suboptimal for smaller and female patients. Alternatively, prescribing the volume of urea cleared (Kt) to patient body surface area (BSA) has recently been shown to be promising (Maduell et al, Kidney Int 2016; Sridharan et al, Am J Kidney Dis 2017). Prescribing more frequent HD (5 or 6 times-per-week) to BSA has not been adequately explored.

Methods: We compared modeled Kt to the nearest L required to achieve a minimal dose of therapy based on BSA as defined by Lowrie et al (Kidney Int 2005) with that recommended by KDOQI Clinical Practice Guideline for Hemodialysis Adequacy Update based on patient V, i.e. weekly stdKt/V=2.1 (NKF, Am J Kidney Dis 2015). Estimates of Kt were calculated for conventional, thrice weekly HD (treatment time=240 min) and 5 and 6 times-per-week HD (treatment times=180 min). Results were compared for patients with different anthropometric estimates of total body water (Vw). BSA was assumed proportional to V to the power of 0.7, and residual kidney function was assumed negligible.

Results: Modeled Kt (L) for the therapies are tabulated. As during conventional thrice weekly HD, minimal Kt for more frequent HD based on BSA is higher for patients with small Vw and lower for patients with large Vw than based on weekly stdKt/V=2.1. Simple Kt prescriptions for 5 times-a-week HD based on the principles from Lowrie et al in L are equal to 20+0.4×(Vw-35). For 6 times-a-week HD, Kt prescriptions in L are equal to 16+0.3×(Vw-35). Such prescriptions require careful consideration of dialyzer type, blood flow rate, and dialysate flow rate (or total dialysate volume).

Conclusions: Prescribing more frequent HD based on BSA as extrapolated from Lowrie et al suggests the minimal dose of Kt is higher for small patients and lower for large patients than based on a weekly stdKt/V=2.1. Other aspects of dialysis adequacy require additional consideration.

The Cost of Dialysis in Canada: A Contemporary Cost Minimization Analysis Thomas W. Ferguson,[2] Sandi M. Dumanski,[1] Alain Beaudry,[3] Navdeep Tangri,[1] Claudio Rigatto,[1] Paul Komenda.[3] [1]*Winnipeg, MB, Canada;* [2]*Seven Oaks General Hospital, Winnipeg, MB, Canada;* [3]*University of Manitoba, Winnipeg, MB, Canada.*

Background: Over 5,000 patients experience renal failure in Canada every year. Most of these patients will be unable to secure a transplant and will require life-saving hemodialysis or peritoneal dialysis. These therapies are expensive and require a substantial investment from the Canadian public health care system, with over 1.8 billion dollars spent annually. In this study, we aimed to describe the costs of dialysis modalities, including facility hemodialysis, home peritoneal dialysis (PD), and home hemodialysis (HHD) (both for conventional home hemodialysis and with the NxStage System One).

Methods: We determined costs from the perspective of the Canadian public health payer; namely, human resource expenses, medical and surgical supplies, dialysis-related drugs, equipment, utilities, and capital costs. Cost estimates were sourced from hospital statements of operations, product suppliers, established utility rates, and activity-based dialysis workload estimates. Human resource time estimates are based on a review of literature, yielding mean direct and indirect resource consumption.

Results: The model outputs provide accurate estimates of expenditures for dialysis delivery over time. From this, we can generates clear thresholds for life expectancy, below and above which the most cost-effective dialysis modality may be identified. Annual maintenance expense totaled $64,214 for facility dialysis, $38,658 for PD, $39,236 for HHD, and $43,817 for HHD using the NxStage System One. Substantial cost drivers were human resources in facility dialysis (68% of total cost including benefits) compared with 12% for PD and 16 – 18% for home hemodialysis. Medical and surgical supplies accounted for 72% of PD costs compared with 13% for facility dialysis and 40 – 45% for home hemodialysis.

Conclusions: Beyond a model-defined threshold of treatment duration, home-based renal replacement therapy is less expensive than facility-based hemodialysis. When treatment and quality of life outcomes are similar between both treatments, these therapies should be recommended in patients who are capable of self-care. Ease of administering home modality should also be considered in its relation to patient uptake rates. Assisted home dialysis programs should be evaluated in more complex cases.

Technique Failure in a Multicenter Canadian Home Hemodialysis Cohort Robert P. Pauly,[1] Iram Usman,[1] Rhonda J. Rosychuk,[1] Frances D. Reintjes,[2] Maliha Muneer,[2] Christopher T. Chan,[3] Michael A. Copland,[4] Robert M. Lindsay,[5] Jennifer M. MacRae,[6] Gihad E. Nesrallah,[7] Andreas Pierratos,[8] Deborah Lynn Zimmerman,[9] Paul Komenda.[10] *[1]University of Alberta, Edmonton, AB, Canada; [2]Alberta Health Services, Edmonton, AB, Canada; [3]Toronto General Hospital, Toronto, ON, Canada; [4]University of British Columbia, Vancouver, BC, Canada; [5]London Health Sciences Centre, London, ON, Canada; [6]University of Calgary, Calgary, AB, Canada; [7]The University of Western Ontario, Toronto, ON, Canada; [8]University of Toronto, Toronto, ON, Canada; [9]University of Ottawa, Ottawa, ON, Canada; [10]University of Manitoba, Winnipeg, MB, Canada.*

Background: Increasing uptake of home hemodialysis (HD) has led to interest in characteristics that predict modality failure. Recent reports of practice pattern variability led us to hypothesize there are patient- and center-specific factors that influence outcomes in home HD.

Methods: We assembled a retrospective cohort of incident home HD patients from 7 centers in Canada from 2000 to 2010 to evaluate case-mix and process of care characteristics on technique failure and mortality. Care characteristics included intervals of follow up/blood work/vascular access monitoring, nursing and physician models of care, patient-to-nurse ratio, and presence/absence of routine home visits and technique audits among others.

Results: The cohort consisted of 579 patients. Mean age was 49.9±14.1 years, 74% were Caucasian, with a median dialysis vintage of 1.9 years (IQR 0.6, 5.2); 68% used an AVF or AVG. Mean duration of dialysis 31.2±12.6 hrs/wk. Unadjusted 1 and 2 year technique survival (censored for death and transplantation) and overall survival was 90% and 83%, and 94% and 86%, respectively. Treating center was a strong predictor of adverse outcomes (Table). With baseline adjustment for center effect, few patient-specific variables remained significant predictors of either study outcome; we did not identify significant program-specific characteristics of care processes to explain the center effect.

Conclusions: The home HD treating center has a significant impact on technique failure and patient mortality. We did not identify specific components of programmatic care to explain this observation. The relationship between process of care and patient outcomes is critical and requires further investigation.

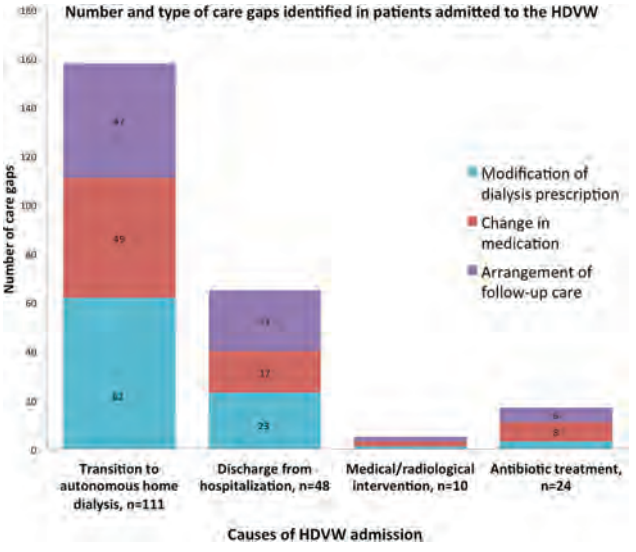
Predictors of Care Gaps in the Home Dialysis Virtual Ward Annie-Claire Nadeau-Fredette,[3] Karthik K. Tennankore,[7] Joanne M. Bargman,[9] Michael A. Copland,[6] Deborah Lynn Zimmerman,[2] Matthew J. Oliver,[5] Nikhil A. Shah,[4] Simon N. Finkle,[1] Robert P. Pauly,[4] Jeffrey Perl,[8] Christopher T. Chan.[9] *[1]Dalhousie University, Hammonds Plains, NS, Canada; [2]The Ottawa Hospital, Ottawa, ON, Canada; [3]Hopital Maisonneuve-Rosemont, Montreal, QC, Canada; [4]University of Alberta, Edmonton, AB, Canada; [5]Sunnybrook Health Sciences Center, Toronto, ON, Canada; [6]University of British Columbia, Vancouver, BC, Canada; [7]Dalhousie/Nova Scotia Health, Halifax, NS, Canada; [8]St. Michael's Hospital, Toronto, ON, Canada; [9]Toronto General Hospital, Toronto, ON, Canada.*

Background: Despite the benefits of home dialysis, home dialysis patients are prone to medical complications, especially at time of a transition/change in care. The home dialysis virtual ward (HDVW) initiative aimed to describe gaps in care following these transition periods.

Methods: The HDVW is a multicenter Canadian study conducted between January 2014 and December 2015. Patients admitted to the HDVW experienced a transition event defined as one of: (1) transition from peritoneal dialysis (PD) or home hemodialysis (HHD) training to autonomous home dialysis (2) a discharge from hospitalization, (3) receipt of a medical/radiological procedure and (4) treatment with antibiotics. HDVW admission consisted of a maximum of 14 days of follow-up using repeated clinician-led telephone interviews. Gaps of care were identified when a change of management was required in any of these 3 domains: dialysis prescription, medication and follow-up care. Predictors of the care gaps were assessed in an adjusted ordinal logistic regression.

Results: Ninety HHD and 103 PD patients were included. Overall, 245 care gaps were identified in 135 patients. (Figure 1) Higher age > 65 years (odds ratio [OR] 2.92, 95% confidence interval [CI] 1.15-7.42, p=0.02) and female (OR 1.73, 95% CI 1.18-2.52, p=0.005) were associated with an increased risk in care gaps while medical procedure as a cause for HDVW admission (OR 0.22, 95% CI 0.09-0.54, p=0.001) or antibiotic-treatment (OR 0.35, 95% CI 0.14-0.87, p=0.03) had lower risk of care gaps compared to post hospital discharge HDVW admissions.

Conclusions: Gaps in care are frequent in the home dialysis population particularly following hospital discharge. Efforts should be directed toward improvement of transitional care especially among older individuals.



SA-PO672

A Single Center Cross-Sectional Study of Health Literacy Levels in Pre-Dialysis, Home Dialysis, and In-Center Hemodialysis Patients Fabrice Mac-Way,[3] Yannick Bégin,[4] Mathieu Rousseau-Gagnon,[2] Mohsen Agharazii.[1] *[1]CHUQ-HDQ, Quebec City, AB, Canada; [2]CHUQ-Hôtel-Dieu-de-Québec, Lac-Beauport, QC, Canada; [3]None, Quebec, QC, Canada; [4]Université Laval, Québec, QC, Canada.*

Background: Health literacy is the ability to obtain, understand and use healthcare information to make appropriate health decisions. Recent studies have suggested that chronic kidney disease (CKD) patients may have low levels of health literacy. We aimed to evaluate and compare the health literacy levels in pre-dialysis and dialysis patients.

Methods: This is a cross-sectional single-center study conducted at CHU de Québec-Laval University. Adult patients attending pre-dialysis clinic, and ongoing home hemodialysis, peritoneal dialysis and in-center HD completed a French Canadian version of the Health Literacy Questionnaire (HLQ), a validated questionnaire. Cronbach's Alpha analysis was used. The HLQ measures nine specific domains of health literacy: feeling understood and supported (D1), having sufficient information (D2), actively managing health (D3), social support (D4), appraising information (D5), engaging with health providers (D6), navigating the health care system (D7), finding good information (D8) and understanding information (D9). Each domain is composed of 4 to 6 questions.

Results: A total of 353 patients (152 pre-dialysis, 157 in-center hemodialysis, 38 peritoneal dialysis (PD) and 16 home hemodialsysis (HHD)) completed the HLQ. There was a high level of agreement within each domain's questions with a Cronbach's Alpha of at least 0.75. Patients on HHD and PD were more likely to feel understood and supported (D1 p<0.001). HHD patients were more likely to understand and appraise health information (D5 and D9 p<0.001). There was a nonsignificant tendency for them to feel like they had sufficient information (D2 p=0.06), that they could actively manage their health (D3 p=0.07) and that they had a good social support (D4 p=0.09). However, we did not find any difference between the CKD groups regarding the ability to actively engage with healthcare providers (D6), to navigate through the healthcare system (D7) or to find good health information (D8).

Conclusions: This study reports for the first time detailed health literacy levels in pre-dialysis, home dialysis and in-center hemodialysis patients. Our findings will be useful in implementing strategies that take into account these nine domains of health literacy in order to improve CKD patient outcomes and quality of life.

SA-PO673

Nephrologist/Patient Conversations About Renal Replacement Meg Wise,[3] Dorian R. Schatell,[1] Betty Chewning,[2] Micah R. Chan.[3] *[1]Medical Education Institute, Madison, WI; [2]University of Wisconsin, Madison, WI; [3]University of Wisconsin-Madison, Madison, WI.*

Background: Patient-centered, valued-based decision-making is the gold standard for choosing complex medical treatments.

Methods: We conducted a mixed-method conversation study to understand how nephrologists and patients communicate about renal replacement therapy (RRT), with 8 nephrologists from 3 clinics and 61 of their patients with eGFR ≤25. Analysis of verbatim transcripts of audio-recorded clinic visits assessed word ratios and discussion of RRT options. Surveys collected demographics and RRT preferences.

Results: Nephrologists established rapport with patients and worked to delay dialysis. RRT was the most uncomfortable part of the conversation for both nephrologists and patients: clinicians spoke ~3.25 times more in the whole visit, but ~8 times more about RRT, suggesting that patients shut down. In-center hemodialysis (HD), peritoneal dialysis (PD), and transplant (despite non-eligibility) were most often discussed; home HD was hardly discussed. Nephrologists' used scripted didactic (teaching) versus dialogic (two-way) communication about RRT, perhaps overwhelming patients. Nephrologists may have inadvertently discouraged PD by emphasizing a need for a care partner (vs. optional), a sterile home (vs. just the dialysis room), and extensive training (vs. easy to learn). Home vs. center-borne infections, or that the "professionals" administering HD are largely technicians were not cited. Nephrologists did not talk about end-of-life or address patients' emotional or existential concerns. They did not directly elicit patients' values or tailor information-giving to those values even when patients inserted them. All but one nephrologist said they would use tools to help communicate more easily with their patients about RRT options.

Conclusions: A patient-centered values-based dialysis decision aid might serve as an ice-breaker, include the patients' values into the RRT conversation, and increase patients' participation in the RRT conversation and preferences for home dialysis.

Higher Likelihood of Home Hemodialysis Training Graduation in Patients Using Nx2me Connected Health Technology Eric D. Weinhandl,[1,2] Allan J. Collins.[1,2] *[1]NxStage Medical, Inc., Victoria, MN; [2]University of Minnesota, Minneapolis, MN.*

Background: In the United States, approximately 1 in 6 patients who initiate home hemodialysis (HHD) training fail to complete training. Strategies that increase the likelihood of training graduation would permit more patients to dialyze at home and improve the economics of home dialysis programs. Digital tools that are introduced during HHD training and that "go home" may accelerate development of patient understanding about HHD equipment and procedures. We assessed whether introduction of the Nx2me iPad app during HHD training was associated with higher likelihood of training graduation.

Methods: We ascertained HHD patients that initiated use of Nx2me during the first 2 weeks of HHD training with the NxStage System One. For each Nx2me user who was prescribed *q* treatments per week and had accumulated *t* training days with the System One at first use of Nx2me, we identified potential controls who were prescribed *q* treatments per week and had accumulated at least *t* training days (without use of Nx2me), and we randomly selected 3. We followed Nx2me users and their respective matched controls from *t* days after training initiation until either HHD training graduation or training dropout. We used Cox regression to model incidence of training graduation, with stratification by matched cluster and adjustment for age, race, sex, vascular access modality, and center-level metrics of training activity and success (number of trainees during the past 12 months, probability of graduation among trainees, and mean duration of training among graduates).

Results: We identified 94 Nx2me users. The mean number of days between HHD training initiation and Nx2me introduction was 7.2. In Nx2me users (matched controls, but without adjustment), the cumulative incidence of training graduation was 5.3% (5.5%) after 1 week of follow-up, 23.1% (18.0%) after 2 weeks, 46.9% (34.9%) after 3 weeks, 71.6% (49.8%) after 4 weeks, 88.0% (66.0%) after 6 weeks, and 93.6% (71.9%) after 8 weeks. The adjusted hazard ratio of training graduation for Nx2me users versus matched controls was 1.53 (95% confidence interval, 1.02-2.29).

Conclusions: Introduction of the Nx2me iPad app during the first 2 weeks of HHD training is associated with significantly higher likelihood of training graduation, even after adjustment for center-level performance metrics.

SA-PO675

Effects of a System-Wide Application of a Comprehensive Pre-Dialysis Education Program on Home Dialysis Therapies Colin A. Hinkamp,[3] Emma R. Segal,[3] Teri B. Martinez,[3] Michelle Thomas,[1] Shahab Bozorgmehri,[2] Tezcan Ozrazgat-baslanti,[3] Ashutosh M. Shukla.[3] *[1]Dialysis Clinic, Inc., Gainesville, FL; [2]None, Newberry, FL; [3]University of Florida, Gainesville, FL.*

Background: The efficacy of comprehensive pre-dialysis education (CPE) with respect to its ability to improve home dialysis (HoD) choice and utilization, across the unselected, spectrum of prevalent US advanced CKD patients has not been examined.

Methods: We present a retrospective analysis of the first 20 months of our CPE program to show the impact of implementing a new CPE program across the entire spectrum of CKD, in a university CKD population with respect to its impact on HoD choice and utilization. Details of our CPE protocol has been prior published.

Results: Over the first 20 months, 200 patients were referred for CPE, of which 32% (n=63) patients chose not to participate in the awareness effort. Of the 137 patients enrolled, the majority (91%) chose to participate in only one session of CPE whereas 8% and 1% attended 2 and 3 sessions, respectively. At the end of the CPE, 72% chose HoD (69% peritoneal dialysis (PD) and 3% home HD (HHD)) whereas 11% chose in-center HD (IHD) with 17% remaining undecided. Over the 20 months of follow-up, 25% needed initiation of renal replacement therapy therapies. Amongst these, 73% were initiated on HoD. Univariate and multivariate analyses showed that age, gender, race, insurance status, marital status, smoking status, body mass index and comorbidity status (Diabetes/CHF), had no impact on the individual choice of HoD. The institution of CPE program led to an overall 66% (p trend<0.001) increase in utilization of HoD over the first 20 months with HoD representing 32% of all prevalent dialysis subjects.

Conclusions: The results validate that institution of CPE program leads to increase to HoD choice and utilization. We further show that benefits of CPE are not limited to only those with socio-economic privilege.

SA-PO676

Feasibility and Effectiveness of an Online Portal for Delivery of Care to Home Dialysis Patients Karthik K. Tennankore,[1] James Kiberd,[1] Kenneth A. West,[1] Christopher T. Chan,[2] Steven D. Soroka.[1] *[1]Dalhousie University, Halifax, NS, Canada; [2]Toronto General Hospital, Toronto, ON, Canada.*

Background: Home dialysis has a number of advantages over in-center hemodialysis. However, there is the potential for improvement in patient communication and experience. The purpose of this study was to determine if an online portal improved patient experience and quality of life (QoL) for home dialysis patients.

Methods: We conducted a pilot interventional study of home dialysis patients. Consecutive patients were enrolled over a four-month period and asked to join the portal via email. The portal (RelayHealth®) consisted of an online messaging platform that permitted asynchronous communication between patients and home dialysis staff. The Consumer Quality Index (CQI, a tool to measure patient experience) and EQ-5D QoL index were recorded at baseline, six and 12 months after enrollment. Satisfaction with the portal was evaluated at the end of follow-up using a Likert scale.

Results: 63 patients were approached, 41 patients consented to participate and 27 (66%) joined the online portal. Mean age was 57.1± 1.9 years and 48% were female. Monthly messaging frequency is noted in Figure 1. 25% of patient-initiated messages were sent for health-related issues. Sixteen and 10 patients completed follow-up at six and 12 months, respectively. Patients had a positive experience with their care at baseline, and there was no improvement in mean CQI during follow-up. EQ-5D QoL also did not differ significantly during follow-up. Overall, patients' were satisfied with the portal (mean Likert score 6.5 ±0.6; 1 completely dissatisfied-10 completely satisfied), felt it was easy to use and did perceive it to be helpful in some aspects of their care.

Conclusions: While feasible, we found no significant improvement in patient experience or QoL after using the portal. Participants were generally satisfied with the portal and it did improve some aspects of their dialysis care.

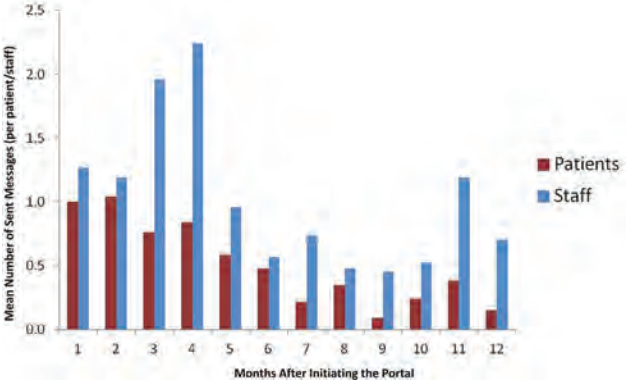

Figure 1. Patient Portal Mean Messaging Frequency (Patients/Staff)

SA-PO677

Quality of Life in Caregivers Compared with Dialysis Recipients: The CO-ACTIVE Substudy of the ACTIVE Dialysis Trial Nicholas A. Gray,[4] Daqing Hong,[3] Brendan Smyth,[2] Min Jun,[6] Kirsten Howard,[8] Kris Rogers,[7] Vlado Perkovic,[7] Li Zuo,[1] Meg J. Jardine.[5] *[1]Peking University People's Hospital, Beijing, China; [2]Newtown, NSW, Australia; [3]Sichuan Provincial People's Hospital, CHENGDU, China; [4]Sunshine Coast University Hospital, Birtinya, NSW, Australia; [5]The George Institute for Global Health, UNSW, Newtown, NSW, Australia; [6]The George Institute for Global Health, UNSW Sydney, Newtown, NSW, Australia; [7]The George Institute for Global Health, Sydney, NSW, Australia; [8]University of Sydney, Sydney, NSW, Australia. Group/Team: ACTIVE Dialysis Steering Committee.*

Background: The support of people living with chronic illness may be dependent on voluntary caregivers whose well-being is critical for patient management.

Methods: A subgroup of participants in the ACTIVE Dialysis study and their nominated caregivers completed quality of life (QOL) questionnaires including the EQ5D, SF-36 physical composite score (PCS) and mental composite score (MCS) as well as the Personal Wellbeing Index. Data was collected at baseline (prior randomisation to standard or extended hour dialysis) and every quarter until study end at 12 months. Baseline caregiver QOL was compared with dialysis patient QOL using paired t test for continuous variables, while predictors of baseline caregiver QOL were determined using multivariable regression.

Results: There were 54 patient and caregiver pairs, predominantly from China. Caregivers had a mean (SD) age of 53.4 (11.3) years and 56% were female. Most (89%) were married or lived with a partner and 24% were in paid employment. Half were educated to secondary school and 33% to university level. Caregivers mostly cared for their spouse/partner (67%) or child (11%), while 20% reported admission to hospital in the preceding year. At baseline, caregivers had a better physical but similar mental QOL compared with dialysis patients (PCS: 46.9±8.7 vs 40.4±10.2, P<0.001); MCS: 47.8±9.7 vs 49.6±12.0, P=0.84). Chinese SF-36 population norms are 77.5 for PCS and 73.6 for MCS. EQ5D for caregivers was 0.9 (0.2) compared with 0.8 (0.2) for dialysis patients (P=0.054). The Chinese EQ5D norm is 0.92. Personal Wellbeing Index was 43.7±15.5 for caregivers (Chinese norm 60-70). Higher SF-36 scores among caregivers was predicted by university education but not age, gender or daily hours spent caring.

Conclusions: Caregivers have a higher physical QOL and equivalent mental QOL to dialysis patients but poorer physical QOL, mental QOL and personal wellbeing than the general Chinese population. University education predicts better QOL and may be a surrogate for current financial resources or other socioeconomic factors.(NCT00649298)

Patient Satisfaction with a Home Dialysis Virtual Ward Karthik K. Tennankore,[1] Annie-Claire Nadeau-Fredette,[2] Joanne M. Bargman,[6] Michael A. Copland,[7] Simon N. Finkle,[1] Matthew J. Oliver,[5] Robert P. Pauly,[3] Jeffrey Perl,[4] Nikhil A. Shah,[3] Deborah Lynn Zimmerman,[3] Christopher T. Chan.[6] *[1]Dalhousie/Nova Scotia Health, Halifax, NS, Canada; [2]Hopital Maisonneuve-Rosemont, Montreal, QC, Canada; [3]None, Edmonton, AB, Canada; [4]St. Michael's Hospital, Toronto, ON, Canada; [5]Sunnybrook Health Sciences Center, Toronto, ON, Canada; [6]Toronto General Hospital, Toronto, ON, Canada; [7]University of British Columbia, Vancouver, BC, Canada.*

Background: The home dialysis virtual ward (HDVW) initiative aimed to address gaps in care after periods of patient transition. The purpose of this study was to assess patient satisfaction with the HDVW.

Methods: The HDVW was a multicenter Canadian trial of home dialysis patients conducted from January 2014-December 2015. The intervention consisted of 5-6 clinician-led telephone interviews over 14 days using a standardized questionnaire to identify and address gaps in care (including medication discrepancies and dialysis prescription changes). The intervention occurred after four care transition events: graduation from home dialysis training, discharge from hospital, following a medical procedure and after treatment with antibiotics. Satisfaction with the HDVW including perceived impact on several care domains was assessed following the intervention using a visual analogue scale (VAS; 1 not satisfied to 10 completely satisfied).

Results: Fifty-five percent (106/193) of patients completed satisfaction surveys and most transitioned to the HDVW after completion of home dialysis training (65%). The mean age of responders was 55+/- 15 years and 51% were female. 58% of patients were performing peritoneal dialysis and most patients (87%) were independent in performing their dialysis. Overall, patients were satisfied with the HDVW (median VAS 8, IQR 2). Patients perceived that the HDVW had a positive impact on their overall health, understanding of medications and access to a nephrologist. In contrast, patients perceived a neutral impact on their chance of needing readmission or travel for dialysis care (Figure 1).

Conclusions: Patients enrolled in the HDVW were highly satisfied with their care. This intervention may be valuable in supporting home dialysis patients during care transitions.

Funding: Commercial Support - Baxter: Investigator Initiated High Dose Hemodialysis Grant

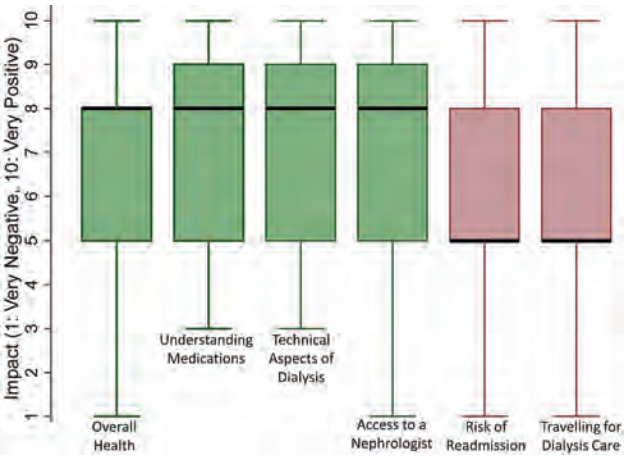

Figure 1. Patient perceived impact of the HDVW on several domains of care

Use of an NxStage Machine at Home for Vegetative, Disabled, and Home Bound Dialysis Patients: A Preliminary Result of a Unique Experience Bassam O. Bernieh,[2] Fredric Calaud,[1] Musa Ahmed,[1] Bienmelyn L. Hernandez.[1] *[1]Al Ain Life, Abu Dhabi, United Arab Emirates; [2]The Heart Medical Center, Al Ain-Abu Dhabi, United Arab Emirates.*

Background: Home hemodialysis (HHD) was invented to treat active, autonomous, and relatively, healthy dialysis patients. The number of dialysis patients, who are vegetative, debilitated, bed and home bound is steadily increasing, creating a major burden on the health care system. We are presenting our new and unique experience of treating these highly co-morbid and disabled dialysis patients, with nursing assisted home hemodialysis (NAHHD). The purpose of this modality is to decrease risks, financial, and emotional burdens, of the patients, their families, and of the health care providers.

Methods: Hemodialysis patients who were fulfilling the National Insurance Company criteria for HHD were accepted in the NAHHD program. These criteria include mainly bed and home bound patients. NxStage System One is used to deliver the hemodialysis at home or at long term care facility with a hemodialysis nurse. Duration of session, weekly number of session and volume of fluid are calculated by dose calculator given by NxStage Company, with a target standardized KT/V of 2.

Results: Nineteen dialysis patients on NxStage machine at home or in a long term care facility were included in this preliminary study. 7(36.8%) males and 12 (63.2%) females. Median age 73 year (42-88). Median duration on NAHHD was 3 months (2-8). Etiology of end stage renal disease was DM 13(68.5%), HTN 5 (26.5%), and familial nephropathy 1(5%). Indications of NAHHD were: vegetative status 1, bed and home bound 17, and 1 HIV case. Vascular access: AVF 8 (42%), AVG 1(5%), and tunneled catheter 10(53%). Average dialysate volume was 25 L. Number of session per week was 4, and average duration of session 3:10 hours. Pre-dialysis BP 131.2±30.5/66±9.3, post dialysis BP 136.6±36.7/ 64.4±5 (p=NS).). The average of the standardized KT/V was 1.94. There was a positive impact of the NAHHD on the patients' quality of life, as measured by time of recovery of 13.75 minutes, average sleeping of 6 hours, and satisfaction of 7.5/10.

Conclusions: NAHHD by using NxStage machine is a very promising modality for treating vegetative, debilitated, bed and home bound dialysis patients, providing a good quality of care, managing the sufferance of the patients, and of their families, and decreasing the risks and the cost of special transportation.

SA-PO680

Correlation between Changes in Body Mass Index and Mortality in Patients Undergoing Long Intermittent Hemodialysis without Dietary Restriction Manabu Hishida,[1] Takahiro Imaizumi,[1] Sawako Kato,[1] Toshiro Nishiyama,[3] Hiroshi Kaneda,[2] Shoichi Maruyama.[1] *[1]Nagoya University Graduate School of Medicine, Nagoya, Japan; [2]Nephrology, kamome clinic, Yokohama, Japan; [3]Nephrology, kamome clinic, Kitaibaraki, Japan.*

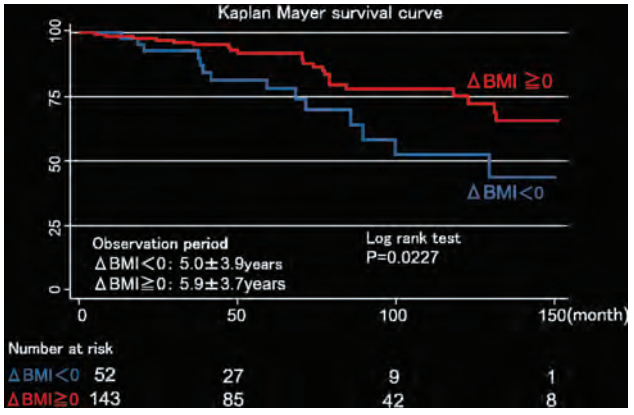
Background: Poor nutritional status is a known mortality risk in chronic kidney disease (CKD) patients. Patients undergoing long intermittent hemodialysis (LIH) without dietary restriction are generally well nourished. We aimed to study whether body mass index (BMI) in patients undergoing this therapy is maintained better and longer than those in conventional hemodialysis (CH), and to understand the association between BMI changes and mortality.

Methods: We examined patients undergoing LIH without dietary restriction with at least one-month dialysis vintage at Kamome Hitachi Clinic (KHC) between January 2002 and April 2016. BMI was calculated based on dry weight. Longitudinal BMI changes were monitored in these patients, and compared to those in CH patients, obtained from previous reports. Using the Cox proportional hazard model, we evaluated mortality risk associated with decrease in BMI.

Results: We enrolled 195 patients, with a mean observation period of 5.7 ± 3.7 years. The baseline BMI at the onset of LIH without dietary restriction was 23.36 ± 3.81. The

mean BMI increased for 3 years after initiation of this therapy, similar to the pattern in CH patients. However, BMI in this study population remained stable longer than that in CH patients. BMI in 52/195 patients decreased from the third to 12th month after initiation of this therapy. The hazard ratio (HR) of mortality was 3.004 [95% confidence interval (CI); 1.415-6.374].

Conclusions: We showed that patients undergoing LIH without dietary restriction maintain BMI for a longer period. Additionally, we found that decreased BMI was associated with an increased mortality risk, suggesting that preserving a good nutritional status in these patients contributes to a better prognosis. In conclusion, although further studies are needed, non restricted dietary therapy in LIH maintains good nutritional status and lowers mortality risk in CKD patients.



SA-PO681

Change in Blood Pressure and Body Weight in Incremental Hemodialysis Patients Inkyong Hur,[1] Yoshitsugu Obi,[1] Elani Streja,[1] Melissa Soohoo,[1] Connie Rhee,[1] Csaba P. Kovesdy,[2] Kamyar Kalantar-Zadeh.[1] *[1]UC Irvine, Orange, CA; [2]University of Tennessee Health Science Center, Memphis, TN.*

Background: Fluid status is expected to improve by increasing hemodialysis (HD) frequency from twice-weekly to thrice-weekly (i.e., incremental HD), but there are scarce data about how much improvement in blood pressure that can be achieved in such patients.

Methods: We retrospectively examined 569 HD patients who transitioned from twice-weekly to thrice-weekly HD within 3 months (M). We compared the pre-dialysis systolic BP (SBP) and post-dialysis body weight (BW) before and after the transition (i.e., -3M to 3M). Data at -1M served as the reference and SBP was categorized into three groups (i.e., <140 [27%], 140-<160 [42%], and ≥160 mmHg [31%]).

Results: The mean±SD age of the cohort was 66±14 years and included 46% women. SBP was increased up to -1M. Patients with the highest baseline SBP showed the greatest improvement in SBP after transition (-7.6±13.1, -10.4±15.8, and -11.9±15.9 mmHg at 1M, 2M, 3M, respectively; $p<0.001$) while patients with the lowest showed slightly increased (0.9±10.2, 1.4±12.0, 3.3±12.9 mmHg at 1M, 2M, 3M, respectively; $p=0.022$). Decreasing trends in post-dialysis BW after transition was consistently observed across the three groups, but was greater in higher baseline SBP patients (-0.7±1.8, -1.0±2.7, and -1.2±3.0 Kg at 1M. 2M, 3M, respectively; $p<0.001$) [Figure].

Conclusions: The transition from twice-weekly to thrice-weekly frequency resulted in an improvement in pre-dialysis blood pressure control especially in patients with higher baseline SBP, which coincided with decreasing trends in post-HD body weight.

SA-PO682

Seven Days a Week Dialysis Service to Achieve an Effective In-Center Short Daily Hemodialysis Program Pedro Pascoal, Adolfo Simon, Kelia Xavier, Vilber Bello, Juliane Lauar, Istenio Pascoal. *Centro Brasiliense de Nefrologia & Dialise, Brasilia, Brazil.*

Background: In-center hemodialysis programs usually operate Monday through Saturday, encompassing two conventional thrice-weekly schedules: Mon-Wed-Fri or Tue-Thu-Sat. On Sundays, in the midst of the long 72-hour Fri-Mon or Sat-Tue interval, dialysis centers are regularly closed and patient care relies on emergency rooms. After setting up a 6 days a week in-center short daily hemodialysis program, we started to provide dialysis treatments also on Sundays. We have now examined the 10-year impact of the seven-day availability on patient schedule and compliance as well as on hospitalization and survival rates.

Methods: We assessed the conversion rate from 6 to 7 times a week, the prevalence of absences from hemodialysis treatments (no shows), the hospitalization rate and the actuarial survival curve of 160 private-insured patients (98M/62F; mean age at dialysis initiation 57.3±8.2 yrs, range 8-92) receiving in-center short daily hemodialysis treatments (6-7 times/week; lasting 118±18.7 min, range 90-180; ultrapure dialysate and single-use highflux dialyzer). To accommodate all patient needs, our hemodialysis schedule encircles five 2-hour duration shifts on weekdays, 3 shifts on Saturdays and 2 shifts on Sundays.

Results: From June 2007 to May 2017, 24 out 160 (15%) of our cumulative short daily hemodialysis patients extended their schedule from 6 to 7 treatments per week, 9 (6%) chose Saturdays as their regular day-off, and the remained 127 (79%) have ocasionally dialysed on Sundays to replace most of the missed treatment occurring in their original track. Over the 10-year study period, the average missed treatment rate was 1.47% or 4.5 days per patient-year and the hospitalization rate was 0.4 admissions per patient-year. In parallel, the 5-year cumulative patient survival rates were 98%, 92%, 82%, 69% and 60% at 12, 24, 36, 48 and 60 mo, respectively. Sunday dialysis additional costs have been offset by favoring low missed treatment rate and very low hospitalization rate.

Conclusions: Historically all but a few dialysis centers have provided treatments and care for patients Monday to Saturday, leading to concerns of higher mortality over weekends. To sustain a short daily hemodialysis program and to overcome its compliance and economic challenges, our dialysis center has successfully established a regular seven days a week schedule.

SA-PO683

Quasi-Frequent Hemodialysis Affects Hospitalization for Cardiovascular Disease and Cardiac Function in ESRD Patients with Severe Heart Failure Masataka Banshodani, Hideki Kawanishi, Misaki Moriishi, Sadanori Shintaku, Shinichiro Tsuchiya. *Tsuchiya General Hospital, Hiroshima, Japan.*

Background: Previous reports indicated that frequent hemodialysis (FHD) maintained cardiac function. However, no reports have evaluated the impact of quasi-FHD (q-FHD) on hospitalization for cardiovascular diseases (CVDs) and cardiac function in end-stage renal disease (ESRD) patients with severe heart failure.

Methods: This is a retrospective observational study that evaluated hospitalizations for the period from 1 year before to 1 year after q-FHD initiation (≥4 times a week) and ejection fraction (EF) by using echocardiography in ESRD patients with severe heart failure (New York Heart Association Functional Classification III or IV) at a single center between 1995 and 2014.

Results: Of 1,955 hemodialysis (HD) patients, 60 (3.1%; 42 men; mean age, 65.4 years; mean dialysis vintage, 80.0 months) started q-FHD (mean, 4.3 ± 0.7 times a week) and 52 continuously received q-FHD (4.6 ± 0.8 times a week) 1 year later. The 1-year mortality rate after q-FHD initiation was 13.3%. The mean EF decreased from 61.8% at dialysis initiation to 50.6% at q-FHD initiation ($P < 0.001$) but did not change 1 year later (49.4%; $P = 0.7$). All-cause hospitalization rates (per person-year) were similar between before and after q-FHD initiation (1.79 [102 hospitalizations] vs 2.07 [115 hospitalizations]; $P = 0.2$). On the other hand, the emergency hospitalization rate for CVDs significantly decreased from 0.73 to 0.37 after q-FHD initiation ($P = 0.002$). However, the emergency hospitalization rates for infectious diseases, including vascular access-related infection, were similar between before and after q-FHD initiation (0.12 vs 0.16; $P = 0.5$).

Conclusions: The hospitalization rate for CVDs significantly decreased after the q-FHD initiation in the ESRD patients with severe heart failure. Moreover, q-FHD maintained cardiac function in these patients. Further multicenter studies are needed to evaluate these findings.

SA-PO684

Change in Ultrafiltration Volume in Incremental Hemodialysis Inkyong Hur,[1] Yoshitsugu Obi,[1] Elani Streja,[1] Connie Rhee,[1] Csaba P. Kovesdy,[2] Kamyar Kalantar-Zadeh.[1] *[1]UC Irvine, Orange, CA; [2]University of Tennessee Health Science Center, Memphis, TN.*

Background: Incremental hemodialysis (HD) is a strategy of the gradual increase from twice-weekly to thrice-weekly HD in incident ESRD patients. While it is expected that augmentation of dialysis frequency leads to improvement in patients' health status, there are scarce data about changes in ultrafiltration in such patients.

Methods: We retrospectively examined 569 HD patients who underwent incremental HD between 2007 and 2011. We compared the ultrafiltration volume (UFV) per session and weekly interdialytic weight gain (IDWG) before and after the transition (i.e., -3 months (M) to 3M). Ultrafiltration (UF) at -1M served as the reference and was categorized into tertiles (<1.7, 1.7 to <2.8, and ≥2.8 L/session).

Results: The mean±SD age of the cohort was 66±14 years, and included 46% women. Patients with the highest baseline UFV showed a decreasing trend in UFV/session after transition (-0.3±0.7,-0.5±0.7, and -0.5±0.7 L at 1M, 2M, 3M, respectively; $p<0.001$), but patients with the lowest baseline UFV paradoxically showed an increasing trend (0.1±0.6, 0.3±0.7, and 0.4±0.7 L at 1M, 2M, 3M, respectively; $p<0.001$). Increases in weekly IDWG after the transition were consistently observed across UFV tertiles, but were greater among patients with lower baseline UFV (2.8±1.8, 3.5±1.9, and 4.1±2.2 L at 1M, 2M, 3M, respectively; $p<0.001$) [Figure].

Conclusions: Transitioning from twice-weekly to thrice-weekly HD resulted in less UFV/session among patients with higher baseline UFV, but paradoxically resulted

in increased UFV/session among patients with the lowest baseline UFV. Weekly IDWG increased irrespective of baseline UFV.

SA-PO685

Calcium (Ca) and Phosphate (P) Balance in Short Daily Hemodialysis (SDHD) with the NxStage System One Cycler (NSO): Comparison with Standard Bicarbonate Dialysis (BHD) Chiara Carla Maria Brunati,[1] Roberto Corciulo,[3] Francesca Gervasi,[5] Costanza Casati,[5] Simone Corciulo,[2] Loreto Gesualdo,[4] Giacomo Colussi.[1] *[1]ASST Niguarda, Milano, Italy; [2]University of Foggia, Foggia, Italy; [3]Azienda Ospedaliera Policlinico Bari, Bari, Italy; [4]University of Bari, Altamura, Italy; [5]University of Milan Bicocca, Milan, Italy.*

Background: SDHD with NSO has gained popularity as home HD prescription. Short HD sessions, as in use with NSO, might not allow adequate removal of P, which benefits from time to optimize removal.

Methods: We compared single run and weekly balances of P and Ca, and changes in plasma levels, in 25 pts treated with NSO in 2 centers with different prescription: 14 pts (Milan) were prescribed 6 runs/week (dialysate 22.7±3.8L/run, time 154±23min/run), 11 pts (Bari) 4 or 5 runs/week (mean 4,8±0,48, dialysate 24,1±3,5, time 194±24). Data were compared to those in 14 pts treated with BHD (3/week, 4 hours, dialysate 500ml/min).

Results: Are shown in table 1.

Conclusions: Despite lower P removal per run in NSO, weekly removal was equal (Bari) or higher (Milan) than in BHD. More frequent NSO runs (6) are more efficient than less frequent runs (4/5). Plasma P decrease was quantitatively similar in NSO and BHD, despite lower run duration. P removal was directly correlated with pre-HD plasma levels in both NSO and BHD. Plasma Ca level increased less in NSO than in BHD, yet PTH fell along the run; Ca balance was correlated to basal Ca levels and net UF; at observed UF, it was negative at plasma Ca>8.5mg/dL. Our data show that SDHD with NSO, despite lower run time and dialysate volume, allows similar P removal as compared to BHD; plasma Ca changes and balance do not substantially differ in NSO and BHD.

SA-PO686

Cardiovascular Assessment in Patients on Nxstage System One (NxO) Chiara Carla Maria Brunati,[1] Francesca Gervasi,[2] Costanza Casati,[2] Giacomo Colussi.[1] *[1]ASST Niguarda, Milano, Italy; [2]University of Milan Bicocca, Milan, Italy.*

Background: Left ventricular hypertrophy (LVH) is an independent risk factor for mortality in patients on conventional hemodialysis (HD). According to the Frequent Haemodialysis Network daily trial, increased frequency of conventional in-centre HD is associated with a reduction in antihypertensive therapy, extracellular fluid (ECW) and left ventricular mass. Little data exists with the non-conventional daily dialysis system, NxO.

Methods: From May 2011 to December 2016, we enrolled 12 patients (median age 49yrs, from 25yrs - 66yrs) on a NxO home program, follow up of 22 months (variation 3 to 68months, 6runs a week, QD 22±4L, duration of session 144±25min StKt/V 2,4±0,2). Treatment effects of volume parameters were evaluated monthly in all patients in the interdialytic period, according to BIA parameters (BIA impedentiometry Frisenius) including the proBNP levels. In 6 patients with 12 months of follow up, an echocardiography was also performed in order to evaluate the cardiac mass and compare with data at baseline. We compared BIA evaluation, measurements of the cava diameter and of the presence of lung comets in NxO patients, a total 134 tests, with those of 30 patients on traditional HDB treatment who were evaluated directly post session, as normohydratate. ProBNP was evaluated in both groups.

Results: We observed a reduction of mean blood pressure (from 97±17 to 81±5mmHg) and this even despite a reduction in antihypertensive drug units (median of –2UD from 0 to – 15UD). In 7 patients with 12 months of follow up, a significant reduction in cardiac mass was recorded (148±44 gr/m^2 to 120±35gr/m^2 p≤0.05). The BIA evaluation evidences an overhydratation state in only 10% of measurements. In comparison with normohydratate HBD patients, no difference in ECW/TBW values were recorded. NxO patients had higher levels of ICW/TBW values, indicating a more physiological distribution of volume as reflected by lower levels of proBNP.

Conclusions: According to our results, daily HD sessions using NxO improves certain cardiovascular parameters. Although no reduction in extra-cellular volume was seen, we can hypothesize excellent volume control due to the interdialytic measurements.

Successful Home Hemodialysis in a Patient with an LVAD (Left Ventricular Assist Device) Shubha Ananthakrishnan,[1] Munir Janmohamed.[2] *[1]UC Davis, Sacramento, CA; [2]Cardiology, UCSF, San Francisco, CA.*

Background: LVADs for end-stage heart failure are on the rise as a bridge to transplant, including in patients on dialysis. There are many technical and logistic challenges faced by patients with an LVAD, who dialyze at a dialysis center. Here we describe successful home hemodialysis by a patient with an LVAD, awaiting a combined heart-kidney transplant.

Methods: The patient is a 39 yr old African American male, with ESKD due to FSGS, formerly on peritoneal dialysis for 6 years, who started home hemodialysis in 2015. He also has a h/o non-ischemic cardiomyopathy with EF around 18%. Given cardiac status and pulmonary hypertension, a decision was made to implant a HeartWare® LVAD in March 2016 as a bridge to transplant, with a flow of 5L/min, speed 2400 RPM, pulsatility of 7. The patient continued on home hemodialysis after the LVAD insertion, caring for the LVAD equipment, drive line dressing changes, as well as performing home hemodialysis without a partner. Home hemodialysis was performed using the NxStage® platform, Qb 400 ml/min, Flow fraction 35%, 1K, 3Ca bath, 5 days a week, using a L forearm AV fistula. BPs were controlled to goal SBP < 100 mm Hg targeting optimal dry weight and medication use. The patient had palpable radial pulses and was able to record blood pressures at home using a standard BP cuff and monitor. Warfarin anticoagulation was used for VAD patency, with goal INR 2-2.5. The patient did not require ESA therapy and was able to maintain Hb around 10 – 12 with intermittent iron alone. Other labs of interest: standard Kt/V 2.11, Albumin 4.3, Ca 9.3, Phos 4.9, PTH 655. He had one episode of bacteremia that was successfully treated with antibiotics. The patient continues to dialyze at home and is closely cared for by the home hemodialysis team and the LVAD team.

Results:

Conclusions: Hemodialysis in LVAD patients has been reported in center-based dialysis setting. However, due to several logistic challenges including training and familiarity of dialysis center staff to care for these patients, there are only a handful of hemodialysis centers that are able to accept patients with LVAD. Home hemodialysis in LVAD patients is feasible and overcomes these challenges of in-center dialysis. Very close communication and coordination between the LVAD team and HHD team is crucial.

SA-PO688

Case Report: Patient with a Total Artificial Heart Maintained on Outpatient Dialysis While Listed for Combined Organ Transplant: A Single Center Experience Ramy M. Hanna,[2] Huma S. Hasnain,[3,2] Mohammad Kamgar,[1,2] Raffi R. Minasian,[1] James Wilson.[1,2] *[1]Manhattan Beach, CA; [2]UCLA Health, Rolling Hills Estates, CA; [3]UCLA Nephrology, Los Angeles, CA.*

Background: Advanced mechanical circulatory support is increasingly being used with more sophisticated devices that can deliver pulsatile rather than continuous flow. These devices are more portable as well, allowing patients to await cardiac transplantation in an outpatient setting. It is known that patients with renal failure are at increased risk for developing worsening acute kidney injury during implantation of a ventricular assist device (VAD) or more advanced modalities like a total artificial heart (TAH).

Methods: Dealing with patients who have an implanted TAH who develop renal failure has been a challenge with the majority of such patients having to await a combined cardiac and renal transplant prior to transition to outpatient care. Protocols do exist for VAD implanted patients to be transitioned to outpatient dialysis care, but there are no reported cases of TAH patients with ESRD being successfully transitioned to outpatient dialysis care.

Results: In this report, we identify a patient with a TAH and ESRD transitioned successfully to outpatient Hemodialysis (HD) and maintained for more than two years, though he did not survive to transplant

Conclusions: It is hoped that this report will raise awareness of this possibility, and assist in the development of protocols for similar patients to be successfully transitioned to outpatient dialysis care.

SA-PO689

In Vitro Mast Cell Degranulation Assay to Assess Hemodialysis Sorbent Cartridges Stephen Merchant,[4] Mark Costanzo,[4] Claudy Mullon,[4] Mayuri Thakuria,[3] Amparo L. Figueroa,[1] Robert J. Kossmann.[2] *[1]Fresenius, Boston, MA; [2]Fresenius Medical Care North America, Waltham, MA; [3]Fresenius Medical Care, North America, Waltham, MA; [4]Fresenius Medical Care, Oklahoma City, OK.*

Background: Hemodialysis (HD) sorbent cartridges aimed at dialysate regeneration contain urease to hydrolyze urea into bicarbonate and ammonium. Urease may come from sources that can cause allergic reactions. Here, we compared in vitro, two sorbents in their propensity to cause allergic reaction.

Methods: In vitro mast cell degranulation method was used to examine dialysate samples from an FDA cleared sorbent cartridge (REDY) and a new cartridge (PAK). Both sorbent cartridges were primed with typical hemodialysis dialysate and recirculated for 30 minutes. Samples for analysis were taken from the recirculated dialysate in the reservoir at 10, 20, and 30 minutes. Diluted (50 µl) concanavalin A (Con A) standards in complete RPMI plus IL-3 medium (positive controls), culture medium (negative control), or sorbent cartridge effluent test articles were added to 200 µL of culturing medium containing ~0.3 million MC/9 cells, in duplicate. Cells were incubated for 24 hours at 37 degrees C under 5% CO_2. Histamine levels in each cell culture supernatant sample were determined using Histamine ELISA Cell Culture Kit. To evaluate the responsiveness of the method, various concentrations of Con A were used as positive controls.

Results: There was no significant difference (p=NS) in the histamine concentrations between both the PAK and REDY sorbent dialysates vs. negative control at 10, 20, and 30 minutes. At Con A concentration of 0.1 – 0.8 µg/ml, positive correlation was observed with histamine release, r=0.95, p<0.001. At con A concentration of 0.1 – 0.8 µg/ml, the mean histamine release was between 17.76 -94.52 ng/ml. On the other hand, the negative control had a mean histamine release of 17.68 ng/ml.

Conclusions: In this proof of concept study, we report the first ever in vitro histamine release testing of sorbent cartridge dialysates incubated in the presence of mast cells. The findings demonstrate that the histamine release from the dialysate generated by the PAK sorbent is not significantly different to that of the negative control culture medium and the dialysate generated by the REDY sorbent.

SA-PO690

Natural History of Thyroidal Functional Disease in Peritoneal Dialysis Jean-christophe Szelag,[1] Carlos Cardozo,[1] Myriam Pastural,[1] Maurice Laville.[1,2] *[1]AURAL, LYON, France; [2]Université de Lyon, Pierre-Bénite, France.*

Background: Thyroidal functional disease (TFD) is frequent in chronic kidney disease. The main reported abnormalities are hypothyroidism, especially in its subclinical pattern (SCH), and low circulating triiodothyronine (low T3 syndrome). Recent data has established a link between TFD and mortality in stage V CKD, however, little is known about the natural evolution of TFD in end stage renal disease patients, especially treated with peritoneal dialysis.

Methods: We studied a cohort of 114 incident peritoneal dialysis patients (mean follow up, 23 +/- 19 months; men: 59,6%, diabetes: 25%, 61,7+/-16.6 years old) tested for thyroid function on a quarterly basis. THS above the highest normal lab value (4.2 mIU/L) with normal fT4 defined SCH, an isolated fT3 below the lowest normal lab value (2,5 pmol/L) defined low T3 syndrome, in untreated patients.

Results: At baseline, 96 patients were euthyroid, 17 (14,9%) displayed a SCH and only one a low fT3 condition (0,8%). Low fT3 corrected in less than three months. Thyroid function corrected in all but two SCH patients along an average period of 9 +/- 7,7 months. A late recurrence was observed in one patient. Multivariate analysis didn't suspect any predictive variable associated with baseline SCH (age, sex, diabetes, hemodialysis before PD, cardio-renal syndrome, nutrition status, inflammation status) while two previous stories of thyroiditis and one exposition to amiodarone were found in three patients with persistent/recurrent SCH. Eight patients (8,3%) with normal thyroidal status at baseline subsequently evolved to SCH (4) or low fT3 syndrome (4) after a mean follow up of 6,2 +/-5,9 and 7,1+/-6,9 months, respectively. Diabetes (SCH, *p= 0,02*) and albuminemia (low fT3, *p=0,043*) were the only factors associated with the occurrence of a thyroid disturbance in baseline euthyroid patients. Of interest, low fT3 was always transient and disappeared spontaneously while SCH became a constant disorder in all but one patient (75%), No patient developed overt hypothyroidism over the follow-up.

Conclusions: SCH is highly prevalent in patients starting PD but disappeared within the first year in the absence of previous thyroid disease. Its signification could be different when occurring in initially euthyroid individuals. Low fT3 syndrome is less common and seems to be a transient condition associated with albumin variations.

SA-PO691

Dialysis Modality in PD Patients Undergoing Laparoscopic Surgery Janis Cho,[5] Jennifer L. Waller,[5] Mufaddal F. Kheda,[5] Stephanie L. Baer,[1] Rhonda E. Colombo,[5] Lu Huber,[2] John J. White,[5] Troy J. Plumb,[4] N. Stanley Nahman.[3,1] *[1]Augusta VA Medical Center, Augusta, GA; [2]Avera Medical Group Nephrology, Sioux Falls, SD; [3]Medical College of Georgia at Augusta University, Augusta, GA; [4]University of Nebraska Medical Center, Omaha, NE; [5]Augusta University, Augusta, GA.*

Background: Historically, PD patients requiring abdominal surgery required a change to hemodialysis (HD). Laparoscopic surgery (LPS) has been used for many abdominal procedures, but it is unclear if PD patients can undergo LPS and continue with PD. To address patterns of dialysis modality change in PD patients undergoing LPS, we queried the USRDS.

Methods: Incident PD patients from 2004 – 2011 (n=56,192) who underwent LPS were studied. Groups included: no interruption of PD(P); planned temporary (PT) HD then back to PD($_{PT}$HD-P); permanent switch (PS) to HD($_{PS}$HD); urgent temporary (UT) HD then back to PD($_{UT}$HD-PD); or urgent(U) HD with PS to HD($_{U}$HD-$_{PS}$HD). Demographics and outcomes were determined. The relative risk (RR) of complications versus no interruption of PD (P) up to 3 months post-op were estimated.

Results: 7298 PD patients had LPS, 45% women, 74% White, with mean±SD age 55±3 years, and time on dialysis of 16.6±1.9 months. Outcomes and group comparisons are shown in the table. Continuing PD was the most common form of dialysis in PD patients undergoing LPS, had the lowest complication rate, and may represent the lowest-risk cohort for LPS. Planned switches to HD were better than urgent switches, and were likely applied to higher risk patients. Urgent switches that returned to PD had the highest complication rates for peritonitis, bacteremia, and wound infection, and may indicate cohorts of patients developing complications with or during LPS.

Conclusions: Continuing PD during laparoscopic surgery is common and appears safe. The need for urgent HD is uncommon, but if PD is resumed, it is associated with a higher risk of post-op complications. Risk stratification may help predict whether to switch dialysis modality in PD patients prior to LPS.

Dialysis Modalities Among PD Patients Undergoing LPS

Variable	$_{PT}$HD-P	$_{PS}$HD	$_{UT}$HD-P	$_{U}$HD-$_{PS}$HD	P	p Value
N (%)	2801 (27)	1465 (19)	250 (3.3)	159 (2.1)	3529 (47)	NA
Final logistic regression model comparing switches to P (RR (95% CI))						
Level	Peritonitis		Bacteremia		Wound Infection	
$_{PT}$HD-P vs P	1.98 (1.41 – 2.79)		5.76 (4.44 – 7.47)		2.72 (1.50 – 4.95)	
$_{PS}$HD vs P	0.44 (0.24 – 0.81)		1.48 (1.03 – 2.12)		2.24 (1.14 – 4.42)	
$_{UT}$HD-P vs P	5.64 (0.35 – 9.24)		6.37 (4.15 – 9.79)		6.05 (2.57 – 14.22)	
$_{U}$HD-$_{PS}$HD vs P	1.79 (0.71 – 4.53)		4.50 (2.48 – 8.18)		5.32 (1.76 – 16.03)

Comparison of Two Different Neutral Peritoneal Dialysis Fluids in Japan, Bicarbonate/Lactate-Buffered Fluid versus Lactate-Buffered Fluid Yudo Tanno, Nanae Matsuo, Yukio Maruyama, Ichiro Ohkido, Keitaro Yokoyama, Takashi Yokoo. *Division of Nephrology and Hypertension, Department of Internal Medicine, The Jikei University School of Medicine, Tokyo, Japan.*

Background: Recently, new neutral peritoneal dialysis fluid (PDF) contained bicarbonate 25mEq/L and lactate 10mEq/L (Bic/Lac PDF), instead of lactate 40mEq/L contained neutral fluid (Lac PDF), was available in Japan. Bic/Lac PDF is expected to achieve better biocompatibility and to compensate overcorrection of metabolic acidosis by reducing total alkaline buffer. However, there are few reports comparing Bic/Lac PDF and neutral Lac PDF. Therefore, we conducted a prospective study to clarify the effect of Bic/Lac PDF on clinical status including acid-base disturbance.

Methods: Sixty-three stable PD patients were included (60±12 y/o, male 76%, PD duration 43.6±30.2 months). All PDF contained 40 mEq/L of lactate before changing to Bic/Lac PDF, and the daily volume of PDF was not changed until the end of the examination period. The patient's existing medications were not changed during the study period. The patients' data (bicarbonate, pH, ionized calcium, carbon dioxide and Lactate levels) were obtained before and 3 months after the induction of Bic/Lac PDF. We also investigated the change in effluent drain volume, D/P creatinine ratio from the 4-hour peritoneal equilibration test and residual renal function.

Results: After switching PDF, bicarbonate and carbon dioxide were decreased significantly (26.5±2.8 vs. 24.4±2.6 mEq/L; P<0.01, 46.6±6.4 vs. 43.2±5.8 mmHg; P<0.01, respectively). Patients treated with low dose PDF (3.3±0.5 L/day) demonstrated insufficient correction of metabolic acidosis (bicarbonate 24.0±2.7 vs. 21.9±3.8 mEq/L; P<0.01) as compared with middle dose PDF (5.6±0.6 L/day, bicarbonate 26.7±2.2 vs. 23.9±2.0 mEq/L; P<0.01) and high dose PDF (7.5±1.0 L/day, bicarbonate 29.7±2.5 vs. 26.8±1.6 mEq/L; P<0.01). Whereas, other parameters did not change significantly between before and after induction of Bic/Lac PDF.

Conclusions: The new Bic/Lac PDF is effective for overcorrection of metabolic acidosis in PD patients, although it must be carefully managed in such a patient who is treated with low dose PDF.

Association of Gender with the Utilization of Peritoneal Dialysis Savannah Vogel,[2] Brad C. Astor,[1] Sana Waheed.[1] *[1]University of Wisconsin, Madison, WI; [2]University of Wisconsin - Madison, Madison, WI.*

Background: Peritoneal dialysis (PD) is underutilized in the United States compared to other countries. We analyzed data from the USRDS and US census to assess the association between gender and initial dialysis modality to determine whether gender might impact PD utilization. We also investigated gender-specific associations of age, race/ethnicity, median household income and employment status on the incidence of PD.

Methods: We estimated the proportion of USRDS patients utilizing PD as their initial modality between 2000-2014, adjusting estimates to the mean value of all covariates (age, race, ethnicity, cause of ESRD, comorbidities, incidence year, income and employment status) and compared these estimates for women and men.

Results: 108,022 patients (45% women) initiated PD and 1,375,825 patients (44% women) initiated hemodialysis during this time period. Women were more likely than men (OR: 1.16, 95% CI 1.15-1.18) to utilize PD as their initial dialysis modality. Women were more likely than men to initiate PD for age <67. However, this relationship was reversed for those ≥68 years [Fig. 1]. Other factors influencing the likelihood of being on PD included black race (OR: 0.56), median household income (OR for each $10K higher: 1.03), and being employed (OR: 2.49) [Table 1].

Conclusions: Our results indicate that women in the US were more likely than men to utilize PD as their initial modality, but this association varies with age. This study emphasizes the role gender may play in medical decision making and highlights the need to further investigate the factors that influence patients of each gender to choose PD.

Table 1. Gender, race, income and employment influence the likelihood on being on PD.

	Odds Ratio	95%CI
Women/Men	1.16	1.15-1.18
Black/White	0.56	0.55-0.57
Each $10K higher in median household income	1.03	1.02-1.04
Part or full-time employed/unemployed	2.49	2.45-2.53

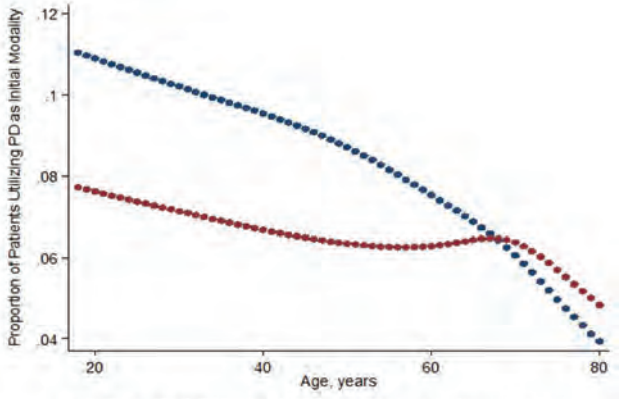

Figure 1. Incidence of PD decreases with age. Men are more likely than women to utilize PD after age 67.

Engaging Stakeholders in Protocol Development for Qualitative Research on Remote Management for Peritoneal Dialysis Lalita Subramanian,[1] Rosalind H. Kirk,[2] Rachel Perlman,[3] Therese T. Adamowski,[3] Margie D. Mccall,[4] Erica E. Perry,[5] Kathy A. Restovic,[5] Lisa M. Fitzpatrick,[6] Nicole E. Bryant,[7] Rachel Tocco,[1] Kimberly Fox,[1] James A. Sloand,[8] Jeffrey Perl,[9] Ronald L. Pisoni.[1] *[1]Arbor Research Collaborative for Health, Ann Arbor, MI; [2]Independent Qualitative Research Consultant, Edinburgh, United Kingdom; [3]University of Michigan Health Center, Ann Arbor, MI; [4]Greenfield Health Systems, Detroit, MI; [5]Stakeholder Group, Arbor Research Collaborative for Health, Ann Arbor, MI; [6]McLaren Northern Michigan, Harbor Springs, MI; [7]National Kidney Foundation-Michigan, Ypsilanti, MI; [8]Baxter Healthcare Corporation, Deerfield, IL; [9]St. Michael's Hospital, Toronto, ON, Canada.*

Background: Remote management (RM) involves various technologies designed to remotely monitor and manage a range of health conditions in order to alert healthcare professionals (HCPs) of any changes that might need follow-up. In this study, patients, social workers, nurses and nephrologists, together with researchers, developed interview and focus group guides for qualitative data collection on factors important to different stakeholders in considering RM technology for patients on peritoneal dialysis (PD).

Methods: Researchers introduced concepts and shared information on current RM technology for PD before proceeding with four brainstorming sessions with the stakeholder group on positives and negatives of RM for patients, care partners and HCPs in turn. Interviews of five HCP teams in the United Kingdom, United States and Canada using or transitioning to RM use for PD care provided insight on current technology. Concepts derived from all these sessions were categorized and mapped to domains in the COM-B framework (Figure 1).

Results: Literature, stakeholder and RM user perspectives, and a theoretical framework to explore the role of RM in modifying behavioral factors influencing PD and RM use informed the semi-structured interview and focus group guides for collecting data from patients, care partners and HCPs, as well as the study protocol.

Conclusions: This stakeholder-engaged process will increase the relevance of questions to participants and improve the quality of data collected, without the limitations of researchers' pre-conceived views on RM. Data from this study will provide deeper understanding of factors related to skill, access and motivation in PD and RM use which will inform HCPs and technology developers leading to improved care for patients.

Funding: Commercial Support - Baxter Healthcare Corporation

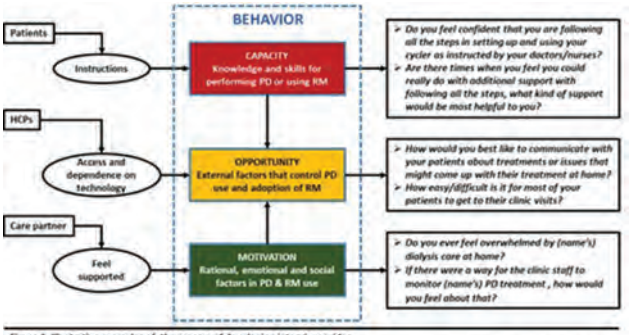

Figure 1. Illustrative examples of the process of developing interview guides.
Concepts (ovals) relevant to each stakeholder group involved in RM and PD were mapped to domains (colored boxes) of the COM-B* framework to drive questions on the respective interview guides.

Ribonucleases Defend the Peritoneum from Invading Pathogens During Chronic Peritoneal Dialysis Neha Dhingra,[1] Hanna H. Cortado,[1] Sudipti Gupta,[2] Birong Li,[1] Ashley R. Jackson,[1] Ariel Cohen,[1] Christina B. Ching,[2] John D. Spencer,[1] Rose M. Ayoob,[1] Brian Becknell.[1] *[1]Nephrology, Nationwide Children's Hospital, Columbus, OH; [2]Urology, Nationwide Childrens Hospital, Columbus, OH.*

Background: Peritonitis is a rare but serious complication in ESRD patients undergoing chronic peritoneal dialysis (PD). Improvements in standardized technique have reduced but not eliminated the incidence of peritonitis, which remains the leading cause of PD failure and change in dialysis modality. The RNase A superfamily encodes cationic antimicrobial peptides (AMPs) with broad spectrum activity against pathogens implicated in peritonitis in the PD population. Here, we evaluated the expression of these AMPs in the baseline PD effluents of pediatric ESRD patients undergoing chronic PD, in the absence of peritonitis.

Methods: PD effluent was collected from seven pediatric patients undergoing chronic cycling PD, prior to starting nightly dialysis. We also collected ascites fluid from patients with acute kidney injury undergoing paracentesis or acute PD. RNases were analyzed by immunocytochemistry, qRT-PCR Western blotting, and ELISA. RNase localization within omentum was analyzed by immunofluorescence microscopy. RNase bactericidal activity was evaluated by incubation with *Staphylococcus epidermidis*, followed by plating and colony enumeration.

Results: Viable cells recovered from PD effluent express RNase3, RNase6, and RNase7 mRNA and protein. These AMPs are present in cell-free supernatants from ascites and PD effluent, and RNase7 levels are the most abundant. Immunocytochemistry identifies RNase3+ eosinophils, RNase6+ macrophages, and RNase7+ mesothelial cells as sources of these AMPs. These RNases are distributed similarly in omentum, and RNase7 expression is detected in immortalized mesothelial cells. Functionally, recombinant peptides derived from RNase 3, 6, and 7 exhibit potent bactericidal activity toward *S. epidermidis.*

Conclusions: Multiple AMPs in the RNase A superfamily are present in peritoneal fluid of patients with ESRD undergoing PD. These AMPs have distinct cellular sources and exhibit antimicrobial activity toward *S. epidermidis*. The omentum is a source of multiple AMP producing cells, a finding with potential clinical implications given the practice of omentectomy at PD catheter insertion. Strategies aimed at preserving or enhancing RNase levels and antimicrobial activity may comprise a formidable approach to peritonitis prevention and treatment.

SA-PO696

Activation of mTORC1 Disrupted LDL Receptor Pathway: A Potential New Mechanism for the Progression of Peritoneal Fibrosis by High-Glucose PDS Liu Jing. *Institute of Nephrology, Affiliated Drum Tower Hospital, Medical School of Nanjing University, Nanjing, China., Nanjing, China.*

Background: High-glucose peritoneal dialysis solution (PDS) play important roles in the peritoneal fibrosis. Recent studies demonstrated that high glucose could promote the intracellular accumulation of cholesterol via low density lipoprotein receptor (LDLr) in peritoneal mesothelial cell (PMC), which induce the expression of extracellular

matrix protein in PMC. This study aimed to explore the potential mechanisms of the dysregulation of LDLr under the stimulation of high-glucose PDS.

Methods: Human PMCs (HMrSV5) was stimulated by high-glucose PDS. Oil red O and filipin staining were used to examine lipid accumulation. The expression of LDLr regulation, mammalian target of rapamycin complex1 (mTORC1) pathway and extracellular matrix proteins were assessed by real-time PCR and western blot.

Results: Results demonstrated that high-glucose PDS increased lipid accumulation in PMCs. These effects were correlated with an increase in LDLr transcription, which was mediated through the up-regulation of sterol regulatory element-binding protein (SREBP) cleavage-activating protein (SCAP), SREBP-2, and through enhanced translocation of the SCAP/SREBP-2 complex from endoplasmic reticulum (ER) to Golgi. In addition, our data indicated that there was a parallel increase in the expression of extracellular matrix proteins such as fibroblast specific protein-1, a-smooth muscle actin and collagen I. Further analysis showed that high-glucose PDS enhanced the protein phosphorylation of mTOR, eukaryotic initiation factor 4E-binding protein 1, and p70 S6 kinase. Interestingly, blocking mTORC1 activity inhibited the gene transcription of LDLr and decreased extracellular matrix deposition.

Conclusions: Our findings demonstrated that increased mTORC1 activity exacerbated peritoneal fibrosis by disrupting LDLr transcriptional regulation.

SA-PO697

Effect of Lipo-PGE1 on Peritoneal Transport Function and Micro-Inflammatory State in Peritoneal Dialysis Patients Hao Zhang,[1] Jianwen Wang.[2] *[1]The Third Xiangya Hospital of Central South University, Changsha, China; [2]The third Xiangya Hospital of Central South University, Changsha, China.*

Background: Besides the low molecular weight(LMW) solutes, macromolecule such as proteins can also be transported from plasma to peritoneal cavityin peritoneal dialysis(PD). Prostaglandin E1 incorporated in lipid microspheres (Lipo-PGE1) is a potent vasodilator. It was shown to protect vascular endothelial cellsand inhibit the infiltration of inflammatory cells. The aim of this study was to investigate the effect of Lipo-PGE1 on peritoneal transport function and micro-inflammatory state in PD patients.

Methods: We recruiteda total of 89 CAPD patients in the Third Xiangya Hospital from January 2015 to January 2017. Patients were divided into 2 groups, namely the experimental group (Lipo-PGE1 group, n=46) and the control group (not treated with Lipo-PGE1, n=43). The MTACs of urea and creatinine were regarded astheindexes for the transport of LMW solutes. Peritoneal clearances of β2-microglobulin, cystatin C, and albumin were taken asthe indexes to evaluate peritoneal macromolecule transport. IL-6 appearance rate(AR)in the PD effluent, serumIL-6, and hs-CRP were the inflammatory indicators.

Results: The results in the same group before and after2-week treatment showed that: in the experimental group, peritoneal clearances of β2-microglobulin,cystatin C and albumin increased significantly(P<0.05); IL-6 AR, serum IL-6 and hs-CRP level decreased obviously (P<0.05); The MTACs of urea and creatininehave no statistical significance (P>0.05). In the control group, after 2-week treatment, all above indexes have no statistical significance (P>0.05). Thecomparison between two groups showed that: in the experimental group, peritoneal clearance of β2-microglobulin and cystatin C are significantly higher than that in the control group (P<0.05). Peritoneal clearance of albumin, MTAC urea,and MTAC creatinine are also higher than that in the control group, but with no statistically significant difference (P>0.05). IL-6 AR are obviously lower than that in the control group (P<0.05); Serum IL-6 and hs-CRP are also lower than that in the control group, but with no significant difference (P>0.05).

Conclusions: Lipo-PGE1 significantly increases peritoneal transport of macromolecules. Lipo-PGE1 can decrease inflammatory cytokines IL-6 concentration, and reduce micro-inflammatory state in CAPD patients, especially peritoneal cavity local inflammation response.

SA-PO698

Comparison of Mesenchymal Stem Cells (MSCs) and Extracellular Vesicles (EVs) in the Treatment of Experimental Peritoneal Fibrosis Priscila Q. Gouveia, Cleonice Silva, Irene L. Noronha. *Cellular and Molecular Nephrology Lab, University of São Paulo, São Paulo, Brazil.*

Background: Long-term peritoneal dialysis is associated with the development of structural and functional changes in the peritoneal membrane, leading to fibrosis and ultrafiltration failure. Infusion of MSCs represents a potential strategy to treat fibrotic processes, due to paracrine effects. EVs released by MSCs are responsible for cell-cell interactions and possibly for the therapeutic effects of MSCs on tissue regeneration. Our aim was to compare the effects of MSCs with EV in an experimental model of peritoneal fibrosis (PF).

Methods: PF was induced in male Wistar rats by intraperitoneal (IP) injections of 0.1% chlorhexidine gluconate (CG), on alternate days for 30 days. MSCs obtained from adipose tissue were isolated and characterized by flow cytometry and *in vitro* differentiation. EVs obtained from MSCs supernatants were isolated by differential ultracentrifugation and characterized by Bradford assay, Zetasizer Nano and scanning electron microscopy. MSCs or EVs were administrated IP on days 3 and 10 after PF induction. The study groups consisted of: **Control** (n=6), normal rats receiving only vehicle (saline); **PF** (n=9), rats receiving CG injections to develop PF; **PF+MSC** (n=7), PF rats treated with $2x10^6$ MSCs and **PF+EV** (n=7), PF rats treated with 30μg EVs.

Results: Administration of MSCs or EVs prevented peritoneal thickening and ameliorated ultrafiltration. Both treatments significantly decreased the expression of genes associated with fibrosis (TGF-β, FSP-1 and SMAD3). In addition, both treatments reduced the inflammatory infiltrate and the expression of TNF-α and VEGF.

Conclusions: We conclude that MSCs and EVs are equally efficient in blocking the PF process in this experimental model of PF.

SA-PO699

Patient On Line (POL) Software as Useful Tool in Assessing Nutritional Status of Peritoneal Dialysis Patients Ewa Suchowierska,[1] Beata Naumnik.[2] *[1]I Department of Nephrology and Transplantation with Dialysis Unit, Medical University of Bialystok, Poland, Bialystok, Poland; [2]Medical University of Bialystok, Bialystok, Poland.*

Background: Moderate to severe malnutrition is associated with increased risk of death in peritoneal dialysis (PD) patients. Serum albumin concentration below 3,8 g/dl is a biochemical surrogate for malnutrition. Protein loss into dialysate and urine contributes to malnutrition problems. The nPCR (normalized Protein Catabolic Rate), mentioned as protein equivalent of nitrogen appearance, is useful in assessing protein intake. Patient on Line (POL) software, calculating the adequacy parameters, is widely used to adjust therapy to patient's needs. This method involves direct measurement of 24 hour dialysate and urea appearance rate to which a value for estimated dialysate and urine protein loss is added.

Methods: We compared classical measurements such as Kt/V, CCr and nPCR (by Randerson formula) with values calculated with POL software created by Fresenius Medical Care (Bad Homburg, Germany). 20 PD patients (mean age 49 +/-14.5 yrs) were included. Measurements were done at the same time using two methods (classical and POL). LTM (Lean Tissue Mass), % LTM, FAT and % FAT were assessed by Fresenius Body Composition Monitor. Total protein, albumin, calcium and phosphate levels as well as mean dialysate and urea protein loss were assessed by routine tests. SATISTICA 10.0 was used for data analysis.

Results: Kt/V was lower than Kt/V POL (p=0.0001), CCr was higher than CCr POL (p=0.0045) and nPCR was higher than nPCR POL (p=0.0001). We observed a strong positive correlations between total protein level and Kt/V POL (r=0.69, p<0.05), CCr (r=0.56, p<0.05), CCr POL (r=0.55, p<0.05) as well as between blood urea level and nPCR calculated classically (r=0.77, p<0.05) and with POL formula (r=0.69, p<0.05). Phosphatemia was negatively correlated with Kt/V (r=-0.51, p<0.05), Kt/V POL (r=-0.62, p<0.05), CCr (r=-0.61, p<0,05) and CCr POL (r=-0.65, p<0.05).

Conclusions: POL software seems to be a better tool in assessing PD patients' nutritional status than Randerson formula, because it takes into account dialysate and urine protein loss. Kt/V POL, but not Kt/V values, positively correlated with total protein level. Phosphatemia and urea concentration were strong predictors of adequacy and nutritional parameters in PD patients.

SA-PO700

Are Peritoneal Protein Losses Related to Peritonitis Risk in Patients on Peritoneal Dialysis? Sara S. Rodrigues, Clara Santos, Ana Marta Gomes, Joao C. Fernandes. *Centro Hospitalar Vila Nova de Gaia-Espinho, Vila Nova de Gaia, Portugal.*

Background: Peritoneal protein losses (PPL) are an inevitable process on peritoneal dialysis (PD). Few studies have supported a positive correlation between PPL and infections or general morbility and mortality. The aim of this study was to investigate whether baseline PPL (bPPL) was a risk factor of peritonitis in PD patients.

Methods: We retrospectively studied all incident PD patients in our center during the last 9 years. bPPL, serum hemoglobine (Hb) and albumin (alb) and other relevant analytic and clinical data were recorded at baseline. Number and timing of peritonitis episodes were registered. Patients were distributed by 3 groups of bPPL (group 1: <4,5 gr/day, group 2: 4,5-9gr/day and group 3: >9gr/day) in order to compare their peritonitis risk.

Results: 104 patients were included, 54% male, median age: 57 years, median follow-up: 29 months. Group 3 patients had lower baseline hb and alb (p=0.03 and p 0.02). Higher bPPL patientes had a greater chance of having at least one peritonitis (group 3:72%, group 2:69%, group 1:39%, p=0.02) and removal of the PD catheter by PD related infection was higher (group 3:74%, group 2:47%, group 1:19%, p=0.01). bPPL was shown to be an independent predictor after adjustment for age, sex and diabetes (p=0.02). Time until the first peritonitis was shorter in higher bPPL groups (p=0.02) and, after adjustment for covariates, group 3 maintained a significant higher risk of peritonitis over group 1 (*HR* 2.38, p=0.04). bPPL and age significantly increased the absolute number

of peritonitis during the follow-up (p=0.03 and p=0.02). No difference was observed in mortality as well as in the occurrence of severe non-PD related infections between groups.

Conclusions: Higher bPPL were able to independently predict risk for peritonitis, reflecting its impact on the morbidity of PD patients. The association between higher bPPL with lower basal serum alb and hb may highlights the hypothesis that bPPL can be a marker of disease severity at the onset of PD, possibly being related to a malnutrition and pro-inflammatory state. It would be useful to explore these effects prospectively and understand the underlying mechanisms in future. This could include a better characterization of the type of protein loss and its quantification of immunoglobulins, which could theoretically explain the higher infectious risk.

SA-PO701

Effect of Peritoneal Dialysis on Cardiac Functional Parameters in Patients with Congestive Heart Failure Andreas Bozikas,[1] Panagiotis Pangidis,[1] Fotini Lazaridou,[2] Eleni Kitoukidi,[1] Iliana Kiriakoutzik,[1] Theotokis Kaltzidis,[2] Pinelopi Pisanidou,[1] Stella Vakiani,[1] Antigoni Martika,[1] Nikolaos Georgilas,[1] Ioannis Tsounos,[2] Sofia Spaia.[1] *[1]Nephrology, General Hospital of Thessaloniki "Agios Pavlos", Thessaloniki, Greece; [2]Cardiology, General Hospital of Thessaloniki "Agios Pavlos", Thessaloniki, Greece.*

Background: Limited data support that peritoneal dialysis (PD) applied in patients (pts) with congestive heart failure (CHF), resistant to diuretic therapy, results in significant improvement of their status. We examined the long term effect of PD, as a continuous ultrafiltration treatment to pts with CHF, NYHA stage IV & Renal Disease stage > IIIb on cardiac functional parameters. We have applied a detailed Cardiac Echo (CE) examination in an effort to identify markers to distinguish population that might benefit of early PD application.

Methods: We enrolled 18 pts (mean age 80.3 years) in PD. Inclusion criteria were NYHA IV class symptoms & deterioration of renal function. Monthly complete biochemical workup & assessment of the cardiac function by (CE) on initiation of PD & 6-12 months later. We recorded the Ejection Fraction (LVEF), Relative Wall Thickness (RWT), Left Ventricular Mass Index (LV), E/E', Left Atrium Volume Index (LA), Pulmonary Artery Systolic Pressure (PASP), Tricuspid Annular Plane Systolic Excursion (TAPSE).

Results: Mean time on the method was 10.1 (6-12) months. We observed body weight decrease (p=0.0083), improved eGFR (p=0.026), decrease of bilirubin levels (p=0.0475), substantial decrease of diuretics, as well as elimination of hospitalizations due to CHF decompensation & remarkable improvement of NYHA class. Significant reductions of LA and LV (p<0.05) were noted in every patient. The rest of the parameters remained unaffected. LVEF showed equivocal changes. One pts died on the 8th month of therapy due to sudden death.

Conclusions: All pts demonstrated clinical improvement of their living status, as a result of the gradual & continuous removal of excess fluid. Therefore, dramatically diminishing hospitalizations, due to cardiac events, & restoring pts autonomy. Furthermore, there was an improvement of left cardiac function. However, markers of right cardiac function did not change, probably due to technical or individualized causes. For the same reasons interpretation of LVEF changes is ambiguous & cannot be used as an objective marker to identify this population. The results of this prospective, but small sized, study encourage the application of PD in selected pts with CHF.

SA-PO702

Glucose Metabolism as Part of Metabolic Syndrome in Non-Diabetic PD Patients: Results from PD-CRAFT Mark Lambie,[1,2] Simon J. Davies.[1,2] *[1]Keele University, Crewe, United Kingdom; [2]University Hospital of North Midlands, Stoke-on-Trent, United Kingdom.*

Background: Dialysate glucose loading has been associated with an increase in metabolic syndrome in ethnically Chinese patients however the impact on other populations is not clear, and neither is the impact on systemic glucose metabolism.

Methods: This was a cohort study of prevalent patients on peritoneal dialysis in 39 centres in the UK. Whole blood samples were stored in the BioCentre and transferred to a central laboratory for glycated haemoglobin assays. Waist circumference was measured with dialysate in situ, and other demographic and clinical measures were stored in a bespoke database (PDDB). Adjusted analysis was by linear regression models, with backwards selection of variables.

Results: 628 non-diabetic patients were included but 26 patients with values >8.0% were excluded from further modelling. There was a median glycated haemoglobin of 5.7% (IQR 5.4-6.0). There was no significant correlation between glycated haemoglobin and dialysate glucose load (-0.08). Correlations with individual components of metabolic syndrome were absent/weak (body mass index 0.05, triglycerides 0.09, HDL cholesterol -0.06) apart from waist circumference (0.17). Results for random plasma glucose levels were similar to glycated haemoglobin. In multivariable modelling there was strong evidence for an effect of age, and decreasing strength of evidence for an association with triglycerides, waist circumference and ischaemic heart disease with no evidence for other variables including dialysate glucose load. The multivariable model had an adjusted R-squared value of 0.18. Waist circumference provided a better model than body mass index (Δ-2LL=3.58).

Conclusions: There does not appear to be any significant association between glycated haemoglobin and dialysate glucose load in non-diabetic PD patients. This could be partly because the variability in glycated haemoglobin is poorly explained by other aspects of metabolic syndrome.

SA-PO703

Determinants of Carnitine and Acetylcarnitine in Peritoneal Dialysis Patients: Results from PD-CRAFT Mark Lambie,[1,2] Simon J. Davies.[1,2] *[1]Keele University, Crewe, United Kingdom; [2]University Hospital of North Midlands, Stoke-on-Trent, United Kingdom.*

Background: In haemodialysis (HD) patients carnitine metabolism plays an important role in lipid metabolism and oleoylcarnitine levels independently predicted death. The role of carnitine in peritoneal dialysis patients is less clear.

Methods: PD-CRAFT is a cross-sectional observational study of 1349 UK prevalent PD patients. A substudy of 961 patients included blood samples taken at the time of data collection assayed for carnitine (C0) and acetylcarnitine (C2) levels with mass spectroscopy. Linear mixed modelling accounting for clustering by centre with backwards variable selection was used in multivariable modelling of log-transformed C0 and square root transformed C2 levels.

Results: The population was representative of the UK PD population (mean age 59.2 years, 65% male, 27% diabetic and median duration of PD 9 months). C0 and C2 had median levels of 23.7 (IQR 26.4-32.1) and 15.5 (IQR 9.7-22.5) respectively. Higher C0 levels were associated with male gender (0.17, 95%CI 0.04, 0.31), lower LDL-cholesterol (-0.07, 95%CI -0.12, -0.01) and not using Icodextrin (0.23, 95%CI 0.09, 0.37). Higher C2 levels were associated with male gender (0.19, 95%CI 0.005, 0.38), lower plasma albumin levels (-0.030, 95%CI -0.049, -0.011), higher BMI (0.030, 95%CI 0.014, 0.047), use of APD (0.22, 95%CI 0.02, 0.42) and not using Icodextrin (0.31, 95%CI 0.10, 0.51). The associations with Icodextrin and use of APD persisted when adjusted for dialysate glucose load and peritoneal solute transport.

Conclusions: Higher carnitine levels were associated with reductions in LDL-cholesterol in PD patients. The gender difference in carnitine levels described previously in the general population persists in PD. The association between C2 and use of APD replicates a previous smaller study, whilst the consistent and robust association between both C0/C2 and Icodextrin could reflect either a direct effect or indirect via reduced dialysate glucose loading over a prolonged period.

SA-PO704

Candida glabrata Fungal Peritonitis in a Peritoneal Dialysis Patient: A Case Report Sina Emami,[2] Susie Q. Lew.[1] *[1]George Washington University Medical Center, Washington, DC; [2]George Washington university, MClean, VA.*

Background: Fungal peritonitis is a rare but serious complication in patients undergoing peritoneal dialysis (PD), and is associated with high morbidity and mortality. Fungal peritonitis accounts for 3% - 6% of all PD-associated peritonitis episodes. The most common cause of the disease is Candida, predominately C. albicans, and C. parapsilosis. C. glabrata peritonitis has not been reported in the United States. The main factors associated with the development of fungal peritonitis include previous antibiotic therapy (particularly for bacterial peritonitis), fungal overgrowth in the gastrointestinal track, and declining peritoneal defenses because of peritonitis. A major obstacle in C. glabrata infection treatment is their innate resistance to azole antimycotic therapy, which is very effective in eradicating infections caused by other Candida species.

Methods: A 74-year-old female with a history of diabetes, hypertension and end stage renal disease on peritoneal dialysis with multiple previous episodes of bacterial peritonitis presented with signs and symptoms typical of peritonitis. Empiric antibiotic therapy with intraperitoneal ceftriaxone and vancomycin was initiated to treat peritonitis. Following identification of yeast on the Gram stain, oral fluconazole therapy was started. The culture was identified as Candida glabrata resistant to fluconazole, itraconazole and voriconazole. Oral fluconazole was switched to micafungin and the PD catheter was removed. Micafungin 100 mg IV every 24h was administered for a total 15 days. She transitioned to in-center HD. Although she wanted to return to PD, the team thought she was not a good candidate due to her age and home situation.

Results:

Conclusions: The approach to fungal peritonitis has changed considerably in recent years. The conventional antifungal regimens include fluconazole, amphotericin B, and flucytosine alone or in combination, optimally based on fungal sensitivities. Anti-fungal agents generally continue for at least 2 weeks after catheter removal. Observational studies suggest that prompt catheter removal probably improves outcome and reduces mortality. The newer agents such as caspofungin, micafungin and voriconazole have the potential to alter treatment strategies for fungal peritonitis, but further studies are required to clarify the precise role of these agents in this patient cohort.

SA-PO705

Right versus Left Insertion of Peritoneal Dialysis Catheters in ESRD Patients by Open Surgical Technique Jin ho Lee,[3,4] Seon Deok Hwang,[4,5] Hee yeoun Kim,[3] Dongyeol Lee,[3] Joon Seok Oh,[2] Yong hun Sin,[1] Joong Kyung Kim.[2] *[1]Bong Seng Hospital, Busan, Republic of Korea; [2]Bong Seng Hospital, Korea, Dong-gu, BUSAN, Republic of Korea; [3]Bong Seng Memorial Hospital, Busan, Republic of Korea; [4]None, Pusan, Republic of Korea; [5]Inha University College of Medicine, Incheon, Republic of Korea.*

Background: The open surgical technique is a traditional and old method of peritoneal dialysis catheter(PDC) insertion. Left-sided insertion is the same direction as peristalsis, thus reducing the frequency of malposition. However, if surgery is not possible to the left side or suspected adhesion due to previous major surgery, it can be inserted to

the right side. In this study, we compared left-side and right-side insertions of peritoneal catheter by surgical technique.

Methods: We retrospectively compared the right approach for PDC insertion by open surgical technique with the left approach. From June 2013 to September 2016, 69 of the catheters were successfully inserted Rt. side and 79 of catheters were inserted Lt. side. Primary outcome was catheter survival. Secondary outcome were peritonitis free survival and exit site infection free survival.

Results: The mean(±SD) age of patients was 63 ± 12 years, the ratio of male to female is 42.6% vs. 57.4%. Of all patients, 55.1% of patients have diabetes and 70.7% have hypertension. The repositioning operation due to malposition was 2 of 66(3%) in Rt. side insertion(RSI) and 3 of 76(3.8%) in Lt. side insertion(LSI)(p=0.30). Exit infection was 6 of 66(9.1%) in RSI and 4 of 76(5.1%) in LSI(p=0.513). Peritonitis was 15 of 66(22.7%) in RSI and 13 of 76(16.5%) in LSI (p=0.401). The catheter survival was not statistically significant for RSI compared to LSI(p=0.126). Catheter survival(Fig.1) and exit site infection free survival were not different between two groups(p=0.432). However, peritonitis free survival of RSI was significantly higher than LSI(p=0.020)(Fig.2).

Conclusions: When the peritoneal dialysis catheter was inserted by open surgical technique, catheter survival was not inferior to the left side insertion on the right side insertion. In addition, peritonitis free survival showed statistically superior results in the right side insertion.

The Choice of Urgent-Start Peritoneal Dialysis versus Hemodialysis through a Tunneled Central Venous Catheter: A Single Center Experience in the United States Delin Wang, Eric S. Kerns, Jonah Licht, Susie L. Hu. *Division of Kidney Disease and Hypertension, Brown University, Providence, RI.*

Background: Peritoneal dialysis (PD) has been underutilized for patients with unplanned need for initiation of renal replacement therapy compared to hemodialysis (HD) through a tunneled central venous catheter (CVC) in the United States.

Methods: We examined outcomes related to urgent start PD versus HD (with a tunneled CVC) in a retrospective cohort of 47 adults who required urgent dialysis initiation from January 2015 to December 2016. Those who are unstable with critical illness were excluded. In addition to baseline demographics and comorbidities, we compared dialysis access related complications and total number of procedures required related to dialysis modality selection. Comparisons were performed using t-test for linear variables, and chi-square test for categorical variables.

Results: 28 patients had tunneled CVC placed for HD and 19 patients had PD catheter placed. Mean follow-up was 60 months for HD patients and 46 months for PD patients. The PD group was significantly younger, with less heart failure, more hypertension, and higher pre-dialysis serum creatinine (Table). 75% of patients who underwent HD with a tunneled CVC versus 47% who performed urgent start PD had any access related procedures.

Conclusions: The complication rate related to dialysis modality choice between urgent start PD and HD with a tunneled CVC is similar. There was a trend towards fewer procedures required for urgent start PD and should be more commonly considered for those requiring dialysis urgently.

Comparisons between urgent start PD and HD

	HD	PD	P-value
Age (years)	60 ± 15	46 ± 17	0.007
Follow-up duration (months)	60	46	0.85
Potassium (mEq/L)	4.8 ± 0.9	4.3 ± 0.7	0.05
HCO3 (mEq/L)	19 ± 4	18 ± 4	0.64
BUN (mg/dL)	97 ± 41	111 ± 38	0.25
Creatinine (mg/dL)	8.1 ± 4.7	12.0 ± 6.1	0.01
Coronary artery disease (%)	39	16	0.08
Congestive heart failure (%)	43	5	0.005
Hypertension (%)	89	95	0.01
Diabetes mellitus (%)	57	21	0.51
Access-related procedures (%)	75	47	0.05

Impact of Medicare Bundled Payment on Provision of Peritoneal Dialysis among Existing versus New Dialysis Providers Virginia Wang,[1,2] Cynthia Coffman,[1,2] Linda L. Sanders,[1] Richard A. Hirth,[3] Shoou-Yih D. Lee,[4] Matthew L. Maciejewski.[1,2] *[1]Duke Univ, Durham, NC; [2]Durham VAMC, Durham, NC; [3]U of Michigan, Ann Arbor, MI; [4]UNC-Chapel Hill, Chapel Hill, NC.*

Background: One of the goals of Medicare's 2011 implementation of ESRD bundled payment is to encourage greater peritoneal dialysis (PD) provision among providers. Service strategies may differ between facilities operating prior to bundled payment proposals in 2005 versus new entrants in the dialysis market. We examine the differential response to dialysis payment reform on PD service availability among existing versus new dialysis providers.

Methods: We used the USRDS and Medicare data to construct a longitudinal cohort of US outpatient dialysis facilities in 2006-2013 and identified facilities operating before 2005 (existing) and opening after 2005 (new). Our outcome of interest was facility-level offering of PD service. We applied generalized estimating equations to examine whether the 2011 policy effect on PD services differed between existing and new facilities, adjusting for facility and regional ESRD and general demographic characteristics.

Results: Of 6,194 dialysis facilities operating in 2006-2013, 70.5% were in operation before 2005 and 29.5% were new facilities. Over time PD provision modestly increased from 37% of facilities with PD in 2006 to 42% in 2013. Similar rates of existing and new facilities offered PD (38.6% vs. 39.8%), but there was a greater presence of new facilities exclusively offering home-based dialysis (1.9% of existing vs. 7.4% of new). In adjusted analysis, PD provision was greater after bundled payment ($p<0.001$), but there were no pre-post policy differences between existing and new facilities ($p=0.67$). PD services differed for new vs. existing by urban location: PD in existing facilities was similar but new, urban facilities offered PD at higher rates than new, non-urban facilities ($p<0.001$). Existing and new facilities differed in their relationship between facility size and PD provision, with a slower rate of PD provision by increasing facility size for new facilities ($p=0.009$).

Conclusions: Existing and relatively new entrants to the US dialysis market differ in their service strategies when it comes to PD services. However, existing and new dialysis providers responded similarly to the 2011 bundled payment reform.

SA-PO708

Peritoneal Dialysis Modality Is Independently Associated with Salty Taste Impairment in Patients with ESRD Miki Torigoe,[1] Yoko Obata,[1] Kenta Torigoe,[1] Takashi Harada,[2] Satoshi Funakoshi,[2] Tomoya Nishino.[1] *[1]Department of Nephrology, Nagasaki University Hospital, Nagasaki, Japan; [2]Nagasaki Renal Center, Nagasaki, Japan.*

Background: In chronic kidney disease (CKD) patients, it is reported that the gustatory threshold for salty taste is increased, and its increase is associated with excessive oral salt intake and result in high blood pressure or volume overload. However, little is known about the relationship between the patients with end-stage renal disease (ESRD) requiring renal replacement therapy and the gustatory threshold for salty taste. The aim of this study was to assess the gustatory threshold for salty taste and clarify relevant factors in ESRD patients.

Methods: In this cross-sectional study, we enrolled 29 healthy volunteers and 79 dialysis patients (22 peritoneal dialysis (PD) patients, 57 hemodialysis (HD) patients) in Nagasaki University Hospital and Nagasaki Kidney Center in Japan. For the assessment of gustatory threshold for salty taste, we used a salt-impregnated taste strip, Salsave® (Advantech Tokyo Co, Tokyo, Japan) which are impregnated various salt concentrations (0.6, 0.8, 1.0, 1.2, 1.4 and 1.6 mg/cm^2). The clinical data were collected from electronic medical records and we analyzed risk factors of salty taste impairment.

Results: Compared with healthy volunteer, prevalence of salty taste impairment (recognition threshold of salt at ≧1.0 mg/cm^2 concentration) was higher in ESRD patients (3% vs 58% $p<0.001$). Among ESRD patients, rate of PD modality was higher in salty taste impaired group (37.0% vs 15.6% $p=0.04$). Moreover, in multiple logistic regression adjusting for age, gender, sex, duration of dialysis, serum zinc, C-reactive protein and KT/V, PD modality was independently associated with salty taste impairment (Odds ratio 8.0, 95% confidence intervals 1.1 – 57.4, $p=0.04$). Among PD patients, the gustatory threshold for salty taste was positively correlated with serum creatinine ($\rho=0.44$, $p=0.04$), serum β_2-microglobulin ($\rho=0.63$, $p=0.002$) and transferrin saturation ($\rho=0.50$, $p=0.02$), negatively correlated with 24-hour urine volume ($\rho=-0.50$, $p=0.02$) and residual renal KT/V ($\rho=-0.55$ $p=0.01$).

Conclusions: This study demonstrated that prevalence of salty taste impairment was higher in ESRD patients, and PD modality was independently high risk of salty taste impairment. Moreover, the gustatory threshold for salty taste was negatively correlated with residual renal function in PD patients.

Non-Infectious Peritoneal Dialysis Exit Site Rash: Unusual Case Report and Review of Literature Srilakshmi Ravula,[3] Mohammed M. Siddiqui,[1] Omar Rabadi,[4] Manisha Singh.[2] *[1]Little Rock, AR; [2]University of Arkansas For Medical Sciences, Little Rock, AR; [3]University of Arkansas Medical Center, Little Rock, AR; [4]University of Arkansas for Medical Sciences, Little Rock, AR.*

Background: Peritonitis is one of the leading causes of morbidity in patients on peritoneal dialysis(PD). Exit site infections(ESI) can cause six-fold increase in the risk of peritonitis. Exit site infection is characterized by purulent drainage, erythema, pain and swelling at PD catheter site. On review of literature case reports of non-infectious exit site rash are found to be rare, hence we are reporting this case of PD exit site non-infectious rash that was finally diagnosed as granuloma gluteal adultorum.

Methods: A 74-year-old white man with ESRD from diabetes on CCPD(continuous cycler assisted PD) presented with localized area of redness, itching and serous drainage around PD catheter site measuring 1x1cm. The lesion was noticed week ago that progressively worsened. He denied trauma to catheter site, pain, fever or cloudy effluent. He was compliant with exit site care instructions and was using mupirocin ointment as part of catheter care regimen, denied changes in medications or povidone iodine use. On exam, abdomen was soft and no purulent drainage was expressed from exit site. PD fluid cell count ruled out peritonitis. Exit site cultures were obtained & keflex was started. On follow up exam, it was noted that areas of skin desquamation had gotten worse with increased itching. Dermatology was consulted and shave skin biopsy was done. Histopathological findings were consistent with spongiotic dermatitis with eosinophils, diagnosis of granuloma gluteale adultorum was made. Topical zinc oxide was prescribed in addition to continuing topical antibiotic therapy. Patient had significant improvement in one week. As discussed, erythema with pain and purulent discharge are hallmarks of ESI. There have been very few case reports published reviewing non-infectious PD site dermatitis.

Results:

Conclusions: ESI is a differential for catheter site erythema, pain and discharge. Empiric treatment with antibiotics is warranted. Prompt dermatological assessment and skin biopsy should be considered if there is no resolution of symptoms.

Review of Case Reports

Authors et al	Agent Identified	Description of Rash	Management
Elvira O. Gosmanova	Gentamicin-induced contact dermatitis	Ovoid crusted plaque with peripheral rim of erythema	Stopped gentamicin cream and switch to Mupirocin

Metformin Ameliorates the Phenotype Transition of Peritoneal Mesothelial Cells and Peritoneal Fibrosis via a Modulation of Oxidative Stress Duk-Hee Kang,[1] Hyun-Jung Kang,[4] Eun sun Ryu,[3] Dal-ah Kim.[2] *[1]Ewha University College of Medicine, Seoul, Republic of Korea; [2]Ewha Womans University Medical Center, Seoul, seoul, Republic of Korea; [3]Ewha Womans University School of Medicine, Seoul, Republic of Korea; [4]Ewha Womans University, Seoul, Republic of Korea.*

Background: Phenotype transition of peritoneum is an early mechanism of peritoneal fibrosis. Metformin, 5'-adenosine monophosphate-activated protein kinase (AMPK) activator, has recently received a new attention due to its preventive effect on organ fibrosis and cancer metastasis by inhibiting epithelial-to-mesenchymal transition (EMT)

Methods: EMT was evaluated by morphological changes of human peritoneal mesothelial cells (HPMCs) and the expressions of E-cadherin and α-SMA by real time PCR, WB and ICC. ROS generation was assessed by DCF-DA staining, NOX activity, NOX mRNA expressions, and MitoSox^{R} staining. Activation of Smad2/3, MAPK, GSK-3β phosphorylation, nuclear translocation of β-catenin and snail expression were assessed. The effect of AMPK gene silencing or AMPK inhibitor on peritoneal EMT was evaluated. Animal model of peritoneal dialysis was established by daily infusion of 4.25% glucose-based dialysate for 8 weeks via intraperitoneal catheter. Effects of metformin (50 mg/kg/day, ip) on EMT, peritoneal thickening and an expression of markers of oxidative stress were investigated.

Results: TGFβ1 (1 ng/mL)-induced EMT in HPMC was ameliorated by metformin. Metformin (1 ng/mL) alleviated NOX - and mitochondria-mediated ROS production with an increase in superoxide dismutase (SOD) activity and SOD2 expression. Metformin inhibited the activation of Smad2/3 and MAPK, GSK-3β phosphorylation, nuclear translocalization of β-catenin and Snail. Effect of metformin on TGFβ1-induced EMT was ameliorated by either Compound C (20 μg/mL) or AMPK gene silencing. Another AMPK agonist, 5-amino-1-β-D-ribofuranosyl-imidazole-4-carboxamide (10 μM) partially blocked TGF-β1-induced EMT. In animal model of PD, intraperitoneal metformin decreased the peritoneal thickness and EMT with an increase in ratio of reduced to oxidized glutathione and the expression of SOD whereas it decreased the expression of nitrotyrosine and 8-hydroxy-2'-deoxyguanosine

Conclusions: A modulation of AMPK in peritoneum can be a novel tool to prevent peritoneal fibrosis by providing a favorable oxidant/anti-oxidant milieu in peritoneal cavity and ameliorating phenotype transition of peritoneal mesothelial cells

SA-PO711

Novel Score to Predict the Risk of Loss of Technique at 3 Months in Patients with Peritonitis Associated with Peritoneal Dialysis Monica C. Jimenez cornejo,[1] Daniel Murillo brambila,[1] Jonathan Chavez,[1] Karina Renoirte,[1] Gabriela J. Abundis Mora,[1] Ricardo Rubio,[1] Hernando Amezcua,[2] Guillermo Garcia-Garcia.[1] *[1]Hospital Civil De Guadalajara, University of Guadalajara, Guadalajara, Mexico; [2]IMSS, Zapopan, Mexico.*

Background: CKD is a major public health problem in Mexico, the incidence of CKD G5 reach 377 patients pmh, the most frequent modality of RRT is PD. Peritonitis is the most frequent cause of technique failure.

Methods: A descriptive, prospective study of 116 PD patients with peritonitis, we determinate by multivariate analysis the risk factors associated with loss of peritoneal technique at 3 months of onset of peritonitis Data are shown in numbers, percentages, mean, standard deviation, chi square, according the magnitude of the OR we develop a numeric scale, a ROC curve was done to determinate the AUC of the best cut-off point to predict loss of peritoneal technique at 3 months of the onset of peritonitis.

Results: A total of 116 episodes of peritonitis were recorded, fifty-two (45%) of them resulted in technique failure. Factors independently associated with increased risk were: diarrhea (OR =3.0, P = 0.023), >1000 white cells in PD fluid (OR =1.98, P = 0.006), turbid DP fluid (OR = 5.0, P = 0.032), time in PD (OR=3.6 P=0.014) and first episode of peritonitis (OR =4, P = 0.002). Severity score was set as low risk (≤ 5 points) and high risk (≥6 points). The incidence of technique failure in the first 3 months occurs more often in high-risk patients (OR 7.2 IC95% 1.2 to 2.3, P <0.001), the AUROC was 0.686, sensitivity 70% and specificity 32%

Conclusions: In patients with peritonitis associated with PD, a simple score including clinical and laboratory data available on admission may predict the risk of technique failure in the next 3 months; this finding may assist clinician to ensure a close follow-up of the patient at high-risk and anticipate possible outcomes.

Funding: Other U.S. Government Support, Government Support - Non-U.S.

JAK1/2 Inhibitor and/or Losartan Preserved Long-Term Peritoneal Membrane Structure/Function during Intraperitoneal Instillation of Dialysate in Polycystic Rats Pei Zhang,[1,2] Kana N. Miyata,[1] Sharon G. Adler,[1] Janine A. La page,[1] Cynthia C. Nast,[3] Tiane Dai.[1] *[1]Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA; [2]The First Affiliated Hospital of Anhui Medical University, He Fei, China; [3]Cedars-Sinai Medical Center, Los Angeles, CA.*

Background: Peritoneal dialysis (PD) is limited by reduced efficacy over time. Early peritoneal membrane (PM) injury is characterized by inflammation which progresses to hypervascularity and fibrosis. JAK/STAT signaling mediates inflammatory pathways, including angiotensin signaling. We test whether a JAK1/2 inhibitor (JAK1/2i) and/or an ARB maintains PM structure/function in rats with polycystic kidneys (PCK) chronically infused with 4.25% Dianeal x 16 wks.

Methods: PCK rats were used. Dialysate infusions were performed BID via an implanted subcutaneous port in the neck tunneled to the intraperitoneal cavity. The following treatments were administered: **(1)** No surgery/infusions; **(2)** 0.9% Saline; **(3)** 4.25% Dianeal; **(4)** 4.25% Dianeal + JAK1/2i (5mg/kg BID); **(5)** 4.25% Dianeal +

Losartan (5mg/kg BID); and **(6)** 4.25% Dianeal + Losartan +JAK1/2i (5mg/kg BID each). Peritoneal equilibration testing (PET) measured peritoneal function by calculating initial dialysate glucose at time 0 (D_0) and measuring it 90 minutes after dialysate infusion (D). Parietal peritoneum submesothelial compact zone (SMCZ) width was morphometrically measured in ≥ 60 sections/rat. Data were analyzed by one-way-ANOVA followed by Tukey test. Results are mean±SEM.

Results: Widened SMCZ in Gps 1-3 was due to fibrosis. Fibrosis was reduced in all 3 treatment groups, with the greatest effect in the JAK1/2i group. D/D_0 glucose measurements showed functional impairment in rats receiving Dianeal, with function maintained in all 3 treatment groups similarly (Table). *P<0.05, #P<0.01.

Conclusions: Summary. Treatment with JAK1/2i, losartan, and both preserved peritoneal structure/function during long-term 4.25% Dianeal exposure. Morphologic protection was superior in the JAK1/2i alone group. **Conclusion.**Long-term JAK1/2i and/or losartan intraperitoneal treatment preserves peritoneal integrity by limiting peritoneal fibrosis and functional decline. Angiotensin inhibition is advocated to maintain residual renal function. These data show that ARBs also protect peritoneal structure/function.

Protein Kinase C Isoforms Alpha and Beta Are Differentially Regulated in Glucose-Mediated In Vivo and In Vitro Peritoneal Dialysis Michael S. Balzer,[1] Sibylle Von Vietinghoff,[1] Yulia Kiyan,[1] Hermann G. Haller,[1] Nelli Shushakova.[2] *[1]Hannover Medical School, Hannover, Germany; [2]Nephrology and Hypertensiology, 30625 Hannover, Germany*.

Background: Damage to the peritoneal membrane (PM) during peritoneal dialysis (PD) comprises inflammatory, neoangiogenetic and fibrotic processes. In a PD mouse model, we have previously demonstrated glucose-mediated pro-inflammatory, pro-fibrotic and pro-angiogenic properties of protein kinase C (PKC)-alpha, which is the dominant mesothelial PKC isoform. Preliminary data suggest regulation of PKC-alpha by PKC-beta at the PM. The specific role of PKC-beta and especially its main source in glucose-mediated PM damage are not clear.

Methods: For in vivo PD, PKC-beta KO and WT mice were subjected to a catheter-delivered, high glucose-mediated PM damage model (once daily with 4.25% glucose for 5 weeks) and analyzed for structural and functional PM changes. Peritoneal effluents were analyzed for cellular and cytokine composition. PKC-beta expression was analyzed in omentum, mesothelial cells and macrophages of WT animals. For in vitro PD, both immortalized mouse peritoneal mesothelial cells (MPMC) and primary mouse peritoneal macrophages were stimulated with different glucose concentrations and studied for cytokine and PKC expression.

Results: In comparison to WT mice, PKC-beta KO mice undergoing PD demonstrated a stronger fibrotic and angiogenetic phenotype with higher peritoneal TGF-beta production, larger fibrotic areas and increased peritoneal VEGF and CD31 expression. PKC-beta deficiency in vivo increased peritoneal IL-6, TNF-alpha, MCP-1 and MIP-2 levels as well as PM inflammatory cell influx. In contrast to mesothelium, PKC-beta is the predominant conventional PKC isoform in peritoneal macrophages, which was further up-regulated by high glucose. After LPS stimulation PKC-beta KO peritoneal macrophages demonstrated increased production of pro-inflammatory cytokines IL-6, TNF-alpha and MCP-1and drastically decreased production of anti-inflammatory cytokine IL-10 compared to WT cells.

Conclusions: PKC-beta, the dominant mesothelial PKC isoform in peritoneal macrophages, is up-regulated and exerts peritoneal anti-inflammatory effects during PD through regulation of the dominant mesothelial PKC isoform PKC-alpha. PKC-beta deficient animals present a macrophage phenotype in response to in vivo PD.

Protein Kinase C Isoforms Alpha and Beta Are Differentially Regulated in Glucose-Mediated In Vivo and In Vitro Peritoneal Dialysis Michael S. Balzer, Sibylle Von Vietinghoff, Yulia Kiyan, Hermann G. Haller, Nelli Shushakova. *Hannover Medical School, Hannover, Germany*.

Background: Damage to the peritoneal membrane (PM) during peritoneal dialysis (PD) comprises inflammatory, neoangiogenetic and fibrotic processes. In a PD mouse model, we have previously demonstrated glucose-mediated pro-inflammatory, pro-fibrotic and pro-angiogenic properties of protein kinase C (PKC)-alpha, which is the dominant mesothelial PKC isoform. Preliminary data suggest regulation of PKC-alpha by PKC-beta at the PM. The specific role of PKC-beta and especially its main source in glucose-mediated PM damage are not clear.

Methods: For in vivo PD, PKC-beta KO and WT mice were subjected to a catheter-delivered, high glucose-mediated PM damage model (once daily with 4.25% glucose for 5 weeks) and analyzed for structural and functional PM changes. Peritoneal effluents were analyzed for cellular and cytokine composition. PKC-beta expression was analyzed in omentum, mesothelial cells and macrophages of WT animals. For in vitro PD, both immortalized mouse peritoneal mesothelial cells (MPMC) and primary mouse peritoneal macrophages were stimulated with different glucose concentrations and studied for cytokine and PKC expression.

Results: In comparison to WT mice, PKC-beta KO mice undergoing PD demonstrated a stronger fibrotic and angiogenetic phenotype with higher peritoneal TGF-beta production, larger fibrotic areas and increased peritoneal VEGF and CD31 expression. PKC-beta deficiency in vivo increased peritoneal IL-6, TNF-alpha, MCP-1 and MIP-2 levels as well as PM inflammatory cell influx. In contrast to mesothelium, PKC-beta is the predominant conventional PKC isoform in peritoneal macrophages, which was further up-regulated by high glucose. After LPS stimulation PKC-beta KO peritoneal macrophages demonstrated increased production of pro-inflammatory cytokines IL-6, TNF-alpha and MCP-1 and drastically decreased production of anti-inflammatory cytokine IL-10 compared to WT cells.

Conclusions: PKC-beta, the dominant mesothelial PKC isoform in peritoneal macrophages, is up-regulated and exerts peritoneal anti-inflammatory effects during PD through regulation of the dominant mesothelial PKC isoform PKC-alpha. PKC-beta deficient animals present a macrophage phenotype in response to in vivo PD.

Effect of TonEBP on TGF-β1-induced Phenotype Transition of Mesothelial Cells via Modulation of NLRP3 Inflammasome Duk-Hee Kang,[1] Eun sun Ryu,[3] Dal-ah Kim,[2] Hyun-Jung Kang.[4] *[1]Ewha University College of Medicine, Seoul, Republic of Korea; [2]Ewha Womans University Medical Center, Seoul, seoul, Republic of Korea; [3]Ewha Womans University School of Medicine, Seoul, Republic of Korea; [4]Ewha Womans University, Seoul, Republic of Korea*.

Background: Phenotype transition of mesothelial cells(MC) such as epithelial-to-mesenchymal transition(EMT) is known as an early mechanism of peritoneal fibrosis in peritoneal dialysis(PD). Nod-like receptor 3(NLRP3) inflammasome is comprised of the NLRP3, the adapter ASC and pro-caspase-1, which promotes the maturation of IL-1β and IL-18. Tonicity-responsive enhancer binding protein(TonEBP) is a transcriptional enhancer that enables cellular adaptation to hypertonic stress by promoting expression of specific genes. The aim of this study is to investigate whether TonEBP plays a role on phenotype transition via a modulation of NLRP3 inflammasome in peritoneal MCs isolated from omentum and dialysate effluents from patients on PD

Methods: The expressions of TonEBP and components of NLRP3 inflammasome, nuclear translocation of TonEBP and snail were evaluated by western blotting. E-cadherin promoter activity was confirmed by luciferase assay. Effect of either TonEBP or NLRP3 gene silencing on EMT was examined using siRNA technique. MCs were also isolated from overnight dwell dialysates from 9 clinically stable PD patients (MC-DE) to assess the expression of TonEBP and NLRP3 inflammasome, and to clarify the association with the markers of EMT

Results: TGFβ1 enhanced TonEBP expression with an increased nuclear translocation in MC, which was followed by an altered expression of epithelial and mesenshymal cell markers. TGFβ1 also activated the expression of NLRP3, ASC and procaspase-1 with an increased production of IL-1β and IL-18. TGFβ1-induced EMT was ameliorated by either siTonEBP or siNLRP3, which was associated with a decrease in snail expression and an increase in E-cadherin promotor activity. TonEBP gene silencing also alleviated TGFβ1-induced activation of NLRP3 inflammasome pathway. The expressions of TonEBP and NLRP3 were higher in MC-DE compared to MC never been exposed to dialysate, which were significantly correlated with the degree of EMT assessed by an altered expression of E-cadherin and α-SMA

Conclusions: This data suggest TonEBP plays a key role in peritoneal EMT via tonicity-independent mechanism by either an inhibition of E-cadherin transcription or an activation of the NLRP3 inflammasome. Modulation of TonEBP in MCs could be a novel approach to protect the peritoneum from the development of EMT and peritoneal fibrosis in PD patients

SA-PO716

A Strategy for the Simultaneous Preservation of Residual Renal Function and Peritoneal Structure/Function Kana N. Miyata,[1] Pei Zhang,[1,2] Sharon G. Adler,[1] Janine A. La page,[1] Tiane Dai.[1] *[1]Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA; [2]The First Affiliated Hospital of Anhui Medical University, He Fei, China*.

Background: Residual renal function (RRF) preservation is key to maintaining peritoneal dialysis (PD) long-term. In a separate abstract, we showed that in rats with polycystic kidneys (PCK), the peritoneal fibrosis and functional decline due to 16 wks of dialysate infusion with 4.25% Dianeal was attenuated by the intraperitoneal administration of Losartan and/or Ruxolitinib (JAK1/2 inhibitor). Here, we investigated their effects on renal function.

Methods: Tunneled PD catheters were placed in PCK rats who received BID infusions of normal saline, 4.25% Dianeal, 4.25% Dianeal + Ruxolitinib (5mg/kg), 4.25% Dianeal + Losartan (5mg/kg), or 4.25% Dianeal + Losartan + Ruxolitinib for 16 weeks. Control group did not receive a catheter or PD fluid. We measured tail cuff mean arterial pressure (MAP), BUN, 24h urine protein-to-creatinine ratio (UPCR), urine albumin-to-creatinine ratio (UACR), and total kidney/body weight ratio(KW/BW). Results were evaluated by one-way ANOVA followed by the Tukey test. Values were expressed as mean± SEM.

Results: PCK rats (fibrocystin mutation) develop proteinuria, albuminuria, cystic tubulointerstitial disease, and progressive GFR decline. UPCR, UACR, and MAP were significantly lower in groups given Losartan compared to those without Losartan. BUN rise was lowest in the Dianeal alone and Losartan groups. Ruxolitinib did not significantly affect measured parameters. None of the interventions altered KW/BW ratio. Summary: In PCK rats, Dianeal intraperitoneal infusions alone or with Losartan attenuated a rise in BUN. Losartan also reduced UPCR, UACR, and MAP, but not KW/BW. Ruxolitinib did not significantly alter renal parameters.

Conclusions: Taken together with our work on peritoneal structure/function in this PCK model, Losartan alone, or Losartan in combination with Ruxolitinib, offer the possibility of maintaining peritoneal structure and function and RRF while reducing proteinuria. Strategies that maintain both peritoneal and renal structure and function may enhance PD technique survival.

Lithium-Mediated Protection of Mesothelial Cells during Peritoneal Dialysis Rebecca Herzog,[2,3] Katarzyna Bialas,[2] Christoph Aufricht,[1] Klaus Kratochwill.[2,1] *[1]Pediatric Nephrology, Medical University of Vienna, Vienna, Austria; [2]Christian Doppler Laboratory of Molecular Stress Research in Peritoneal Dialysis, Medical University of Vienna, Vienna, Austria; [3]Research, Zytoprotec, Vienna, Austria.*

Background: Peritoneal mesothelial cells (MC) are harmed by peritoneal dialysis fluids (PDF), at least in part caused by inadequate cellular stress responses. In immortalized MC, we have shown that addition of lithium chloride (LiCl) restored heat shock protein expression. Lithium salts could therefore be a promising group of molecules to be used as cytoprotective additives to PDF. Here, we analyzed the protective potential of LiCl in human primary MC (HPMC) on the gene and protein expression level in a multi-omics approach and *in-vivo* in a chronic mouse model of PD.

Methods: HPMC of 5 individual donors were exposed to PDF (Extraneal, Baxter) without or with 2.5 or 10mM LiCl 30 min and allowed to recover for 4 or 16 h. Cell death was analyzed by LDH-release. mRNA levels were analyzed by gene expression microarrays and significantly altered biological processes were identified using the PANTHER database. Changes of the proteome were analyzed with a 2D difference gel electrophoresis (DiGE) based approach. C57/B6 mice (n=32) were treated with PDF without or with 5mM LiCl for four weeks via an implanted catheter. The parietal peritoneum was analyzed for thickening/fibrosis and effluent cells were characterized following a 30 min dwell by FACS.

Results: PDF-induced cell injury was associated with significantly differential expression of 601 genes compared to control. Six biological pathways (oxidative stress response, VEGF signaling, PDGF signaling, angiogenesis, CCKR signaling, GNRHR pathway) were significantly overrepresented. Added LiCl led to significantly decreased cell death and significantly altered the expression of 1003 genes, of which 62 showed an abolishment of the PDF-effects. These genes are regarded as markers of LiCl-mediated cytoprotection. *In-vivo* LiCl lead to a decrease of PDF-induced peritoneal membrane thickening and increased Treg/IL-17 ratio of the effluent cells.

Conclusions: The cytoprotective effects of added LiCl, combined with the modulation of the cellular stress response, fibrosis and inflammation suggests a therapeutic potential of this intervention. Future studies including pharmacokinetics following once daily exposure to LiCl added to Extraneal are needed to further translate these findings into the clinical setting of PD.

SA-PO718

Impact of Liver Cirrhosis on the Outcome of Peritoneal Dialysis Young Lee Jung,[1] Jae Yoon Park,[2] Hyunjin Ryu,[1] Yaerim Kim,[1] Jae shin Choi,[1] Dong Ki Kim,[1] Chun Soo Lim,[3] Yon Su Kim,[1] Kook-Hwan Oh,[1] Seung Seok Han.[1] *[1]Internal Medicine, Seoul National University Hospital, Seoul, Republic of Korea; [2]Dongguk University Ilsan Hospital, Gyeonggido, Republic of Korea; [3]Seoul National University Boramae Medical Center, Seoul, Republic of Korea.*

Background: Peritoneal dialysis(PD) is popular treatment modality for ESRD. However, its application to liver cirrhosis(LC) and subsequent outcomes have not been thoroughly evaluated yet.

Methods: We retrospectively reviewed 1,366 patients(≥18 yrs old) who started PD at Seoul National University Hospital between January 2000 and December 2015. Radiologic evaluation was applied to define LC at the time of PD initiation. 33 patients were assigned to LC, and their outcomes were compared with non-LC(n=35), which was selected based on the propensity score matching by age, sex, and diabetes mellitus. Primary outcome was the technical failure;secondary outcomes were peritonitis, exit site infection, and all-cause mortality.

Results: Patients were followed for a mean duration of 42.9±35.8 months. During that period, 6 patients with LC encountered technical failures, but this rate was not different from that of non-LC[Figure 1]. This difference did not alter despite adjusting several covariates, such as comorbidities and lab findings. When evaluating infection, common causes for peritonitis and exit site infection were E.coli(5.8%) and S.aureus(19.3%); these rates were not different from those of non-LC. Overall mortality were similar between LC and non-LC. All of these outcomes were not dependent on severity of LC, which was quantitatively determined by Child-Pugh and MELD score. LC with hepatocellular carcinoma(n=6) did not have inferior outcomes including mortality to counterpart group without carcinoma.

Conclusions: The presence of LC and its severity did not affect subsequent outcomes in patients starting PD. Based on the fact that trials with randomization of dialysis modality are not feasible, the present observational results may provide reassurance to the LC starting PD.

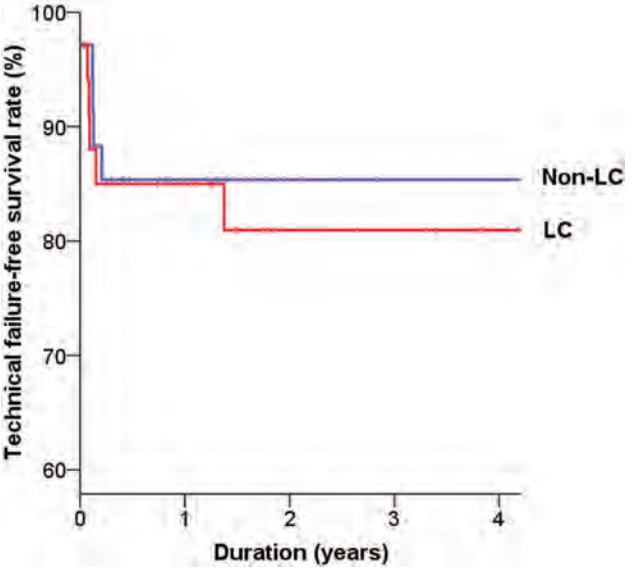

Figure 1. Technical failure-free survival curves between LC and non-LC patients

Staphylococcal Peritonitis in Chronic Peritoneal Dialysis Patients: A Seven-Year Review Tiago J. Carvalho, Patricia Q. Branco, Ana Rita M. Martins, Domingos S. Machado, Maria augusta C. Gaspar. *Nephrology, Santa Cruz Hospital, Carnaxide, Portugal.*

Background: Staphylococcal peritonitis (SP) is a serious complication of chronic peritoneal dialysis (CPD). The aim of this study was to examine the frequency, predictors and clinical outcomes of SP.

Methods: We reviewed all consecutive cases of SP in a CPD unit from 2010 to 2016. The mean number of patients treated per year was 87±14. There were 300 episodes of peritonitis, of which 109 (36.3%) were SP, affecting 59 patients, aged 52±15 years. Peritonitis rates varied from a minimum of 0.32 to a maximum of 0.52 episodes/patient/year. The unit's empirical antibiotic protocol was intraperitoneal cefazolin and ceftazidime.

Results: Among SP affected patients, 30 had one episode, 17 had two episodes and 12 had three or more. There were 63 cases (57.8%) of coagulase-negative SP and 46 (42.2%) of *Staphylococcus aureus* peritonitis, 4 of which were methicillin-resistant. Caucasians had a higher risk of *S. aureus* peritonitis (Odds Ratio (OR) 22.71, 95% Confidence Interval (CI) 5.06-101.85, p<0.001). Overall primary response to treatment was 75.2%.

When compared to coagulase-negative SP, *S. aureus* peritonitis were associated with a higher risk of catheter substitution/removal in a multivariate Cox regression adjusted for age, diabetes *mellitus* and previous exit-site infection (Hazard Ratio (HR) 2.81, 95% CI 1.08-7.29, p=0.033). There was also a trend towards increased hospitalization (OR 2.27, 95% CI 0.95-5.43, p=0.066). There were no differences in relapse rate (34.8% vs 33.3%) or permanent transfer to hemodialysis (0.02% vs 0.07%). No deaths occurred. Other factors associated with a higher risk of catheter substitution/removal were previous exit-site infection (OR 6.68, 95% IC 1.57-28.48, p=0.010) and relapse or repeat episode (OR 11.30, 95% IC 2.93-43.57, p<0.001).

Conclusions: SP remains an important clinical problem in CPD patients. Caucasian patients have a higher risk of *S. aureus* peritonitis. Previous exit-site infection, *S. aureus* peritonitis and relapse or repeat peritonitis episodes are associated with an increased risk of catheter substitution/removal. However, permanent transfer to hemodialysis remained low.

SA-PO720

Alanyl-Glutamine in Peritoneal Dialysis Fluids Restores Cytoprotective Responses of Endothelial Cells Klaus Kratochwill,[3,1] Silvia Tarantino,[1] Rebecca Herzog,[3,1] Maria Bartosova,[2] Claus P. Schmitt,[2] Christoph Aufricht.[1] *[1]Pediatric Nephrology, Medical University of Vienna, Vienna, Austria; [2]Center for Pediatric and Adolescent Medicine, University of Heidelberg, Heidelberg, Germany; [3]Christian Doppler Laboratory of Molecular Stress Research in Peritoneal Dialysis, Medical University of Vienna, Vienna, Austria.*

Background: Peritoneal vascular changes manifested as vasculopathy and increased angiogenesis are major factors causing ultrafiltration failure in patients undergoing peritoneal dialysis (PD). Hyperglycemic conditions created during PD fluid (PDF) exposure are similar to those responsible for cellular pathomechanisms relevant in diabetic retinopathy and nephropathy. This study focused on characterizing endothelial cell (EC) injury and stress responses after exposure to PDF with/without cytoprotective intervention with alanyl-glutamine dipeptide (AlaGln).

Methods: Human umbilical vein ECs (HUVECs) exposed to PDF were subjected to a combined proteomic and bioinformatics approach using 2D-DIGE and fluorescent cyanine dyes. Cellular injury was associated with a molecular landscape of a set of enriched biological processes that characterize PDF cytotoxicity and counteracting cellular repair processes. These include "glucose catabolic process", "cell redox homeostasis", "RNA metabolic process", "protein folding", "regulation of cell death", and of "actin cytoskeleton reorganization".

Results: Supplementation of PDF with AlaGln preserved EC viability and restored control levels of proteins in PDF perturbed processes, especially enhancing protein folding capacity and response to stress. The direct comparison revealed a set of 55 differentially abundant spots of which 58.2% were restored with AlaGln. In support to the findings in our model, cross-comparison with transcriptomic data obtained from human peritoneal biopsies from children on PD showed changes in 12 potential marker genes of PDF cytotoxicity, of which 5 genes were restored to control levels following addition of AlaGln to the PD fluid.

Conclusions: This combined proteomics and bioinformatics approach shows that PDF harms endothelial cells and leads to drastic changes of the cellular process landscape. Cell damage and proteome changes were effectively counteracted by AlaGln. In summary, this study elucidates potential mechanisms by which AlaGln exerts cytoprotective effects in endothelial cells, offering therapeutic targets to reduce side effects of PD.

SA-PO721

Peritonitis and Predictors of Treatment Failure in Peritoneal Dialysis Patients: An Experience of 902 Consecutive Episodes in Thai Centers Chayutthaphong Chaisai,[4,5] surapon nochaiwong,[4,5] Chidchanok Ruengorn,[3,5] Kiatkriangkrai Koyratkoson,[4,5] Kajohnsak Noppakun,[6] Ratanaporn -. Awiphan,[2,5] Wilaiwan -. Chongruksut,[7,5] Sirisak Nanta.[1,5] *[1]Maesai District Hospital, Chiang Rai, Thailand, Chiang Rai, Thailand; [2]Chiangmai University, Chiangmai, Thailand; [3]Faculty of Pharmacy, Chiang Mai University, Chiang Mai, Thailand; [4]Faculty of Pharmacy, Chiang Mai University, Chiang Mai, Thailand; [5]Pharmacoepidemiology and Statistics Research Center (PESC), Chiang Mai University, Chiang Mai, Thailand; [6]Faculty of Medicine, Chiang Mai University, Chiang Mai, Thailand; [7]Faculty of Medicine, Chiang Mai University, Chiang Mai, Thailand. Group/Team: Thai Renal Outcomes Research (THOR) Investigators.*

Background: Peritonitis is a common cause of peritoneal dialysis (PD) technique failure as well as a major contributing cause of death in PD patients. Early prediction of treatment outcomes can be major potential subsequent management for PD-related peritonitis. To date, existing evidences regarding the prognostic factors for treatment failure are scarce. We therefore determine factors predicted treatment failure among PD-related peritonitis.

Methods: A multicenter, retrospective observational study was based on the PD registry database of patients aged ≥ 18 from three PD center in Thailand. Baseline sociodemographics and laboratory examination characteristics were collected between January 2006 and December 2016. Treatment failure was defined as catheter removal or peritonitis-associated death. Predictors related to treatment failure were investigated by univariable and multivariable logistic regression.

Results: A total of 902 PD-related peritonitis episodes were included, 224 (24.8%) of which had treatment failure. Of those, 157 (17.4%) required Teckhoff catheter removal and 67 (7.4) had peritonitis-associated death.

Conclusions: In order to make a decision, four key predictors from this study may potentially help to identify patients at risk of treatment failure. Early establishment of the severity of PD-related peritonitis may offer opportunities to improve treatment outcomes.

Funding: Government Support - Non-U.S.

The Influence of Duration of Peritoneal Dialysis on the Proteomic and Metabolomic Profiles of Plasma and Peritoneal Fluid Magdalena Luczak,[1] Dorota Formanowicz,[2] Joanna Tracz,[1] Elzbieta Pawliczak,[2] Krzysztof Schwermer,[2] Maria Wanic-Kossowska.[2] *[1]Polish Academy of Sciences, Pozna?, Poland; [2]Poznan University of Medical Sciences, Pozna?, Poland.*

Background: Long-term peritoneal dialysis (PD) is associated with changes of the peritoneal membrane. The major goal of this study was investigation of the effect of PD duration on metabolomic and proteomic profiles of peritoneal fluid (PF) and plasma in order to identify molecular changes occurring through long PD duration.

Methods: Plasma and PF samples were obtained from 35 diabetes and non-diabetes PD recipients in four time-points: at the time of initiation of PD (T1) and after 3 (T2), 6 (T3) and 12 months (T4) of PD. Collected 280 samples were analyzed using LC-ESI-MS/MS and GC-EI-MS/MS. Qualitative and quantitative differences in the accumulation of the individual proteins and metabolites were determined.

Results: One hundred forty-two ANOVA significant differential molecules were identified in plasma and PF samples when time T1 and T4 were compared. For example increased accumulation of CD59 glycoprotein, proliferation-inducing protein 33, insulin-like growth factor-binding protein 4 and 6 were revealed in PF of T4 diabetic samples compared to their T1. The same proteins did not differed T1 and T4 PF samples if derived from non-diabetes. One of the most interesting result concerned monocyte antigen CD14 and lipopolysaccharide-binding protein. Both proteins differentiated T1 and T4 plasma and PF samples obtained from non-diabetes and diabetes but in completely different way. The abundance of CD14 antigen was increased in PF of T4 non-diabetic patients (fold change 3.5; p = 0.004) compared with T1 and in plasma of diabetes (fold change 2.4; p = 0.02). In turn, accumulation of CD14 was 3.4 times lower in PF of T4 diabetic (p = 0.02) and 3.2 times lower (p = 0.005) in T4 plasma of non-diabetes.

Conclusions: Obtained data indicate that PD duration is strongly associated with alterations in proteomic and metabolomic profiles of plasma and PF. Patients starting PDs differed considerably in abundance of many molecules compared to the same patients after 1 year of PD. However large differences in accumulation of proteins between diabetes and non-diabetes may suggest that in these patients molecular mechanisms related to these variations are differ. Especially interesting are differences concerning CD14, a key pattern recognition receptor of the innate immune system.

Peritoneal Dialysis in Sichuan Province of China—Report from the Chinese National Renal Data System Daqing Hong. *Sichuan Provincial People's Hospital, CHENGDU, China.*

Background: The Chinese National Renal Data System (CNRDS) was established in 2010 to collect data from patients undergoing Peritoneal Dialysis in renal department of China. In this study, we aimed to study the patients of Sichuan province in the registry and analysis total characteristics and treatment effect and to examine whether or not the based clinical statistics effected the outcome of peritoneal dialysis, exploring the risk factors for peritoneal dialysis patients.

Methods: This study included 2654 patients undergoing peritoneal dialysis between January 2010 and December 2016. All data were conducted statistical analysis using SPSS 21.0.

Results: Primary glomerular disease, secondary glomerular disease and hereditary nephritis were the first three causes (Figure 2). From 2010 to 2016, the number of patients was on the rise, while patients who died or dropped out were decreasing. All

drugs including Erythropoietin, antihypertensive drugs, iron, calcium agents, phophorus lowering medicine and Vitamin D were beneficial for patients technical survival ($P<0.01$), in which the percentage of using erythropoietin, iron and antihypertensive agents were higher than other drugs. There was no significant association between based clinical variable and outcome of patients, except that ALB had a beneficial effect ($P<0.05$) for technical survival.

Conclusions: Our registry results, representing the first largest report of PD in the Southwest of China, indicate that peritoneal dialysis patients are increasing, which will require more and more medical cost to improve their outcome.

Optimal Dwell Time for Maximal Small Solute Clearances in Peritoneal Dialysis Patients

Suchai Sritippayawan. *Division of Nephrology, Internal Medicine, Siriraj Hospital, Bangkok, Thailand.*

Background: The adequacy of peritoneal dialysis was assessed by urea and creatinine clearances which depend on daily dialysate volume and dwell time. The objective of this study was to identify the optimal dwell time producing maximal small solute clearances in peritoneal dialysis patients.

Methods: Prospective cohort study was performed in chronic peritoneal dialysis patients at Siriraj hospital. We compared small solute clearances at 9 dwell time periods (0, 5, 10, 15, 20, 30, 40, 50 and 60 minutes). Weekly KT/V urea and weekly nCCr were obtained to identify the optimal dwell time which produced maximal small solute clearances. We also compared rate of glucose absorption, ultrafiltration and other small solute removals such as sodium, potassium, calcium, phosphorus and uric acid at each dwell time period.

Results: Twenty-two peritoneal dialysis patients were enrolled. The 20 minutes of dwell time had maximal weekly KT/V urea (5.01; $p < 0.001$), weekly nCCr (104.95 L/1.73m^2; p 0.018) and potassium removal (78.17 mEq/day; p 0.002). Maximal sodium removal was observed at 0 minutes (394.56 mEq/day; p 0.005). There were no significance different of glucose absorption, ultrafiltration rate and other small solute removal (phosphorus, uric acid and calcium) at any periods of dwell time. Small solute clearances, ultrafiltration and solute removals were not associated with the peritoneal membrane transport types.

Conclusions: 20-minutes dwell time had the highest weekly KT/V urea and weekly nCCr in chronic peritoneal dialysis patients. Small solute clearances were not associated with the peritoneal membrane transport types in each short dwell time period.

Use of Composite Endpoint to Improve Feasibility of Clinical Trials in Peritoneal Dialysis

Christoph Aufricht,[1] Harald Herkner,[3] Klaus Kratochwill,[2] Andreas Vychytil.[4] *[1]Pediatric Nephrology and Gastroenterology, Medical University of Vienna, Vienna, Austria; [2]Christian Doppler Laboratory for Molecular Stress Research in Peritoneal Dialysis, Medical University of Vienna, Vienna, Austria; [3]Emergency Medicine, Medical University Vienna, Vienna, Austria; [4]Medicine III, Nephrology and Dialysis, Medical University Vienna, Vienna, Austria.*

Background: Peritoneal dialysis (PD) is frequently complicated by PD–related adverse events, such as peritoneal membrane damage and/or peritonitis. Currently used PD fluids likely contribute to pathological mechanisms responsible for these complications. Low feasibility to recruit PD populations for adequately powered trials may impair clinical development of improved PD fluids. In trials in which more than one outcome is thought to be affected by the treatment, the use of composite endpoint can be recommended. Here, we test the effect of introducing clinically relevant composite PD outcomes on clinical trial design in PD.

Methods: The composite outcome "Major Adverse Peritoneal Events (MAPE)" was designed based on incidence rates of 3 individual endpoints obtained from published clinical trials: ultrafiltration (component 1), peritoneal transport characteristics (2), and peritonitis rate (3). Taking into account that some patients could experience more than one event, several degrees of overlaps of events were investigated. Sample size calculations were carried out using a chi-square test for a parallel group design in binary composite endpoint MAPE with two-sided significance level of 5% to achieve power of 80%.

Results: Based on previously reported clinical trials, event rates of 33% were assumed for each individual component (1,2,3) for the control group. In a scenario with reduction of adverse events by 25%, adequately powered studies would need a sample of more than 1000 patients to test effects on ultrafiltration, peritoneal transport characteristics or peritonitis rate, when studied individually. Combining 2 of these outcome variables reduces the required sample by approximately half, whereas the composite outcome MAPE may reduce the needed sample size to 256 patients.

Conclusions: Introduction of the composite outcome MAPE, covering 3 major PD outcomes, increases power of future clinical trials in PD, thereby improving feasibility. This results in the need for significantly lower sample sizes for assessing clinically relevant effects on PD-related complications.

SA-PO726

Peritoneal Dialysis as a Treatment for Diuretic Resistant, Refractory Heart Failure in Patients with CKD: A Single Centre Experience

Amar M. Mahdi,[1] Madhavan S. Menon,[1] Helen P. Capper,[1] Duwarakan K. Satchithananda,[2] Simon J. Davies.[1] *[1]University Hospital of North Midlands, Stoke-On-Trent, United Kingdom; [2]university hospital north midlands, Staffordshire, United Kingdom.*

Background: To assess the role and feasibility of peritoneal dialysis (PD) on clinical outcomes in patients with diuretic resistant refractory heart failure (HF) and Chronic Kidney Disease (CKD).

Methods: Retrospective data and case-note review of 20 patients with HF and CKD started on PD for fluid management. Setting: UK PD unit with an established assisted APD programme. The period of the study was between November 2010 and January 2017. Patients with eGFR <15ml/min were only included if believed to have decline in eGFR as a result of decompensating heart failure (cardio-renal syndrome).

Results: Mean age was 72±9 years, 18 (90%) aged 65 year or older, 85% male. Mean eGFR at PD initiation was 23.9±12.47 and 6 (30%) patients had eGFR of ≤15 ml/min at start of treatment. The aetiology of heart failure was ischaemic in 17 patients (85%). All patients had NYHA class III or IV, and diuretic resistance. Recent estimated ejection fraction (EF) before starting PD was available in 15 patients (EF 10%-60%), 46.6%: EF≤35%, 33.3%: EF 35-45% and 20%: EF >45%. All PD catheters were inserted using Seldinger technique and had a patency rate of 95%. The median duration of PD was 9.35 months (IQR 3.41-16.08). During the study period 14 patients (70%) died, 30% (6 patients) died within the first year, and overall the median survival was 14.8 months (IQR 4.81-24.89). Among those who has lasted on PD for at least 12 months the mean number of hospital visits (days per year) for HF or PD related issues in the year before starting PD (52.43±27.8) was significantly higher than the year after starting PD (6.86±5.87) *{p=0.007}*. The median eGFR has shown a rise by 0.5 ml/min/month over the first 3 months and a decline by 0.83 ml/min/month at 6 months.

Conclusions: Peritoneal dialysis could serve as a feasible therapeutic intervention to reduce hospital admissions in fluid management in heart failure patients where symptom control with conventional medical treatment becomes a challenge.

SA-PO727

Carbamylated Albumin Predicts Mortality in Peritoneal Dialysis (PD) Patients

Yang Li,[1] Dongyang Liu,[2] Lanping Jiang,[1] Jie Liu,[2] Zijuan Zhou,[1] Haiyun Wang,[1] Ying Wang,[1] Xuemei Li,[1] Pei Hu,[2] Sahir Kalim,[3] Limeng Chen.[1] *[1]Department of Nephrology, Chinese Academy of Medical Sciences, Peking Union Medical College Hospital, Beijing, China; [2]Clinical Pharmacology Research Center, Chinese Academy of Medical Sciences, Peking Union Medical College Hospital, Beijing, China; [3]Renal Division, Massachusetts General Hospital, Boston, MA.*

Background: Carbamylation is a posttranslational protein modification mediated by cyanate, the dissociation product of urea, which increases in patients with kidney dysfunction. Recently, carbamylated albumin (C-Alb) was reported to be independently associated with mortality in maintenance hemodialysis patients, but its value in peritoneal dialysis populations has not been studied yet. We employed high-performance liquid chromatography-tandem mass spectrometry (HPLC-MS/MS) to measure C-Alb levels and analyze its association with mortality in PD patients.

Methods: We collected serum samples from 114 maintenance adult PD patients at a single university medical center between July 2010 and January 2011, following them until December 2016 (mean length of follow up was 39.6 ± 25.6 months). C-Alb levels were natural log-transformed, and then divided into two groups (high and low levels) according to the cut-off value with highest Youden Index in ROC curve for death. Multifactor Cox regression models were used to analyze the association between C-Alb and death.

Results: The average age of the PD cohort was 63.6±13.3 years, 51% were female, and the average dialysis vintage at baseline was 37.4±29.8 months. The primary causes of ESRD were diabetic nephropathy (DN, 31.6%), hypertensive nephrosclerosis (30.7%) and chronic glomerulonephritis (20.2%). After 6 years follow up, 66 patients died (57.9%), mainly due to cardiovascular events (50.0%). Those who died were older (69.6±10.3 vs. 55.3±12.6, P<0.001), had a higher proportion of DN (40.9% vs. 18.8%, P=0.012), cardiovasular comorbidities (27.3% vs. 6.2%, P=0.004) and hypoalbuminema (Alb<35g/L) rate (63.6% vs. 43.8%, P=0.035). The Kaplan-Meier analysis showed a worse survival rate for PD patients with higher C-Alb level (Log-Rank Test: P=0.017). The univariate Cox regression analysis showed that higher C-Alb levels were associated with death. After adjusting for other important or significant mortality predictors in this cohort including age, gender, DN and cardiovascular comorbidities, higher C-Alb levels (HR=1.763, 95% CI 1.032-3.014, P=0.038) remained an independent risk factor for death in PD patients.

Conclusions: For the first time, we report higher C-Alb level was an independent risk factor for mortality in PD patients confirming similar observations in hemodialysis cohorts.

SA-PO728

Higher Serum Magnesium Is Associated with Lower Abdominal Aortic Calcification Burden in Peritoneal Dialysis (PD) Patients Kostas Stylianou,[4] Dimitra Bacharaki,[1] Olga Balafa,[5] Dimitra Lygerou,[4] Eleftheria-Kleio Dermitzaki,[4] Anastasia K. Georgoulidou,[3] George I. Tsirpanlis,[6] Marios Theodoridis,[7] Konstantinos S. Mavromatidis,[3] Periklis P. Kyriazis,[2] Ploumis Passadakis,[7] Dimitrios V. Vlahakos.[1] *[1]Attikon University Hospital, Athens, Greece; [2]Beth israel Deaconess Medical Center, Brookline, MA; [3]GENERAL HOSPITAL OF KOMOTINI, Komotini, Greece; [4]University Hospital of Heraklion, Heraklion, Greece; [5]University Hispital of Ioannina, Ioannins, Greece; [6]Nephrology, "G.Gennimatas" General Hospital, Athens, Greece; [7]University Hospital of Alexandroupolis, Alexandroupolis, Greece.*

Background: To identify factors potentially capable of preventing the progression of abdominal aortic calcification (AAC), a surrogate of cardiovascular risk in PD patients

Methods: 95 stable PD patients were studied (52 men), with a mean age of 62±15 years and a median dialysis vintage of 43 (IQR 28-71) months. The AAC was evaluated with Leena Kauppila (LK) score (range 0-24) on plain lateral abdominal radiographs. Patients were divided in a Low calcification score (CS) group: (LK score 0-4) and a High CS group: (LK score 5-24,), each comprising 38 (40%) and 57(60%) patients, respectively. Univariate and multivariate regression analysis were used to determine factors associated with a High CS.

Results: Mean CS in the whole group was 6.95±6.3. Patients with a High CS (10.8±5.1) were older, had a higher prevalence of diabetes (38.6 vs. 17.6%; p=0.04) and peripheral vascular disease (PVD) (29.8 vs. 10.5%; p=0.02), higher pulse pressure (PP) (57±14 vs. 51±15 mmHg; p=0.037) and malnutrition inflammation score (MIS) (5.12±3.1 vs. 3.8 ±2.7; p=0.039, lower serum magnesium (sMg) levels (2.12±0.36; vs. 2.37±0.54; p=0.008) and less use of cinacalcet (19.3 vs. 39.5%; p<0.03). In a multivariate analysis every 1mg/dl increase in sMg was associated with 74% lower odds of having a High CS (Table 1). MIS also emerged as a significant predictor of a high CS (Table 1). sMg was significantly (r=0.31; p=0.002) correlated with dialysate Mg concentration (0.50/0.25 mmol/L)

Conclusions: Our data indicate that sustaining higher sMg levels, as by using higher Mg dialysate concentration, and correcting the malnutrition and inflammation complex syndrome may potentially lower the AAC burden and, thus, improve cardiovascular risk in PD patients

The Influence of Alanyl-Glutamine on the Peritoneal Proteome in a Chronic Model of Peritoneal Dialysis Michael Boehm,[1] Rebecca Herzog,[2] Christoph Aufricht,[1] Klaus Kratochwill.[2] *[1]Pediatric Nephrology and Gastroenterology, Medical University Vienna, Vienna, Austria; [2]Christian Doppler Laboratory for Molecular Stress Research in Peritoneal Dialysis, Medical University Vienna, Vienna, Austria.*

Background: Peritoneal dialysis (PD) fluids exert cytotoxic properties towards peritoneal mesothelial cells. Recent studies showed that alanyl-glutamine (Ala-Gln) modulates the cellular stress response, improves survival of mesothelial cells and reduced submesothelial thickening in experimental models of PD, and improved PD effluent cell function with regards to stress and immune responses in clinical studies. However, the mechanism of Ala-Gln-mediated membrane protection is not yet fully understood. Here, we apply a novel proteomics approach in a clinically relevant in vivo model.

Methods: Following experimental PD for 5 weeks, using PD fluid with or without supplementation of Ala-Gln, or sham treatment as control, mesothelial cells from rat peritoneum were directly harvested by detergent extraction and subjected to proteomic analysis based on difference gel electrophoresis (DiGE) and subsequent protein identification by mass spectrometry. Submesothelial thickening was measured in parallel by microscopy of peritoneal tissue sections.

Results: From a total protein spot pattern of 744 spots, in 500 spots proteins were identified, linking to 233 unique protein IDs. Using database information from UniProt, proteins were assigned either to the group of high abundance plasma proteins (serum-type) or to the group of cellular proteins (cell-type). Following statistical analysis of mixed effects of PD fluid and Ala-Gln, pathway analysis allowed further assignment of candidate proteins to specific roles in the stress response and membrane preservation, observed by decreased submesothelial thickening.

Conclusions: This study shows that by combination of proteomics and bioinformatics the separation of residual plasma proteins and cellular proteins of various origin in PD effluent is feasible. Thereby, the peritoneal mesothelial cell stress proteome can be assessed after exposure to different PD fluids. Identified biological processes might allow linking molecular mechanisms of membrane protection in the in vivo model to protective effects observed in vitro and in clinical PD.

SA-PO730

Prospective, Randomized, Multi-Center, Double-Blind, Controlled, Two-Period, Two-Treatment, Crossover, Phase II Trial to Evaluate the Safety and Efficacy of Alanyl-Glutamine in Peritoneal Dialysis Andreas Vychytil,[1] Klaus Kratochwill,[2] Rebecca Herzog,[2] Christoph Aufricht.[3] *[1]Medicine III, Nephrology and Dialysis, Medical University of Vienna, Vienna, Austria; [2]Christian Doppler Laboratory for Molecular Stress Research in Peritoneal Dialysis, Medical University Vienna, Vienna, Austria; [3]Pediatric Nephrology and Gastroenterology, Medical University Vienna, Vienna, Austria.*

Background: Peritonitis and membrane failure remain serious complications of peritoneal dialysis (PD). In early clinical testing, addition of alanyl-glutamine (AlaGln) to a single dwell of glucose-based PD fluids restored peritoneal cellular stress responses and leukocyte function. This study tests effects of a novel AlaGln supplemented PD fluid on relevant biomarkers in a nation-wide trial.

Methods: In a prospective, double-blinded, cross-over design (EudraCT-2013-000400-42) stable PD outpatients were enrolled to undergo 16 weeks of treatment, 8 weeks with standard PD fluid (Physioneal 40, Baxter, US) and 8 weeks with AlaGln supplemented standard PD fluid (Physioneal 40 and Dipetiven (Fresenius-Kabi, Bad Homburg, Germany) in a randomized order. Cancer-antigen 125 (CA-125) appearance rate as marker of peritoneal cell mass and ex-vivo stimulated interleukin 6 (IL-6) release as marker of peritoneal immune competence were assessed in effluents of standard peritoneal equilibration tests (PET) at 1 h (IL-6 release) and 4 h (CA-125). Secondary outcome parameters were peritoneal and systemic markers of inflammation, amino acid metabolism and transport kinetics.

Results: Out of 54 enrolled PD patients in eight Austrian centers, 50 patients were randomized. In the full analysis set (n=41), addition of AlaGln met both primary outcome parameters with significantly increased CA-125 appearance rate and ex-vivo stimulated IL-6 release. No adverse events or safety signals were observed with PD fluid with added AlaGln, all peritonitis episodes in the safety population (n=47) occurred in the control group with standard PD fluid treatment.

Conclusions: We conclude that a novel AlaGln-supplemented glucose-based PD fluid improves biomarkers of mesothelial cell status and peritoneal immune competence compared to treatment with a standard dual-chamber PD fluid. Future clinical trials are needed to translate these findings into reduction of major PD-related clinical adverse events.

SA-PO731

Clinical Outcomes of Patients Receiving Long-Term Continuous Ambulatory Peritoneal Dialysis for More Than 10 Years Seong Sik Kang,[1,2] Hayeon Park,[1] Sang Mok Yeo,[1] Woo Yeong Park,[1,2] Kyubok Jin,[1,2] Sung Bae Park,[1,2] Seungyeup Han.[1,2] *[1]Department of Internal Medicine, Keimyung University School of Medicine, Daegu, Republic of Korea; [2]Keimyung University Kidney Institute, Daegu, Republic of Korea.*

Background: The penetration of peritoneal dialysis (PD) is decreasing lately as it is difficult to keep it stable for a long time due to infectious or non-infectious complications. However, PD is still an important and physiologic modality of dialysis for end-stage renal disease. Our objective is to analyze the characteristics of patients who are safely maintaining PD for long period.

Methods: We retrospectively investigated 78 patients who had performed PD over 10 years. We analyzed the characteristics of patients, the episodes of PD peritonitis, the change of laboratory findings between the beginning of PD and 10 years after PD, and patient survival.

Results: The mean duration of PD was 152 ± 26.6 months. The mean age at which dialysis began was 46 ± 12 years. The mean number of peritonitis episodes was 0.228 times/patient/year. The mean time from the beginning of PD to first episode of PD peritonitis was 57 ± 51.9 months. Patient survival was 100% at 10 year, 63.7% at 15 year, 45.2% at 20 year, and the leading cause of death was infection (16.7%), followed by cardiovascular disease (3.8%). There were no changes of level of serum albumin, TG, LDL, HDL, and CRP between basal and 10 year follow-up result. Nutritional status,

inflammation markers, and chronic kidney disease-mineral bone disease were well maintained compared with overall PD population.

Conclusions: In the long-term PD patients, the mean age at which dialysis began was younger and the mean time to occur first peritonitis was longer, compared with the previous reported studies. It means long-term PD patients had attack of PD peritonitis less and late and maintained good nutrition status and iron, calcium and phosphorus balance for long time. We should pay more attention to maintain good nutritional status and low incidence of PD peritonitis for maintenance of long-term PD.

SA-PO732

Does Intraperitoneal Pressure Vary in Peritoneal Dialysis Patients According to the Moment of Measurement? Fabio Procaccini, Amir Shabaka, Fernando Tornero. *Hospital Clinico San Carlos - Madrid, Madrid, Spain.*

Background: Elevated intraperitoneal pressure (IPP) in peritoneal dialysis patients (PD) is linked to alterations in peritoneal transport. IPP is commonly measured at the start of volume infusion and a maximum IPP of 18 mmHg has been recommended which corresponds to 1400ml/m2 of volume infusion. Nevertheless, there may be an adaptation of the peritoneal cavity that could cause IPP to decrease during peritoneal dwell time. Our aim was to study the hypothesis of peritoneal cavity adaptation, and analyze the relationship between IPP and dialysis infusion and drainage volumes.

Methods: We determined IPP in 17 patients in the PD program at our center by measuring the fluid column of solution in the drainage tube at the beginning and end of the peritoneal equilibration test (PET). No patient presented peritonitis or abdominal complications within 4 weeks prior to measurement. Demographic, anthropometric and PET data were collected.

Results: Out of the 17 patients studied, 12 were men (70.6%); 12 were on CAPD (70.6%) and 5 on APD (29.4%), mean age 61.87±17.8 years, mean body mass index (BMI) was 29.01±5.48 kg/m2, mean body surface area was 1.82±0.23 m2, median time in PD was 499 days (IQR 142-880.5). The mean IPP was 14.47±4.34 cmH2O after infusion and 15±4.64 cmH2O at drainage. Mean ultrafiltration was 516.12±269.5 mL with a mean weekly Kt/V of 2±0.45. We observed a decrease in IPP/volume ratio of 7.97±3.68 cmH2O/mL (p= 0.019) at drainage compared to the initial infusion value. IPP/intraperitoneal volume ratio (at both infusion and drainage) showed strong correlation with volume/BSA ratio (at infusion; r= -0.624, p= 0.007 and at drainage; r= -0.703, p= 0.002). There was a significant correlation between infused volume/initial IPP and final IPP, so that the final IPP= 21.114 - [0.041x (Infused Volume/initial IPP)] (r= 0.578, p= 0.015). There was a correlation between final IPP/BSA and infusion volume so that Volume Infused= 2355.201 - [52.727 * (final IPP/BSA)] (r= 0.630, p = 0.007).

Conclusions: The lower IPP/volume ratio at drainage confirms the adaptation of the abdominal cavity during dwell time, rendering it more important to measure IPP at the end of the exchange. We have determined an equation to predict the final IPP at drainage by measuring IPP at infusion based on infusion volume and BSA. In addition, IPP showed stronger correlation to BSA than to weight.

SA-PO733

Changes in Dialysis Prescription Affect the Time Course of Solute Transport in Peritoneal Dialysis Irene Brenna,[1,2] Emma H. Elphick,[1,2] Mark Lambie,[1,2] Simon J. Davies.[1,2] *[1]Keele University, Stoke on Trent, United Kingdom; [2]University Hospital of North Midlands, Stoke-on-Trent, United Kingdom.*

Background: Long term peritoneal dialysis (PD) is associated with increased peritoneal solute transport rate (PSTR), which correlates with hard outcomes. Whether different clinical approaches affect PSTR rate of increase is unclear.

Methods: This is a single centre retrospective longitudinal analysis, collecting data from 01/01/1990 to 31/12/2016 from PETs routinely performed twice a year in all PD patients at the Royal Stoke University Hospital. Using a linear mixed model approach, 3889 PETs from 865 patients were analysed, follow-up being up to 12.7 years, median 1.6. A random intercept/slope model was fit to assess whether the exposure to different clinical practice patterns (PD type, average glucose exposure, long dwell strategy) had an effect on the PSTR rate of increase, adjusting for patients' demographics, comorbidities, residual renal function (RRF) and peritonitis episodes.

Results: Mean predicted PSTR at PD start was 0.723, average increase 0.012 per year. Average glucose exposure affected PSTR absolute value, but not its rate of increase. The use of icodextrin was associated with higher PSTR at PD start (+ 0.055, 95%CI 0.040/0.070) and slower increase over time (0.005 per year, p=0.002). A dry long dwell resulted in lower PSTR at PD start (- 0.090, 95%CI -0.114/-0.067), but faster increase (0.029 per year, p<0.0001). The pattern of PSTR changed with starting-period too (p<0.001), the starting PSTR being lower in 1990-95 (0.723) and rising until 2005-2010 (0.824), and lower starting values were associated with greater increases over time. The change with starting-period was only partially explained by changes in practice pattern.

Conclusions: Both the initial PSTR and the subsequent change over time are associated with different PD prescription strategies.

SA-PO734

Are We Worried about Early Complications in Urgent-Start Peritoneal Dialysis? Jiri Vlasak. *Dialysis center, Fresenius Medical Care, Sokolov, Czech Republic.*

Background: Urgent-start peritoneal dialysis is defined as initiation of peritoneal dialysis (PD) in patients with newly diagnosed end-stage renal disease (ESRD) who are not yet on dialysis and who require dialysis initiation less than two weeks after PD catheter placement, but do not require urgent hemodialysis. Theoretically, an increase in the incidence of peritoneal leaks could be assumed.

Methods: Since 2011 in our dialysis center eighty-nine patients have started peritoneal dialysis (PD) with laparoscopically introduced PD catheter. Fifteen of them have initiated urgent-start PD and peritoneal dialysis treatment was initiated with lower volumes of exchange. Seventy four of them started with PD conventional (routinly 3-4 weeks after PD catheter placement). We compared retrospectively these groups focusing on early complications - infections, leaks and catheter migration, both following catheter insertion and PD commencement (within 4 weeks).

Results: Urgent-start patiens were more likely to be referred late, some of them were under the control of a nephrologist, but they experienced unexpected impairment of renal function. We did not record leaks in either group and only three patients from conventional started PD had early catheter migration. There were no infectious complications in either group.

Conclusions: Urgent-start peritoneal dialysis appears to be as safe as conventional (planned) peritoneal dialysis.

SA-PO735

An Effective Chronic Peritoneal Dialysis Model in Uremic Rats Jenny C. Nystrom, Kerstin Ebefors, Borje Haraldsson. *University of Gothenburg, Goteborg, Sweden.*

Background: Thousands of patients undergo chronic peritoneal dialysis (PD) every day but it has been remarkably difficult to establish experimental models of chronic PD in uremic animals. Such models are needed for tests of new dialysis fluids, new medications and techniques in order to further improve treatment of patients with PD. For that purpose, we have developed a new system for chronic automated PD (APD) in uremic rats.

Methods: Rats were made uremic using the nephrotoxin orellanine, a mushroom toxin known to induce uremia through selective destruction of the tubular epithelial cells with no other effects on other organs acutely or chronically, as previously investigated by us both in patients and animal models. The uremic rats and a control group of saline treated rats subsequently underwent APD for three weeks in an automated PD system; one additional set of control rats did not undergo dialysis (n=8 in each group). Each day five exchanges of 15 ml of dialysis fluid (Gambrosol® trio 10) were performed in the APD-system. At the end of the experiment, dialysate, serum and peritoneal tissue were collected for further analysis.

Results: APD worked equally well in both groups of rats. Peritoneal dialysis *per se* induced elevated expression levels of the growth factors TGF-ß and VEGF in the peritoneal fluid and tissue compared to rats that did not undergo APD. Orellanine treatment did not affect the rats negatively part from the induced uremia. Anuric rats did well on dialysis and continued to grow, albeit at slower pace compared to healthy rats with APD.

Conclusions: This study shows that it is possible to maintain uremic rats for at least three weeks in peritoneal dialysis. The elevated levels of levels of TGF-ß and VEGF in the peritoneal fluid and tissues were found to be due to APD itself, and uremia did not affect these biomarkers significantly. The use of orellanine to induce uremia in rats is an effective option without the side effects commonly seen in surgical models of uremia. We believe that the APD model shown here is a new, effective and reliable model for the testing of new dialysis fluids or new therapeutic targets in uremic animals. We hope this will improve dialysis treatment of patients in the future.

SA-PO736

Sclerosing Encapsulating Peritonitis Developing Two Years after Peritoneal Dialysis Cessation Rhyan Maditz. *Beaumont Health - Royal Oak, Royal Oak, MI.*

Background: Sclerosing encapsulating peritonitis (SEP) is a rare chronic inflammatory condition of the peritoneum believed to result from recurrent low grade peritonitis. The condition occurs when loops of bowel are encased within the peritoneal cavity by a membrane, leading to intestinal obstruction. Long peritoneal dialysis (PD) duration, acetate-buffered or hypertonic solutions and recurrent episodes of peritonitis may contribute to the development of SEP.

Methods: 46 yo male with PMHx of ESRD secondary to FSGS and loculated sclerosing peritonitis presented with fatigue of one-week duration. He was previously on PD for years but switched to HD two years prior to presentation because he was unable to achieve adequate clearance. He missed two HD sessions prior to arrival due to fatigue. CT performed on admission revealed a large amount of complicated/complex ascites, thickening of the peritoneum and nonspecific colitis and enteritis. Soon after admission, the patient became altered, hypotensive, and was transferred to the medical intensive care unit. Patient was anorexic during the hospitalization, unable to tolerate oral intake. PEG tube insertion was determined to be too risky given his comorbidities and a dobhoff tube was inserted. Methylprednisolone 500 mg daily for three days was trialed, which did not lead to clinical improvement. Further immunosuppression with Imuran/calcineurin

inhibitors was determined to be too high risk. Enterolysis was discussed, however, patient was deemed too high risk for surgery given his debilitated state. Despite the best efforts of a corroboration of medical specialties, the patient unfortunately expired after a one-month hospital stay.

Results:

Conclusions: Clinicians must be aware of SEP as a rare, but dangerous complication of prolonged PD. Patients with SEP secondary to PD progress rapidly and treatment should be immediately initiated after diagnosis. Our patient may have benefited from total parenteral nutrition (TPN), however volume status is difficult to control after TPN initiation. The patient was trialed on a short course of Solumedrol without success. Enterolysis, a last resort treatment modality for SEP, is reported to improve outcomes. Our patient was a poor surgical candidate and likely would have not survived the procedure; therefore, enterolysis was not attempted. Earlier recognition of SEP may have resulted in a better outcome for our patient.

SA-PO737

Trehalose Ameliorates Peritoneal Fibrosis through the Induction of Autophagy and the Downregulation of Snail Protein in Peritoneal Mesothelial Cells Taito Miyake,[1] Norihiko Sakai,[1] Yasutaka Kamikawa,[1] Shinji Kitajima,[1] Tadashi Toyama,[1] Akinori Hara,[1] Yasunori Iwata,[1] Miho Shimizu,[1] Kengo Furuichi,[1] Takashi Wada.[1,2] *[1]Division of Nephrology, Kanazawa University Hospital, Kanazawa, Japan; [2]Department of Nephrology and Laboratory Medicine, Kanazawa University, Kanazawa, Japan.*

Background: Peritoneal fibrosis is a severe complication of peritoneal dialysis, but there are few effective therapies to treat and/or provide for it. Trehalose is a non-reducing disaccharide and can be an osmolyte of peritoneal dialysis solution. Recent studies reveal new biological effects of trehalose as an autophagy inducer and it can be considered to be a hopeful candidate of therapeutic reagent for some diseases. But there are few reports about therapeutic effects of trehalose on fibrotic diseases. We therefore examined if trehalose has anti-fibrotic effects on the peritoneal fibrosis.

Methods: Peritoneal fibrosis was induced by intraperitoneal injection of chlorhexidine gluconate (CG). 5% trehalose or vehicle (normal saline) was administered by intraperitoneal injection to mice every other day. For in vitro study, we isolated primary mouse peritoneal mesothelial cells to investigate the ability of trehalose to attenuate the profibrotic responses.

Results: CG-induced increases in peritoneal thickness, type I pro-collagen mRNA expression and hydroxyproline content were significantly attenuated in trehalose-treated mice (n=4-9). In addition, CG challenges induced a marked peritoneal accumulation of α smooth muscle actin (αSMA)+ fibroblasts that was significantly reduced by trehalose. To specifically identify αSMA+ fibroblasts originated from peritoneal mesothelial cells, dual immunostainings of peritoneal sections were performed using anti-Wilms' tumor 1(WT1) antibody and anti-αSMA antibody. The number of WT1/αSMA dual positive cells in the peritoneum after CG challenges was significantly suppressed by trehalose (n=4). In primary peritoneal mesothelial cells, trehalose attenuates the increase of αSMA and type I pro-collagen mRNA expression induced by TGF-β1, through the induction of autophagy and the downregulation of Snail protein.

Conclusions: Our results suggest that trehalose might be a novel therapeutic reagent for peritoneal fibrosis through the induction of autophagy and the downregulation of Snail protein in peritoneal mesothelial cells.

SA-PO738

Adherence to Mediterranean Diet Predicts the Presence of Left Ventricular Hypertrophy (LVH) and Patterns of LV Remodeling in Peritoneal Dialysis (PD) Patients Dimitra Bacharaki,[2] Ignatios Ikonomidis,[5] Eleftheria-Kleio Dermitzaki,[7] Dimitra Lygerou,[7] Marios Theodoridis,[8] Kostas Stylianou,[7] Ourania Tsotsorou,[2] Anastasia K. Georgoulidou,[4] Olga Balafa,[1] Spiros Katsoudas,[2] Anastasia Korovesi,[6] Dimitra Chatzivasili,[6] Anastasia Markaki,[6] Konstantinos S. Mavromatidis,[4] Periklis P. Kyriazis,[3] Ploumis Passadakis,[8] Dimitrios V. Vlahakos.[2] *[1]University Hospital of Ioannina, Ioannina, Greece; [2]ATTIKON UNIVERSITY HOSPITAL, Athens, Greece; [3]Beth israel Deaconess Medical Center, Brookline, MA; [4]GENERAL HOSPITAL OF KOMOTINI, Komotini, Greece; [5]National and Kapodistrian University of Athens, ATHENS, Greece; [6]Technological Educational Institute of Crete, Heraklion, Crete, Greece; [7]University Hospital of Heraklion, Heraklion, Greece; [8]University Hospital of Alexandroupolis, Alexandroupolis, Greece.*

Background: To examine the impact of adherence to a Mediterranean Diet (MD) on LVH and cardiac geometry in PD patients

Methods: 53 PD patients (27 men) with a mean age of 62±14 years were studied. A MD adherence score (MDS) (range 0-55, 55 representing maximal adherence) was estimated according to a previously reported method (Panagiotakos 2007). Echocardiographic LVH was defined by LV mass index (LVMI) >95g/m^2 in women and >115g/m^2 in men. Based on LVMI and relative wall thickness (RWT), four LV geometric patterns were defined: normal (normal LVMI and RWT), concentric remodeling (normal LVMI and increased RWT>0.42), eccentric LVH (increased LVMI and normal RWT) and concentric LVH (increased LVMI and RWT)

Results: Patients with LVH (n=29) as compared to patients with no LVH (n=24) were older in age (p<0.01), had lower MDS (24.3±2.4 vs. 26.5±2.8; p<0.01) and higher malnutrition inflammation score (p<0.05), pulse pressure (p<0.05) and body mass index (p<0.01). In a multivariate logistic regression analysis adjusted for all factors mentioned above, each 1-point greater MDS was associated with 25% (OR= 0.75, 95%CI:0.57-0.93; *p*<0.05) lower odds of having LVH. The area under the ROC curve for predicting the development of LVH was 0.726 (p=0.005). At an optimal MDS cutoff of 25.5 the sensitivity and specificity of MDS in predicting the occurrence of LVH were 63% and 76%, respectively. Considering LV geometry, there was a progressive decrease in MDS from the normal group (26.4±3.2) to concentric remodeling (26.5±2.7), eccentric (24.7±2.3) and then to concentric LVH (24.1±2.4) group (p=0.038 for the trend). Finally, the MDS was associated positively with serum magnesium (Mg) (rho=0.34; p<0.05) and negatively with serum calcium (Ca) (rho=-0.28; p<0.05)

Conclusions: Greater adherence to a MD is associated with decreased LV mass, an important CVD risk factor and can confer protection against future cardiac dysfunction in PD patients. Whether these associations are partly mediated through opposite changes in serum Mg and Ca levels warrant further investigation

Immunophenotypic Abnormalities of Uremic Patients Undergoing Peritoneal Dialysis Maria Molina, Claudia Yuste, Enrique Morales, Manuel Praga. *Nephrology Department., Hospital Universitario 12 de Octubre, Madrid, Spain.*

Background: Chronic kidney disease (CKD) is usually associated with various immunologic abnormalities. However, there is a scarcely data regarding the impact of peritoneal dialysis (PD) on these abnormalities.

Methods: We presented a descriptive transversal study analysing lymphocyte absolute counts and subpopulations (CD3+, CD4+, CD8+, CD56+, CD19+, and CD4+/CD8+) in patients undergoing PD. Those patients where compared with a similar cohort of haemodialysis (HD) patients.

Results: Nineteen PD patients were studied (mean time on PD 7.6 ± 6.57 [3-20] months, age 48.4 ±18.7 [22,80] years, 57.9% women, 10 % diabetics, mean weekly KTV 2.52 ± 0.43 [2.24, 2.82]). Fourteen patients started PD after a follow up in low clearance clinic, whereas 4 where transferred from HD (mean time on HD 5.5 ±4.1 [2,14] months) and one patient had a previous kidney transplant. Eleven patients (57.9%) presented absolute lymphopenia (<1200 cells/mm^3), where 63.2% had a low CD3+ account (<850 cells /mm^3), 42.1% low CD4+ (<500 cells/mm^3), 15.8% low CD8+ (<160 cells /mm^3), 21.1% low CD56+ (<60 cells /mm^3) and 36.8% low CD19+ (<100 cells /mm^3). Patients on continuous ambulatory PD (n=6) seem to have lower lymphocyte absolute counts compared with patients on automated PD (n=13) (1163 [927-1498] cells /mm^3 vs 1074 [859-1271] cells /mm^3 respectively], secondary to a lower lymphocyte subpopulations. Lymphopenia seem to be more frequent in patients with longer mean time on PD (mean time on PD on lymphopenics 7 [1-19] months vs 4 [3-7.2] non-lymphopenic, NS). When we compared PD with HD patients, PD patients presented a non-significant trend to low lymphocyte account secondary to CD3+, CD4+ and CD8+. However, PD patients could present less changes on CD19+, known for its atherogenic role.

Conclusions: PD patients presented several changes on them immune mediators that could be different from the observed alterations on HD patients that should be studied with larger studies. The different immunological profile could explain the best survival on PD patients.

SA-PO740

Urgent-Start Peritoneal Dialysis in the Outpatient Setting in an Underserved Urban Area Andres Serrano, Melby Philip. *Mount Sinai Hospital, Chicago, IL.*

Background: Despite an increase in End-Stage Renal Disease (ESRD) incident cases selecting Peritoneal Dialysis (PD), the proportion of patients on PD remains below historical levels achieved in the 80s. There is an increased interest in urgent-start PD, as a way of increasing the number of patients on PD, and decreasing the number of patients initiating hemodialysis (HD) through a central venous catheter. However, implementing these programs could be challenging in a community hospital with scarce resources. Also, there is a great level of concern regarding complications at the moment dialysis is initiated. We are presenting our experience with a group of patients who had urgent-start PD.

Methods:

Results: During a period of 8 years, a total of 81 patients initiated PD. Forty-three patients (53%) had an indication for urgent dialysis initiation, and they either decided in advance for PD or after education regarding RRT then decided for PD. The patients underwent laparoscopic PD catheter insertion, and within 14 days they initiated PD training at the dialysis clinic. During the time in training, they received low volume PD. Of the 43 patients, 21 patients (49%) presented through the ER with no history of kidney disease. The average age was 47.9 years, and the majority of patients were Hispanics (67%). In fourteen patients (33%) the etiology of ESRD was unknown. The average estimated GFR at dialysis initiation was 6 ml/min, and the average number of days between PD catheter insertion and PD initiation was 8 days. Seven patients required in-hospital temporary HD because of impending complications related to uremia, but once stable, they had the PD catheter placed and they initiated PD training as outpatient. Two patients started PD immediately in the hospital after the catheter was placed because of emergent dialysis needs and no HD access. In terms of complications, there were 2 mechanical complications (1 pericatheter leakage, 1 poor catheter flow) and one PD related peritonitis, compared to 0 mechanical complications and 3 PD related peritonitis in patients who started PD the traditional way.

Conclusions: Our experience shows that urgent-start PD is a safe alternative to initiate renal replacement therapy avoiding the use of long term central venous catheters. We also demonstrated that urgent-start PD can be done successfully in the outpatient setting.

SA-PO741

Peritoneal Dialysis Modalities Portend Distinct Decongestive Properties Abhilash Koratala, Olanrewaju A. Olaoye, Amir Kazory. *University of Florida, Gainesville, FL.*

Background: Previous studies have established the adverse impact of lingering fluid overload on the outcomes of patients with ESRD treated with peritoneal dialysis (PD). There is mounting evidence that decongestion, if not associated with significant sodium removal, does not improve the outcomes in specific subsets of patients such as those with heart failure. We sought to explore available evidence on the ability of the two main modalities of PD (i.e. continuous ambulatory PD [CAPD] and automated PD [APD]) with regard to sodium removal.

Methods: Articles cited in PubMed database from January 2000 to March 2017 using key words "peritoneal dialysis", "sodium removal", and "ultrafiltration" were searched. Articles evaluating sodium extraction and ultrafiltration (UF) were reviewed. Clinical trials on comparative impacts of CAPD and APD were selected. Relevant data including urine volume, UF volume, and sodium removal were extracted and compared. Using Pearson product-moment correlation, the degree of linear dependence between sodium removal and UF was determined.

Results: A total of 76 citations were reviewed and 7 studies with 654 participants were included. The mean age was 55.7 years and 55.9% were men. The mean PD sodium removal was 142±44 and 87±23 mmol/day for CAPD and APD respectively (p=0.006). There was no difference between urine sodium excretion between the two groups (42.4±25 and 39.9±21 mmol/day for CAPD and APD respectively, p=0.42). The mean UF volume was 1133±331 and 931±210 mmol/day for CAPD and APD (p=0.09). There was a strong correlation observed between PD sodium removal and UF volume for CAPD (r=0.99, p=0.0) while it was only modest for APD (r=0.6, p=0.15).

Conclusions: Currently available evidence suggests that fluid removal is comparable for CAPD and APD. However, CAPD is associated with significantly greater sodium extraction compared to APD, with strong correlation between UF volume and the amount of sodium removal. Therefore, it is conceivable that CAPD would be advantageous in clinical settings such as heart failure where sodium removal *per se* is of utmost importance. Future prospective studies are needed to explore whether the advantageous sodium extraction by CAPD would translate into improved outcomes in these patients.

SA-PO742

Intradialytic Blood Pressure Stability during Hemodialysis with a Novel Hemodialysis Device Luis Alvarez,[2,3] Paul Chen,[4] Dean Hu,[4] Sarah S. Prichard.[1] *[1]Advisor, Ouset Medical Inc, San Jose, CA; [2]Nephrology, Palo Alto Medeical Foundation, Palo Alto, CA; [3]Outset Medical Inc, San Jose, CA; [4]Outset Medical, San Jose, CA.*

Background: Intradialytic hypotension (IDH) is a common event. The literature suggests that up to 20% of dialysis patients have IDH that requires intervention, over 70% of patients have a decrease of systolic BP (SBP) of 20mmHg and up to 27% have a decrease of of 40mmHg. Patients with frequent IDH have worse outcomes. The Tablo™ Hemodialysis System is a novel technology designed to be simple for both patients and staff to use, which enables self-care hemodialysis in a variety of clinical settings. This study reports on the intradialytic BP of patients dialyzed using Tablo.

Methods: 2012 dialysis treatments using Tablo were assessed in the outpatient setting at 10 dialysis units. Tablo automatically takes and records BP at preset intervals during dialysis as prescribed by the physician and transmits them wirelessly in real time. The percent of patients with a change in SBP of 20 mmHg or 40mmHg, a change in mean arterial pressure of 10mmHg, or a SPB < 90mmHg (with a diastolic BP of <60) were calculated. UF and pre/post weights were also collected.

Results: Results are shown in Table 1

Conclusions: Patients dialyzed with Tablo have less IDH compared to that reported in the literature. The reason for this difference may relate to differences in the patient populations or unique features of Tablo. This important clinical observation needs further study to determine if the use of Tablo could favorably influence outcomes.

Funding: Commercial Support - Outset Medical Inc

Table 1

PARAMETER Sample size (n)	Number (%) 2012
Δ Systolic BP > 20mmHg	765(30%)
Δ Systolic BP > 40mmHg	0 (0%)
Δ MAP > 10mmHg	919 (45.6%)
< 90 Sys BP & < 60 Dia BP	130 (6.5%)
Pre-dialysis weight	81.2 + 20.8 kg (45.1-147.2kg)
Post-dialysis weight	78.5 + 20.6 kg (41.0-145.2kg)
Avg ultrafiltration	2486 + 1094 mL (0-6000ml)
Avg UF rate	8.7 + 3.7 mL/kg/h (0-25.2 ml/kg/hr)

SA-PO743

Achieving Dry Weight, Intradialytic Hypotension, and Outcomes in Patients Undergoing Hemodialysis Salim Bou Slaiman, Nabil Zeineddine. *staten island university hospital, Staten Island, NY.*

Background: Patients with end stage renal disease (ESRD) are known to have high rate of hospitalizations and increased mortality compared to the general population. These morbidities might be related to a set of complications that occur during hemodialysis (HD) sessions, such as hypotensive episodes. On the other hand, reaching the dry weight (DW) during a HD session was also linked to improved outcomes.

Methods: This is a retrospective study with patients recruited in a dialysis center in Staten Island, NY; 36 HD sessions per patient in 3 months duration, with the rate of hypotensive episodes (as defined by KDOQI), and whether a DW was achieved or not, will be collected. Hospitalization rate and complications (cardiovascular and fistula-related) will be recorded for the following 12 months.

Results: 49 patients with a mean age of 60.42 (±14.6) years and their 1729 HD session were analyzed so far. They were 50% males and 50% females. Results didn't show any significant difference in hospitalization or complications in patients who had more episodes of hypotension (p=0.25), however a statistically significant difference was found between patients who achieved DW and those who didn't in terms of having a clotted arteriovenous (AV) access (p=0.048). There was a statistically significant negative correlation between hypotension and achieving DW (R= -0.136; p= 0.022). Also female gender was strongly associated with more hypotensive episodes on one hand, and failure to achieve DW during HD sessions on the other hand (p=0.0001 for both differences).

Conclusions: The results seen so far didn't appreciate any significant effect of hypotension or achieving DW during HD sessions on morbidity and complications in the following year except for a slightly significant difference in having a clotted AV access seen more in patients who achieved their DW; this might be secondary to a more aggressive ultrafiltration for attaining the target weight. The strong negative correlation between achieving DW and hypotensive episodes indicates that the main reason for not achieving DW is hypotension. On the other hand, females were more prone for intradialytic complications such as hypotension and failure to achieve DW. A larger population is needed for a better analysis and to further investigate any relation between intradialytic complications and morbidity and mortality in patients with ESRD.

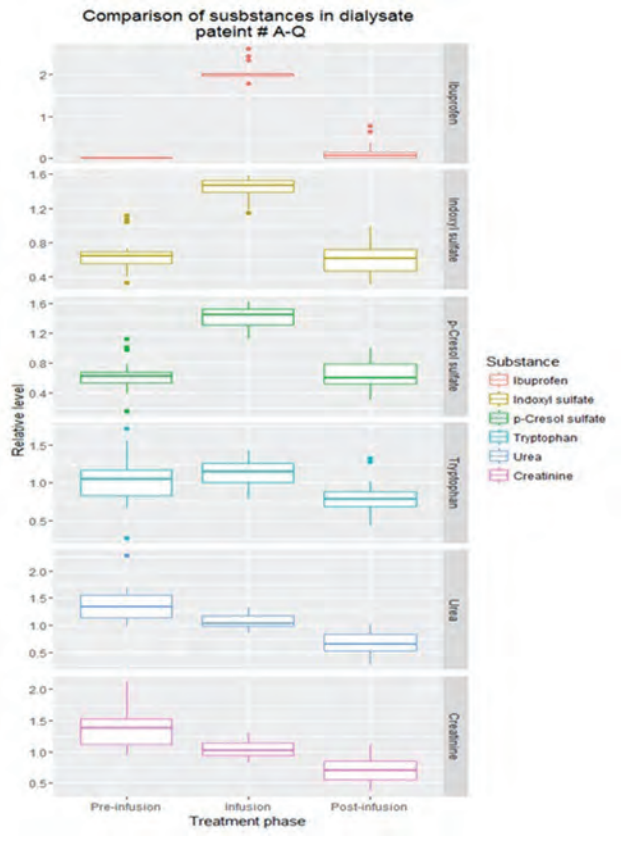
Displacer-Enhanced Dialytic Removal of Protein-Bound Uremic Toxins during Hemodialysis Karla B. Cano Escobar,[1] Xia Tao,[3] Israel Campos,[3] Vaibhav Maheshwari,[2] Jillian Brown,[4] Garry J. Handelman,[4] Stephan Thijssen,[3] Peter Kotanko,[2] BEATRIZ E. CORNEJO MEDELLIN,[1] Magdalena Madero.[1] *[1]INCIC, Mexico, Mexico; [2]Renal Research Insitute, New York, NY; [3]Renal Research Institute, New York, NY; [4]University of Massachusetts, Lowell, MA.*

Background: Hemodialysis(HD) has limited efficiency on protein-bound uremic toxins(PBUTs) removal due to their high albumin binding. Binding competitors to PBUTs("displacers") such as ibuprofen(IBF) can increase the free concentration of PBUTs and enhance dialytic removal. We investigated if infusion of IBF improves the dialytic removal of p-cresyl sulfate(pCS) and indoxyl sulfate(IS)

Methods: Chronic HD patients(National Institute of Cardiology, Mexico City) were studied during a mid-week HD on their standard prescriptions(Q_b300 mL/min;Q_d500 mL/min). IBF(800 mg) was infused at a constant rate into the arterial line, from 20 to 40 minutes into the treatment. Dialysate levels of IS, pCS, IBF, tryptophan(TRP) were measured by HPLC. Concentration data were normalized to the respective patient mean levels, which are reported as mean±SD and were compared before, during and after IBF infusion

Results: Seventeen patients were included(10 females, mean age 36±11 years;HD vintage 24 (3-111) months). IBF infusion was well tolerated. Mean of relative levels in the dialysate outlet before, during and after IBF infusion were 0.67±0.23,1.42±0.14, and 0.61±0.19 for IS, 0.63±0.24,1.42±0.15, and 0.64±0.19 for pCS, respectively, indicating a marked increase of dialytic PBUT removal during IBF infusion. Creatinine and urea, non-protein bound control solutes, continued to decline during the IBF infusion, while TRP, a moderately protein bound molecule, increased non-significantly(Fig.1)

Conclusions: This first-in-man study shows that IBF as a displacer during HD significantly enhanced the dialytic removal of PBUTs. These results should stimulate the search for safe and effective molecules that may be used as displacers during HD



SA-PO745

Assessment of the Impact of Fluid Removal Rate on Central Arterial Waveform Analysis Michael E. Brier,[2] Alfred A. Jacobs,[2] George Aronoff.[1] *[1]DaVita, Inc., Naples, FL; [2]University of Louisville, Louisville, KY.*

Background: Rapid fluid removal during dialysis is associated with poor cardiac outcomes when rates exceed 10 ml/h/kg. We tested the hypothesis that measuring central arterial pressure and waveform analysis including measures of vascular stiffness would help identity those patients at risk.

Methods: Nineteen subjects at the University of Louisville were enrolled in a prospective study measuring central blood pressure and waveform analysis using the SphygmoCor device. Subjects were studied following informed consent on the first and last dialysis treatment of the same week. Measurements were obtained prior to dialysis and at 30 minute intervals. Measurement data were summarized using regression analysis and the resulting slope and intercept were tested against fluid removal rate. We compared central arterial pressures (systolic, diastolic, mean, augmentation), augmentation index, and reflection magnitude. All analyses were performed in SPSS using linear regression.

Results: Subject predialysis weight ranged from 53 to 167 kg. Four subjects were female. Fluid removal rates ranged from 4.1 to 30.8 ml/h/kg and were significanlty related to predialysis weight (p=0.003). The results of the analysis comparing fluid removal rate to measured parameters are shown in the following table.

Conclusions: Comparison of central pressures and vascular stiffness with fluid removal rate demonstrated a significant relationship between central diastolic pressure and central mean pressure. The relationship demonstrated an increase in these measures for those subjects with the greatest fluid removal rate which may be a contributing factor in the observed morbidity and mortality of these patients. This observation is confounded by predialysis weight where the largest fluid removal rates were associated with the smallest patients. Three measures of vascular stiff were not found to be related to fluid removal rates.

Parameter	Regression Estimate	p value
Central systolic pressure	15.2	0.119
Central diastolic pressure	54.6	0.002
Central mean pressure	36.0	0.011
Augmentation pressure	-28.8	0.227
Augmentation Index	-19.2	0.099
Reflection magnitude	-30.8	0.112

Comparison of individual regression slope results to fluid removal rate.

SA-PO746

Routine Hemodialysis Does Not Result in Optimal Plasma Magnesium Concentrations Niki H. Leenders,[2] Tiny Hoekstra,[2] Frans J. van Ittersum,[2] Joost Hoenderop,[1] Marc G. Vervloet.[2] *[1]Radboud university medical center, Nijmegen, Netherlands; [2]VU University Medical Center, Amsterdam, Netherlands.*

Background: Lower plasma magnesium (Mg) concentrations have been associated with a higher overall and cardiovascular mortality in hemodialysis patients. The optimal level of plasma Mg in hemodialysis patients appears to be above the reference range for the healthy population (typically 0.70-1.00 mmol/L). Plasma Mg is not routinely measured after hemodialysis. Aim of this study was to determine the effect of standard hemodialysis treatment on plasma Mg.

Methods: Plasma Mg was measured in duplicate before (Mg_{pre}) and after (Mg_{post}) 6 consecutive dialysis sessions in 34 patients on a regular 3 times weekly hemodialysis schedule with a standard 0.50 mmol/L dialysate magnesium concentration.

Results: Mean Mg_{pre} was 0.88 mmol/L (SD 0.14), 76% of patients had a mean Mg_{pre} below 1.00 and the coefficient of intra-individual biological variation was 5.6%. Post-dialysis, mean Mg was decreased to 0.78 (SD 0.06, p<0.001). Univariate linear regression showed that mean Mg_{pre} and Mg_{post} in an individual were positively correlated (p<0.001) and the regression line indicated that Mg was stable during dialysis at a Mg_{pre} of 0.73, decreased at a Mg_{pre} above 0.73 and increased at a Mg_{pre} below 0.73. In an analysis with linear mixed models a 0.10 mmol/L higher Mg_{pre} was associated with a 0.03 mmol/L higher Mg_{post} (95%-CI 0.024-0.037, p<0.001). If added to the model, baseline factors including gender, age, serum albumin, height and weight; and dialysis characteristics including vascular access type, dialysis duration, ultrafiltration volume, blood flow and dialysis efficiency did not change this association.

Conclusions: In the majority of the hemodialysis patients Mg_{pre} is suboptimal. Routine hemodialysis further declines magnesium in the majority of patients. Current dialysate magnesium concentrations may be too low.

SA-PO747

Enhanced Phosphate Clearance of Dialyzers by Membrane Inner Surface Structure Optimization Tiancheng Xu,[2] Chunyao Zhang,[2] Xingya Wang,[2] Changjun Mu.[1] *[1]WEGO blood purification products Co., Ltd, Weihai, China; [2]Wego Blood Purification Products Co., Ltd., Weihai, China.*

Background: Elevated phosphate levels increased morbidity and mortality among dialysis patients, so the control of serum phosphate concentration is a considerable clinical approach. To enhance the phosphate clearance of dialyzers, hemodialysis membranes with different properties of inner surface structure have been specially developed and researched.

Methods: Firstly, SEM, dextran retention method (DRM), SurPASS and liquid-liquid displacement porometry (LLDP) were used to characterize the zeta potential, mean flow pore diameter of membranes respectively in MF13 and F6HPS dialyzers. In addition, a case-control study including 105 chronic kidney diseases patients (55 males, 50 females, mean age 56 years) enrolled at two hospitals in China who had been undergone stable hemodialysis for at least three months was conducted in 2016. Polysulphone dialyzers (Fresenius F6HPS or Wego MF13) were applied to each hemodialysis treatment. Finally, the SPSS PASW (statistical package of social science) Statistics v18.0 (SPSS Inc., Chicago, IL, USA) was used to analyze the patient data.

Results: When pH=7.0 (close to the blood pH of the hemodialysis patient), the membrane inner surface zeta potential of MF13 (-17.1 mv) was slightly lower than F6HPS (-15.0 mv), but the mean flow pore diameter of membrane of MF13 (28.3 nm) was much larger than F6HPS (22.2 nm). A thinner inner surface and higher inner surface porosity were obtained in the membrane of MF13. According to the tortuous capillary pore diffusion model, the increase of k_M followed by the r_p has been concluded, which leads the prediction of the removal of phosphate in MF13 being superior to F6HPS theoretically. In fact, the clinical datas with significant differences between MF13 and F6HPS for total 105 HD patients being randomly divided into two groups were presented in Table 1.

Conclusions: The mean flow pore diameter, surface thickness and porosity are the determinant factors of phosphate clearance when the other characteristics of membrane inner surface structure were same, such as membrane surface materials and surface zeta potential.

Funding: Other NIH Support - China Association for Medical Devices Industry (CAMDI)

Study of Lung Ultrasound as a Sensitive Tool for Evaluating Fluid Status in Chronic Hemodialysis Patients Hala S. Elwakil. *U of Alexandria - Faculty of Medicine, Alexandria, Egypt. Group/Team: Hemodialysis lung comets group.*

Background: Control of fluid status is an important constituent of adequate and efficient hemodialysis treatment. Dry weight is usually assessed clinically, and several methods have been developed to assess the hydration status in chronic hemodialysis patients. Ultrasonographic lung comets evaluates extravascular lung water while the diameter of inferior vena cava (IVC) estimates central venous pressure, so ultrasound is considered as a useful tool to evaluate the hydration status of hemodialysis patients. The present study was designed to use lung ultrasound to assess lung congestion before and after a dialysis session in correlation to clinical signs and symptoms and the achieved dry weight as well as IVC diameter in hemodialysis patients.

Methods: The present study included 25 patients on maintenance hemodialysis in Alexandria University Hospitals. All the patients were subjected to thorough history taking with special concern on grade of dyspnea and ultrafiltration volume, as well as clinical examination for signs of hypervolemia. Radiological examination including ultrasound lung comets score and diameter of hepatic portion of inferior vena cava (IVC) before and after dialysis session.

Results: The mean lung comets score before dialysis was 54.72±28.47 and decreased significantly after dialysis to 28.52±19.88 (p=0.000). There was a significant positive correlation between ultrafiltration volume and the absolute change of lung comets score (p=0.003) while there was no significant correlation between the ultrafiltration volume and the absolute change of IVC diameter (p=0.219). There was a significant correlation between lung comets score and grade of dyspnea before and after dialysis (p=0.037, 0.001 respectively). Furthermore lung comets were found in asymptomatic patients especially after dialysis. There was a significant positive correlation between the grade of lung comets and IVC diameter both before and after dialysis (p=0.004, 0.003) respectively.

Conclusions: Ultrasound lung comets score is a sensitive marker of lung congestion and even may precede the development of symptoms of lung congestion in hemodialysis patients. Moreover, lung comets score is highly correlated with ultrafiltration volume, thus, it could be used as a good marker for achieving dry weight in hemodialysis patients with more superiority over IVC diameter assessment.

Dietary Sodium Intake and Clinical Outcomes in Hemodialysis Patients Antonio R. Morales,[2] Carlos alberto López lozano,[1] Sandra L. Báez lópez,[1] Anel V. Barbarín vázquez,[1] Javier Soto-Vargas,[2] Jorge fernando Topete reyes.[2] *[1]Clinical Nutrition, University of Guadalajara, Guadalajara, Mexico; [2]Regional General Hosptial 46, Mexican Institute of Social Security, Guadalajara, Mexico, Guadalajara, Mexico.*

Background: Dietary sodium is thought to play a major role in the pathogenesis of hypertension, hypervolemia and mortality in hemodialysis patients. The evidence supporting daily dietary sodium intake of 2 g on hemodialysis is not strong. Our objective was to assess the relation between sodium intake and interdialytic weight gain, hyper and hypotension in hemodialysis sessions, and hospitalizations.

Methods: We included 70 patients receiving thrice-weekly hemodialysis treatment in this prospective observational study. The median follow up was 32.4 months (IQR 24.8-34.3). Available data included demographics, laboratory and clinical measures and details of the dialysis prescription. We examined the dietary sodium intake in a hemodialysis and inter dialytic day with 2-day diet diary-assisted recalls.

Results: There was a male predominance (62.9%). The mean age was 45 years (IQR 29-60.0). The median sodium intake in a hemodialysis day was 1144.5 mg (IQR 576.0-1905.5) and in no HD day of 1499.5 mg (IQR 877-2098.2). The dry weight assessed by impedance was 60.0 kg (IQR 50.4-66.5) the post HD weight was 62.5 kg (IQR 52.0-68.4), with a median ultrafiltration of 2.5 liters (IQR 2.0-3.5), only 24 (34.3%) of the patients were in theirs dry weight. 40 (57%) patients were hypertensive previous to the HD session, and 15 (21.4%) developed hypotension during HD session. There were a weak correlation between sodium intake on HD day and no HD day, with the average ultrafiltration (R2 0.362 and 0.261, p= 0.002 and 0.041 respectively), but no with the systolic or diastolic pressures before and after HD session. There were an inverse association between the amount of sodium intake and hospitalizations (p=0.026). There were no association between sodium intake and the difference of actual weight and dry weight, or the development of hypotension or hypertension.

Conclusions: We find an inverse association between the amount of sodium intake and the number of hospitalizations; however there were no association with interdialytic weight gain, hypertension or hypotension in this cohort of HD patients.

SA-PO750

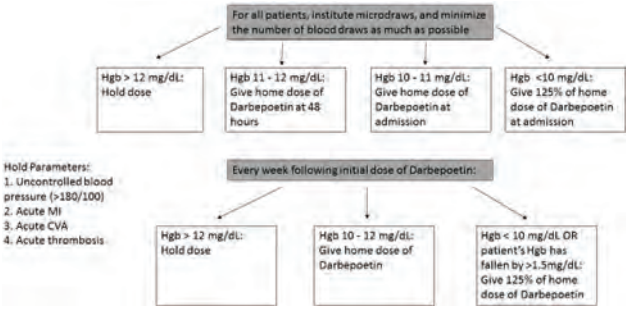
Increasing Erythropoietin-Stimulating Agent (ESA) Administration in Hospitalized ESRD Patients Benjamin Griffin,[3] Elizabeth Flanigan,[1] Cara A. Chao,[5] Diana I. Jalal,[4] John M. Carson.[2] *[1]Memorial Health System, Colorado Springs, CO; [2]None, Aurora, CO; [3]University of Colorado, Aurora, CO; [4]University of Colorado Denver Health Science Center, Aurora, CO; [5]University of Colorado School of Medicine, Aurora, CO.*

Background: Anemia is a common complication in patients with ESRD due to decreased production of erythropoietin in the diseased kidneys. ESAs have been developed to combat anemia in ESRD, and now are widely used to maintain hemoglobin levels in the range of 10 - 11 in ESRD outpatients. ESRD patients who are hospitalized are at greater risk to develop anemia than their outpatient counterparts. Despite this, ESA use rates in the hospital for patients with ESRD patients are exceedingly low. Our magnitude assessment shows that only 30% of patients received their ESA while an inpatient at UCH.

Methods: Given the known harms associated with anemia in the ESRD population, the high rates of anemia following hospitalization, and the low use of ESAs in the inpatient setting, we set out in this QI project to increase inpatient ESA administration from 30% to 60%. Our intervention was to implement a standardized ESA dosing protocol for all ESRD patients based on their outpatient dose and inpatient hemoglobin values (Figure 1). Hold parameters included blood pressure > 180/100, and active myocardial infarct (MI), stroke, or thrombosis. The hemodialysis template was also modified to prompt the provider to include ESA administration information.

Results: Since implementation of the ESA administration interventions in April 2017, 92 ESRD patients have been hospitalized a total of 138 times. During these hospitalizations, the rate of ESA administration, defined as receiving one or more doses of an ESA as an inpatient, was 70%. The rates of thrombosis, cardiac events, and strokes has remained constant since implementation. Hemoglobin values at 3 months from discharge are being collected, but are not yet available for the majority of our patients.

Conclusions: The implementation of an ESA dosing algorithm results in higher rates of inpatient ESA administration without an increase in complications.



SA-PO751

Comparison of Stroke Volume Measurements during Hemodialysis Using Bioimpedance Cardiography and Echocardiography Michael J. Germain,[4] Jyovani W. Joubert,[1] Brian H. Nathanson,[3] Yossi Chait,[5] Nathan W. Levin.[2] *[1]Kidney Care and Transplant Services of New England, Agawam, MA; [2]None, New York, NY; [3]OptiStatim, LLC, Longmeadow, MA; [4]Renal and Transplant Assoc of New England, Hampden, MA; [5]University of Massachusetts, Amherst, MA.*

Background: Inadequate fluid management during hemodialysis (HD) has serious morbidity and mortality consequences. Intradialytic fluid management is typically guided by blood pressure, an indirect measure of hemodynamics status. Direct measurements of hemodynamic parameters may improve cardiovascular outcomes by providing empirical bases for intervention. We compare stroke volume (SV) measurements using a non-invasive, regional biompedance cardiography device (NiCaS) with Doppler echocardiography (Echo) in an HD setting.

Methods: Stroke volumes were simultaneously measured using the devices in 17 patients receiving maintenance HD. Measurements were made during two weekly HD treatments, and twice within each HD treatment during the first and last hourd, for a total of 64 SV measurements. Agreement between devices was assessed using linear regression, Pearson's correlation coefficient, a Bland Altman plot, and 4-Quadrant plot each adjusted for repeated measures within patients.

Results: Echo and NiCaS SV mean and 95% CIs were 58.0 (50.1, 65.8) and 56.7 (49.4, 64.0) ml, respectively. NiCaS SV correlated strongly with Echo SV during the first and last hours of treatments ($r = 0.93$, $p<0.001$ and $r = 0.92$, $p<0.001$, respectively). Linear regression of NiCaS on Echo showed a slope of 0.97, 95% CI (0.91, 1.02) which did not differ from 1, $p = 0.20$. A Bland-Altman plot and 4-Quadrant plot (Figure, left) indicated the two methods produced comparable measurements. Mean arterial pressure (MAP) changes during first and last hours of treatments did not correlate with SV changes during the same periods (Figure, right).

Conclusions: NiCaS SV measurements correlate with and are similar to Echo SV measurements. Thus, noninvasive NiCaS technology may be a practical method for measuring SV during HD.

Funding: Commercial Support - New NI Medical

SA-PO752

Characteristics of ESRD Patients Admitted for Inpatient Dialysis and Its Contribution to Cost of Care Madhuri Ramakrishnan,[1] Siva sagar Taduru,[1] Reem Mustafa.[2] *[1]University of Missouri Kansas City, Kansas CIty, MO; [2]Nephrology, Kansas University Medical Center, Kansas City, KS.*

Background: The United States Renal Data System (USRDS) 2010 report shows that Medicare spent $29 billion, or almost 6% of its annual budget in 2009, on patients with end stage renal disease (ESRD). This covers a variety of expenditure, including hospital admissions. These admissions can be for complications that require emergent dialysis. We aim to present data on admissions of patients with ESRD for complications including hyperkalemia, acidosis and pulmonary edema requiring inpatient dialysis.

Methods: We identified ESRD patients who were admitted with indications of emergent dialysis, and with a length of stay (LOS) < 2 days, and therefore had conceivably no further indication for continued admission. We searched the National Inpatient Sample (NIS) from 2008 – 2014 using International Classification of Diseases Clinical Modification (ICD-9-CM) codes to identify patients with ESRD on long-term dialysis, who were admitted with a primary diagnosis of hyperkalemia, acidosis, or pulmonary edema. We then identified those patients who received dialysis while inpatient, and those whose LOS was < 2 days. We describe categorical variables as proportions and continuous variables as means.

Results: We identified total of 30,918 admissions between 2008 – 2014 for patients with ESRD, who were admitted with indications for emergent dialysis, and had a LOS < 2 days. These represented 1.03% of all-cause admissions in ESRD patients. The patients' mean age was 52.0 ± 15.6 years and 54% were males. Of these patients, 32.2% were Caucasians, 31.3% African-Americans, and 25.8% Hispanics. Hyperkalemia was the primary indication in 79.2% of cases, pulmonary edema in 12.3%, ESRD in 8%, and acidosis in only 0.5% of cases. 63.6% patients were insured by Medicare, 18.8% by Medicaid, 9.1% by private insurance, and 5.8% were uninsured. 55.9% of these admissions were seen in urban teaching hospitals. The mean total charges were $13,141 ± 9,522 per admission, which amounts to a mean annual charge of $58,041,920.

Conclusions: Our study reports on admissions of ESRD patients with indications for emergent dialysis. We hypothesize that a proportion of which could represent preventable admissions, incurring higher costs than outpatient dialysis. Further studies are needed to identify factors associated with such admissions, and form strategies to prevent them.

SA-PO753

A Twelve Month Retrospective Analysis of Corrected Serum Calcium (CSC) and Parathyroid Hormone (iPTH) in Patients Hemodialyzed with Citrate Acidified Dialysate (CD) Linda H. Ficociello,[1] Ludmila Anderson,[1] Paul Balter,[2] Alice Topping,[2] Claudy Mullon,[1] Robert J. Kossmann.[1] *[1]Fresenius Medical Care North America, Waltham, MA; [2]Renal Research Institute, New York, NY.*

Background: CD contains citric acid (citrate) as the acidifying agent. In the blood, citrate binds to calcium (Ca); however, citrate is quickly metabolized by the liver releasing and restoring Ca levels. The objective of this database analysis was to assess potential effects of CD on CSC and iPTH in chronic hemodialysis (HD) patients who converted from acetate acidified dialysate (AD) to CD.

Methods: HD patients with 3 mos. of AD treatment data (baseline [BL]) followed by 12 mos. of CD treatment data were analyzed. Mean pre-HD CSC and iPTH laboratory values for AD and CD treatment periods were compared by quarters (Q1-Q4) and overall. Subanalyses were carried out by iPTH ranges (<130, 130-600, >600 pg/ml) during BL. Changes in concomitant medications (Ca-based phosphate binders [CaPB], cinacalcet, in-center vitamin D [VitD]) were explored. Paired t-test, chi^2, α=.05 were used.

Results: Non-significant changes in CSC were observed after the CD conversion. Increases in iPTH during Q1 leveled off during Q2-Q4, with the exception of the BL iPTH > 600 pg/ml group where a steady iPTH decrease occurred (BL: 1,095.4 vs. Q4: 905.1 pg/ml, p<.001) (Table). From BL to Q4, the proportion of patients treated with CaPB remained the same (18% vs. 22%), cinacalcet use increased from 22% to 31% (p=.01), and in-center VitD use from 81% to 88% (p<.001).

Conclusions: No changes in CSC, and clinically modest changes in iPTH, followed the conversion from AD to CD. Variability was observed according to the BL iPTH range. Limitations include the observational nature of the assessment and inability to account for wide-ranging clinical practices. Future analyses should incorporate ionized Ca.

Funding: Commercial Support - Fresenius Medical Care North America

Control of Uremic Solute Levels in Smaller Pediatric Hemodialysis Patients Frank J. O Brien,[1] Enrica Fung,[1] Natalie Plummer,[1] Timothy W. Meyer,[1] Paul R. Brakeman,[2] Scott M. Sutherland,[3] Tammy L. Sirich.[1] *[1]Stanford University/VAMC Nephrology, Palo Alto, AL; [2]UCSF, San Francisco, CA; [3]Stanford University, Palo Alto, CA.*

Background: Current guidelines for hemodialysis (HD) in pediatric patients are adapted from those for adults, and dialysis is prescribed proportional to urea's distribution volume to achieve a target Kt/V_{urea}. Dosing HD proportional to volume in smaller patients, however, has been questioned. Uremic waste solutes may be produced in proportion to metabolic rate, may be more nearly proportional to body surface area (BSA) than volume. As body size decreases, the ratio of BSA to volume increases. Plasma levels of uremic solutes may thus remain higher in smaller patients when dialysis is prescribed proportional to volume. We tested this hypothesis by measuring plasma levels of pseudouridine (PU), a uremic waste solute whose generation is proportional to BSA, in pediatric dialysis patients.

Methods: PU and urea nitrogen (UN) were measured in plasma and dialysate obtained at the midweek session in 19 pediatric patients with BSA from 0.64 to 1.88 m^2 receiving thrice weekly HD.

Results: The dialytic clearance (K_d) of PU was proportional to that of UN (K_{dPU}/K_{dUN} 0.83±0.06, R^2 0.95, p<0.001). As expected, the generation of PU assessed by PU recovery in the dialysate was proportional to BSA (189±45 μmol/day/m^2, R^2 0.70, p <0.001). spKt/V was well maintained averaging 1.55±0.24 and did not vary over the range of BSA values. As shown in the figure, however, the pre-treatment plasma PU level was significantly higher in the patients with lower BSA (p <0.05).

Conclusions: Dosing HD by volume may leave uremic solutes at higher levels in smaller pediatric patients. Further studies are needed to determine whether prescription of HD based on BSA provides clinical benefit.

Impact of Thrice-Weekly In-Centre Nocturnal Hemodialysis on Health-Related Quality of Life Chance S. Dumaine, Kelvin C. Leung, Jennifer M. MacRae. *University of Calgary, Calgary, AB, Canada.*

Background: Home hemodialysis is associated with improved health-related quality of life (HRQoL); however, few studies have examined the impact of in-centre nocturnal hemodialysis (ICNHD) on HRQoL or on dialysis-related symptoms. We sought to determine whether conversion from conventional hemodialysis to ICNHD (8 hours, thrice weekly) improves HRQoL or reduces the burden of dialysis-related symptoms.

Methods: Prospective cohort study of conventional in-centre HD patients transitioned to ICNHD between October, 2013, and January, 2016. Health-related quality of life and

symptoms associated with dialysis were assessed at baseline using the Kidney Disease Quality of Life-36 (KDQOL-36) survey. Follow-up surveys were completed at 12 months and differences from baseline were assessed using paired t-testing.

Results: Thirty-six patients were enrolled in ICNHD during the study period (69% male, mean age 54). Mean time on dialysis prior to enrollment was 31 months and mean Charlson Comorbidity Index score was 2.19 (range 0-4). Twenty-four patients (67%) were included in final analyses. Table 1 shows changes in the domains of the KDQOL-36. Significant improvements were seen in the "Effects of Kidney Disease" and "Mental Health Composite" domains (increase of 17% and 16%, respectively). Analyses yet to be conducted include an assessment of individual symptoms, as well as a sub-analysis using baseline KDQOL-36 scores to divide the cohort into tertiles.

Conclusions: In-centre nocturnal hemodialysis results in improved HRQoL. Previous studies have shown that patients with the lowest HRQoL at baseline derive the most benefit from home hemodialysis; further analyses will examine whether the same is true for ICNHD. Further studies are needed to determine whether improved HRQoL with ICNHD is associated with improved patient survival.

Table 1: Change in Health-Related Quality of Life

	Baseline Mean (SD)	12-Month Follow-up Mean (SD)	p-value
Symptoms/Problems	73.4 (11.9)	77.0 (12.6)	0.09
Effects of Kidney Disease	48.2 (23.1)	56.4 (22.3)	0.046
Burden of Kidney Disease	29.7 (25.2)	31.8 (23.1)	0.33
Physical Health Composite	34.7 (7.3)	36.4 (10.7)	0.24
Mental Health Composite	43.9 (12.1)	51.0 (10.5)	0.003

Table 1: Mean and standard deviations for each of the 5 domains of the KDQOL-36. Each domain scored on a scale of 1 to 100, with higher values representing superior HRQoL.

Using Intradialytic Blood Pressure Slopes to Assess Extracellular Volume in Hemodialysis Patients Peter N. Van Buren,[2] Hao Liu,[1] Mark T. Sonderman,[1] Shani Shastri.[2] *[1]Internal Medicine, Nephrology, UT Southwestern Medical Center, Dallas, TX; [2]UT Southwestern, Dallas, TX.*

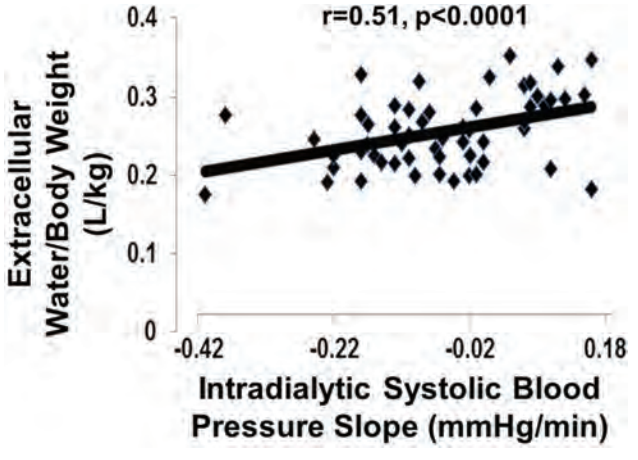
Background: Extracellular volume (ECV) overload increases mortality risk in hemodialysis (HD) patients, but there is no standardized clinical method to assess ECV in them. We evaluated the association between slopes of multiple intradialytic blood pressure (BP) measurements with bioimpedance spectrscopy (BIS)-determined measurements of ECV overload as a novel method to assess ECV using routine clinical data.

Methods: We measured systolic BP every 30 minutes in a mid-week HD treatment. Using multifrequency BIS, we measured pre and post HD extracellular water (ECW), total body water (TBW), ECW/TBW and ECW/weight. Using Pearson correlation and mixed linear regression we compared associations between post-HD ECV overload with multiple peridialytic BP metrics.

Results: Mean intradialytic BP slope (n=58) was -0.06 mmHg/min (±0.1). The correlation between this slope and post-HD ECW/body weight was 0.4 (p=0.003) in all subjects and 0.51 (p<0.0001) in those with post-HD hypertension (SBP>130 mmHg, n=45)(figure 1). This significant association persisted after controlling for age, gender and ultrafiltration rate (β=1.9, p<0.001) and was stronger than associations wtih slope and other ECV metrics. ECW/body weight had a stronger association with intradialyltic BP slope than with pre-HD (r=-0.2, p=0.3), post-HD (r=0.2, p=0.1), or delta SBP (r=0.2, p=0.09).

Conclusions: There is a significant correlation between intradialytic BP slopes and BIS based measurements of ECV overload in hypertensive HD patients. The slope of multiple intradialytic BP measurements better assesses ECV than pre, post or delta SBP. Determining intradialytic blood pressure slope is an innovative way to objectively assess ECV in HD patients.

Funding: NIDDK Support



Among HD patients with post-HD SBP>130, the correlation coefficient for Intradialytic Blood Pressure Slope (mmHg/min) and post-HD ECW/body weight is 0.51 (p<0.0001).

SA-PO757

Impact of High Convective Volumes on Metabolic Profile and Body Composition of Diabetic Patients on Online Hemodiafiltration Nicolás Macías,[4] Tania Linares,[3] Almudena Vega,[6] Esther Torres aguilera,[4] Alba Santos,[1] Marian Goicoechea,[2] Eduardo Verde,[2] Soraya Abad.[5] *[1]Gregorio Mara?on Hospital, Madrid, Spain; [2]Hospital General Universitario Gregorio Marañon, Madrid, Spain; [3]H.G.U. Gregorio Marañon, Madrid, Spain; [4]HGUGM, Madrid, Spain; [5]HOSPITAL GREGORIO MARAÑON, MADRID, Spain; [6]Hospital Gregorio Marañón., Madrid, Spain.*

Background: OL-HDF with high convective volumes improves patient survival compared with high-flux hemodialysis. It has been proposed to limit the amount of convective transport in patients with diabetes mellitus, due to glucose load that is administered with replacement fluid. The aim of this study is to analyze the influence of substitution volume(SV) in the evolution of metabolic profile of diabetic patients incident on OL-HDF.

Methods: Prospective observational study in 29 diabetic patients incident on postdilution OL-HDF, three 4-hours sessions weekly. Baseline data included clinical, demographic, laboratory and body composition(BIS) parameters. Laboratory and SV were collected every four months, and in 23 patients another BIS was performed after a minimum follow-up of one year. Variations of glycosylated hemoglobin(HbA1c), triglycerides(TG), total cholesterol, LDL-c, HDL-c, albumin, prealbumin and C-reactive protein(CRP) were calculated at one-two-three years, and at the end of follow-up. Also quarterly and annual variations were calculated, as well as changes in body composition. Variations were collected to evaluate the influence of SV in these changes.

Results: Age at baseline was 69.7±13.6years, 62.1%male, with 48(35.5 – 76)months on dialysis, 72.3±13.9Kg weight, 27.1±5.4kg/m2 BMI, 1.78±0.16m^2 BSA. 81.5%received insulin, 7.4%antidiabetic drugs and 51.9%statins. Mean SV was 26.9±2.9L per session and follow-up(time on OL-HDF) was 40.4±26months. We found significant correlation between SV and final changes in HDL-c(0.385,p0.039), prealbumin(0.404,p0.003) and CRP(-0.498,p0.007). Also convective dose adjusted with BSA was related with changes in HDL-c(0.393,p0.035) and inversely correlated with changes in TG(-0.423,p0.022) and CRP(-0.573,p0.007) since the second year of follow up. Quarterly comparisons(n 271) showed that quarterly SV correlated with variations in HbA1c(-0.146,p0.021). No correlation was observed between SV and changes in weight, body water, lean or fat tissue in the period between BIS measurements.

Conclusions: Higher convective dose is associated with a slight improvement in metabolic profile in diabetic patients in OL-HDF. There is not evidence to restrict the convective transport in diabetic patients due to the glucose content of the replacement fluid.

SA-PO758

In-Vitro Dialysate Regeneration Using Dharma, the EasyDial Portable Hemodialysis Machine Osman S. Khawar,[1] Timothy R. Mcnamara,[2] Sarah L. Foster.[2] *[1]Balboa Nephrology Medical Group, Escondido, CA; [2]EasyDial, Irvine, CA.*

Background: Dharme is a unique, fully portable dialysis machine, which uses only 5 Liters of dialysate per treatment. In order to achieve this limited dialysate volume, dialysate is regenerated using a chemical filter through which dialysate in recirculated continuously during dialysis, while electrolyes are supplied via an infusion into the dialysate reservior.

Methods: Bovine blood was tested during a 2 hour dialysis, using a 70 mL concentrated mixture of calcium, potassium, and magnesium administered continuously during into 5 Liters of dialysate using an ambIT peristalitc pump. Samples of dialysate were collected every 15 minutes and analyzed for electrolyte concentrations.

Results: The electrolytes were continuously present at acceptable concentations, indicating that dialyate was regenerated during the dialysis. Concentrations are provided in table 1. Baseline and 2 hour concentrations for each ion were: Calcium 37.06 ppm 36.67ppm, Magnesium 10.63ppm and 13.58ppm, potassium 71.03ppm and 5.15ppm.

Conclusions: These results verify that continuous infusion of key electrolytes into the dialysate during dialysis with Dharma maintains electrolyte concentrations in regenerated dialysate. Dharma offers the unique features of portability (18 lbs), no fixed water connection (5L dialysate) and the possilbiity for significantly reducing dialysis treatment times.

Funding: Commercial Support - EasyDial Inc

Quality Improvement Empowerment: Dialysis Clinic Staff Lead Projects for Change Laura J. Maursetter. *University of Wisconsin School of Medicine and Public Health, Madison, WI.*

Background: Quality improvement provides an avenue for delivering healthcare that meets the best practices standards across medicine. Dialysis centers strive to provide the optimal care but in the era of dialysis center ratings measures of care delivery become even more impactful. There are many centers that have provided examples where quality improvement projects have improved the delivery of care. There are none that have created a system where all staff are educated about quality improvement and encouraged to lead their own project.

Methods: In the fall of each year, a portion of the staff meeting is dedicated to quality improvement (QI). The dialysis director talks about the differences between quality improvement and research, noticing gaps in care, methods of analyzing and measuring a problem and thinking of interventions. Each staff member is encouraged to develop a indea and there is a simple QI curriculum available to assist in facilitating the project. Periodically the dialysis direct and charge nurse discuss the projects with each leader and the results of the projects were brought to the hospital administration at the end of the year.

Results: After this program was started, there have been 12 projects initiated. In the first year of the program 80% of the staff developed a project. All types of staff led projects: these included the dietician, the social worker, 75% of the nurses, and 100% of the dialysis technicians. The project topics included improved patient knowledge of emergencies, improved knowledge of dialysis treatment options, discussions with patients about the importance of dialysis adequacy and maintaining the prescribed dialysis schedule, improvement in the time the staff spend with each patient, increase fun activities for patients during dialysis, improved referrals for positive depression screening, and improvement in the albumin level.

Conclusions: Creating an environment and formalized QI program that empowers employees to notice problems and create solutions was able to make an impact on the quality of care provided in this small dialysis center. This simple curriculum could be translated into larger dialysis units to improve the quality of care and satisfaction of the patients or employees of the unit.

SA-PO760

UK Clinical Experiences of a New Expanded Hemodialysis Therapy with a Novel Medium Cut-Off Dialyzer Jyoti B. Baharani,[1] Bernard Barrios,[1] Debbie Hopkins,[2] Wyn Passmore.[2] *[1]Heart of England NHS Foundation Trust, Birmingham, United Kingdom; [2]Morriston Hospital, Swansea, United Kingdom.*

Background: Middle molecules are associated with the pathology of uremia, and their removal is enhanced by increased convection with hemodiafiltration (HDF) therapy. However, HDF therapy may not be suitable for, or available to, all patients. A newly developed medium cut-off (MCO) membrane allows hemodialysis (HD) to be expanded in terms of middle molecule removal (HDx therapy) using conventional HD infrastructure. Here, we describe the experience of two UK clinics trialing HDx therapy.

Methods: At Heartlands Hospital (HH), the patient demographic (n=8) was: 48–90 years of age, mixed ethnicities, and 1–14 years of HD experience. Patients (treated thrice weekly) were switched from high-flux HD with a polysulfone dialyzer (FX60 or FX80, Fresenius) to HDx therapy with the MCO membrane (Theranova 400, Baxter). At Morriston Hospital (MH), patients (n=18) were 25–91 years of age with 2–16 years of HD experience. Patients who had failed to tolerate (n=14) or tolerated (n=4) HDF therapy were switched to HDx therapy with the MCO membrane. Reduction ratios (RRs) of beta-2-microglobulin (β2M) and albumin loss were assessed; data are based on averages of 3 dialysis sessions (HH) or 1 dialysis session (MH).

Results: At HH, average β2M RRs (post- vs pre-dialysis level) with HDx therapy were 69.3% (Week 1) and 69.4% (Week 9) vs 48.8% with high-flux HD. At Week 9, serum albumin levels increased during dialysis by 0.8 g/L. Following 9 weeks of HDx therapy, pre-dialysis levels of β2M were reduced by 11.7%, and no difference in albumin level was seen. At MH, average β2M RRs with HDx therapy were 71.0% (Week 1) and 73.9% (Week 9). For patients who tolerated HDF, at Week 1 β2M RRs were 72.2% and 73.9% with HDx and HDF therapy, respectively. Based on serum albumin levels, albumin loss in both groups was minimal.[a] No adverse events were noted; 1 patient with arthritis did not experience any arthritic flare-ups during HDx therapy.

Conclusions: HDx therapy was convenient, simple to implement, and achieved high β2M RRs with low albumin loss. It offers opportunity for achieving the clearance of middle molecules delivered by HDF, when patient factors exist or HDF is not available.
[a]Based on 2 of 4 HDF patients and all 14 HDx patients.

SA-PO761

Comparison of Albumin Binding Capacity and Uremic Toxins in Hemodiafiltration versus Novel Dialysis Membrane Sebastian Koball,[4] Christina Westphal,[1] Silvius Frimmel,[2] Michael Hinz,[5] Sebastian Klammt,[3] Steffen R. Mitzner.[4] *[1]Fraunhofer Institiut for Cell Therapy and Immunology, Rostock, Germany; [2]Rostock University Medical Center, Rostock, Germany; [3]University Rostock, Rostock, Germany; [4]University of Rostock, Rostock, Germany; [5]Universität Rostock, Rostock, Germany.*

Background: Albumin is an important transport protein for non-water-soluble protein-bound drugs and uremic toxins. A decreased transport capacity may lead to endogenous intoxication and worsening of uremic symptoms. It is known that the albumin binding capacity (ABiC) is reduced in patients with advanced stages of chronic kidney disease. Moreover, ABiC is an important marker of the detoxification capacity of extracorporeal treatments. It is presumed that open-pored filters remove high molecular substances more efficiently than conventional treatment, thereby increasing the detoxification capacity. The Baxter-Theranova (HDx) filter is the first approved filter which could meet these requirements. The study aim was to evaluate the effectiveness of the HDx dialyzer with regard to the improvement of ABiC and the removal of uremic toxins (e.g.hippuric acid, paracresylglucoronid, indoxylsulfate, paracresylsulfate, indolacetic acid), phosphate, urea, albumin concentration during standard hemodialysis/ hemodiafiltration treatment.

Methods: The efficacy of HDx was assessed by comparing Baxter Theranova 500 filters with the standard Fresenius FX80 filters (HDF). We included 32 patients with dialysis-dependent chronic kidney disease (stage 5d); above age 18 who provided written informed consent. Key exclusion criteria were acute infectious diseases, bleeding and a hospital stay within the last 14 days. All patients were first treated with HDF for 14 days (3 times a week) and blood samples were drawn (15ml) before and after treatment at study entry, before and after first HDx treatment and before/after 6 HDx treatments, to determine ABiC and other clinically relevant parameters. Alteration of ABiC and other relevant parameters was assessed by using Wilcoxon matched-pairs signed-rank test.

Results: ABiC improved significantly in both therapies (HDx/HDF), however, no significant differences were found between the two therapies. The same was true for phosphate, indoxylsulfate, urea, creatinine, and uric acid. A reduction of albumin concentration during HDx treatment was not observed, neither during single treatment nor over the 14 days period.

Conclusions: Expanded hemodialysis enabled by Theranova demonstrates equal effects on ABIC and uremic toxins in comparison to OL-HDF.

SA-PO762

Influence of Dialysis Membranes on Bisphenol A Serum Levels in Online Hemodiafiltration Sebastian Mas,[3] Enrique Bosch,[1] Alberto Ruiz,[1] Esther Civantos,[1] Jesus Egido,[2] Alberto Ortiz,[2] Emilio E. Gonzalez-parra.[2] *[1]IIS- FJD, Madrid, Spain; [2]Fundacion Jimenez Diaz, Madrid, Spain; [3]IIS-FJD, Madrid, Spain.*

Background: In uremia, the environmental toxin Bisphenol A (BPA) accumulates bound to proteins. BPA-containing dialyzers contribute to increase plasma BPA concentration in conventional hemodialysis patients. Online hemodiafiltration (OL-HDF) more efficiently clears high molecular weight molecules, and this may improve BPA clearance. However, OL-HDF requires high infusion volumes of replacement fluid generated online by using BPA-containing membranes and, thus, can be a source of BPA load. Objectives:To assess plasma BPA levels in OL-HDF patients using BPA-free or BPA-containing dialyzers.

Methods: In a prospective study, plasma BPA was assessed at baseline and 3 months after switching from baseline BPA-free polynephron to BPA-containing polysulfone (n=31) dialyzers, or from baseline polysulfone to polynephron (n=27) dialyzers in OL-HDF patients. Results were compared to a prior study on conventional hemodialysis.

Results: OL-HDF patients had lower plasma BPA than those in conventional hemodialysis (12.12±15.91 vs. 64.55±93.8 ng/mL) and both were several fold higher than healthy controls (<2 ng/ml). However, this was influenced by the dialysis membrane. Thus, baseline BPA was 8.79±7.97 ng/ml in patients dialyzed ≥6 months with polynephron versus 23.42±20.38 ng/mL with polysulfone. During the first single OL-HDF session with the switch membrane, BPA decreased in the polysulfone-to-polynephron group (pre-dialysis 23.42±20.38 ng/ml to post-dialysis 6.44±10.77 ng/mL, $p < 0.01$), but remained unchanged in polynephron-to-polysulfone patients. After 3 months on polysulfone, BPA levels rose non-significantly from 8.79±7.97 to 11.02±16.17 ng/mL in the polynephron-to-polysulfone group, while they decreased 51% in the polysulfone-to-polynephron group ($p<0.01$).

Conclusions: Optimal reduction in BPA levels is achieved by using OL-HDF with BPA-free dialyzer membranes. Attempts at optimizing net BPA clearance in OL-HDF are justified by the residual higher plasma BPA levels when compared to healthy controls.

Dialyzer Reuse in Prevalent Hemodialysis Patients: Mortality and Clinical Outcomes Daniel Murillo brambila,[1,2] Monica C. Jimenez cornejo,[1,2] Karina Renoirte,[1,2] Gabriela J. Abundis Mora,[1,2] Guillermo Garcia-Garcia.[1] *[1]Hospital Civil De Guadalajara, University of Guadalajara, Guadalajara, Mexico; [2]Nephrology, PISA SANEFRO, Jalisco, Mexico.*

Background: Dialyzers reuse has been a common practice in the US. In Mexico, economical restrains related to CKD have forced to seek cheaper options to provide RRT among ESRD patients. Thus, dyalizer reuse has become a common practice in most of the hemodialysis clinics across the country. It is regulated by the Ministry of Health. Previous studies have reported no difference in mortality among patients with dialyzer reuse versus one single use. The aim of this study was to evaluate the clinical implications of dialyzer reuse in prevalent HD patients from Jalisco, Mexico

Methods: A cross-sectional, multicenter study in prevalent hemodialysis patients in Jalisco. 2561 insured and uninsured patients conformed the national data base. Only patients who had a Kt/V ≥1.2 were included for analysis. Mortality, vascular access, clinical variables and laboratory values were compared among patients with reusable dialyzers and those with single use dialyzers.

Results: 2561 patients were evaluated for analysis. Only 597 patients (23.3%) had a kt/v ≥ 1.2. Reuse of dialyzer was performed in 482 of them (80.7%). Average reuse was 5.5 times per dialyzer (range 1-12). Serum electrolite, creatinine, uric acid, albumine, PTH, iron kinetics, urea pre/post did not differ among both patients who underwent reuse of dialyzer vs those with one single use dialyzer.

Conclusions: Serum electrolite, creatinine, uric acid, albumine, PTH and iron kinetics did not differ among patients who underwent reuse of dialyzer vs those with one single use dialyzer. Hemoglobine, urea pre and post values were statistically better for patients with dialyzer reuse. Time to death and mortality did not differ among both groups. Dialyzer reuse continues to be a controversial practice, but according these findings, it appears to be a safe. Further studies are needed to asses the long term clinical impact of this practice, since the financial panorama of CKD points to an urgent and generalized need to optimize economical resources in order to provide safe treatments to more patients at lower costs.

Acute Effects of Hemodialysis on Circulating Microparticle Levels Fengxia Xiao,[3] Hussein Abujrad,[4] Teik C. Ooi,[4] Alexander Sorisky,[3] Marcel Ruzicka,[2] Dylan Burger.[1] *[1]Kidney Research Centre, Ottawa, ON, Canada; [2]None, Ottawa, ON, Canada; [3]Ottawa Hospital Research Institute, Ottawa, AB, Canada; [4]University of Ottawa, Ottawa, ON, Canada.*

Background: Individuals with end stage kidney disease (ESKD) are at increased risk of cardiovascular complications. Previous studies have shown that levels of circulating microparticles are increased in ESKD and that an increase in circulating endothelial microparticles is a predictor of cardiovascular morbidity and mortality (Amabile, 2012). The purpose of this study was to examine the effect of a single hemodialysis session on levels of circulating microparticles in patients with ESKD.

Methods: We studied 23 patients (age 58±3 years, 12 M/11F) undergoing a single hemodialysis session. Levels of circulating total, endothelial, leukocyte, and platelet microparticles were assessed by flow cytometry immediately prior to, and at the completion of, hemodialysis (3 times weekly, 4 hour sessions).

Results: Participants had been treated by hemodialysis for 50±8 (mean±SEM) months prior to enrollment. The mean ultrafiltration volume on the day of study was 2.06 ±0.17 L. The level of total microparticles was significantly reduced by ~55% following hemodialysis ($5.15x10^7$±1.1 $x10^7$ [Pre] vs $2.32x10^7$±$4.27x10^6$ [Post], P<0.05). Similarly, the level of platelet microparticles was significantly reduced by ~75% following hemodialysis ($4.33x10^7$±1.06 $x10^7$ [Pre] vs $1.06x10^7$±$3.8x10^6$ [Post], P<0.05). In contrast, the level of leukocyte microparticles was not altered by hemodialysis ($2.65x10^6$±3.19 $x10^5$ [Pre] vs $2.15x10^6$±$3.2x10^5$ [Post], P=n.s). The level of endothelial microparticles also remained the same before and after hemodialysis ($2.09x10^6$±4.85 $x10^5$ [Pre] vs $1.39x10^6$±$2.94x10^5$ [Post], P=n.s). There was no correlation between the degree of ultrafiltration and the reduction in platelet, leukocyte, or endothelial microparticles.

Conclusions: Hemodialysis is associated with reductions in circulating total and platelet microparticles with no impact on circulating endothelial or leukocyte microparticles. These results suggest that dialytic clearance selectively influences the levels of circulating microparticle subpopulations in ESKD patients undergoing hemodialysis. Consideration should therefore be given to the timing of sampling for circulating microparticles in any study involving hemodialysis patients.

Cognitive Impairment and Depression among Hispanic Hemodialysis Patients in Puerto Rico Neysha J. Sanchez,[2] Angel F. Delgado garrastegui.[1] *[1]Internal Medicine, University of Puerto Rico, Medical science campus, San Juan, PR; [2]University of Puerto Rico, San Juan, PR.*

Background: Cognitive Impairment and Depression are prevalent in patients with End Stage Renal Disease on hemodialysis (HD). Studies have shown as many as two thirds of these patients suffer cognitive impairment, which is higher than in the age matched population. Cognitive Impairment in HD patients is an important public health problem given the increasing age and prevalence of comorbidities, such as diabetes and vascular disease. Similarly, depression with prevalence of 40% in these patients has significant effects on individual patient well-being and delivery of medical care. The prevalence of cognitive impairment and depression is unknown in our Hispanic population.

Methods: The population is 43 of 55 patients receiving ambulatory HD at The University Hospital in PR three times per week. Exclusion criteria included patients suffering from dementia or prior cerebrovascular accident. The instrument included The Beck Depression Inventory and The General Practitioner assessment of Cognition. Statistical Analysis was summarized using descriptive statistics for continuous variables and frequency distributions for categorical variables. Chi-square (X 2) test and Fisher's test were conducted to evaluate the associations between cognitive impairment and depression.

Results: The prevalence of depression was 26.30% and of cognitive impairment 88%. There was no statistically significant association between age, gender, education status, income or dialysis vintage and depression. Most of the subjects who screened positively for depression were active smokers (p-value < 0.05). There was no statistically significant association between age, gender, smoking status, education status, income or dialysis vintage and cognitive impairment.

Conclusions: There were no statistical significant associations between gender, age, education, income and dialysis vintage with the presence of cognitive impairment and depression. Subjects who screened positively for depression reported more smoking. As found in others studies, cognitive impairment was common and undiagnosed in HD patients. Further studies are needed to determine whether dialysis exacerbates the cognitive impairment attributable to underlying disease. Contrary to the findings in our study, depression and education levels were shown to be independent predictors for cognitive impairment in multivariate analysis of other studies.

SA-PO766

Effect Modification by Age and Pulse Pressure (PP) on the Association Between Mediterranean Diet (MD) and Telomere Length (TL) in Hemodialysis (HD) Patients Anastasia Markaki,[3] Dimitra Lygerou,[4] Eleftheria-Kleio Dermitzaki,[4] Periklis P. Kyriazis,[2] Andriana Pilarinou,[3] Kalliopi K. Gkouskou,[5] Aikaterini Charonitaki,[3] Konstantina Kyriakidi,[3] Argyro Gioume,[3] Dimitra Bacharaki,[1] Kostas Stylianou.[4] *[1]ATTIKON UNIVERSITY HOSPITAL, Athens, Greece; [2]Beth israel Deaconess Medical Center, Brookline, MA; [3]Technological Educational Institute of Crete, Greece, Siteia, Greece; [4]University Hospital of Heraklion, Heraklion, Greece; [5]Embiodiagnostics, Athens, Greece.*

Background: TL is considered to be a biological marker for aging. Telomere shortening is associated with age-related health outcomes and risk of death. Here, we investigated whether the associations of greater adherence to a MD with longer TL depend on age and pulse pressure in HD patients

Methods: 46 HD patients, (28 men) were studied. A MD adherence score (MDS range 0-55, 55 representing maximal adherence) was estimated using a previously reported method (Panagiotakos 2007). TL was measured from leukocyte DNA using a realtime PCR to measure T/S ratio, the ratio of telomere (T) to single copy gene (S) sequence. TL was analyzed as a dichotomous variable: above (High TL group) and below (Low TL group) the median value of T/S ratio (1.13)

Results: Patients in the high TL group were younger in age (56±14 vs. 70±9 years; p<0.001), had higher MDS (30±4 vs. 28±3; P=0.037) and lower PP (58±14 vs.68±14 mmHg; p=0.02), prevalence of diabetes mellitus (DM)(8.7 vs. 34.8 %; p=0.032) and peripheral vascular disease (PVD) (30.4 vs. 65.2%; p=0.018). Logistic regression analysis, after adjusting for age, PP, DM and PVD, showed that MDS was associated with longer TL (OR=1.6, 95%CI: 1.13-2.28; p=0.009). An interaction effect between MDS and age was significant (p=0.014), after controlling for the main effects, CVD, DM and PP. The same was true for the interaction between MDS and PP (p=0.006). Stratifying by age (above and below the median= 65 years), we found a significant association between MDS and TL in the younger age group (OR=2.269, 95%CI: 1.021-5.042; p=0.044), but not in the older patients. Also, stratifying by PP tertiles (first <56 mmHg vs. second and third), a significant association between MDS and TL was detected in the high PP group (OR=1.49, 95%CI: 1.051-2.13; p=0.025). Similar results were obtained when TL was examined as a continuous variable.

Conclusions: Our results show that adherence to a MD is associated with longer TL in patients under the age of 65 and in patients with increased arterial stiffness (PP>56 mmHg), indicating that adoption of a MD may have beneficial effects in these specific subgroups of HD patients.

Variability of Pre-Dialysis Serum Sodium and Its Association with Survival in Hemodialysis Patients: Results of the MONDO Consortium

Xiaoling Ye,[8] Jeroen Kooman,[6] Bernard J. Canaud,[1] Nathan W. Levin,[7] Cristina Marelli,[2] Albert J. Power,[9] Frank van der Sande,[5] Stephan Thijssen,[8] Xiaoqi Xu,[3] Len A. Usvyat,[4] Yuedong Wang,[10] Peter Kotanko,[8,11] Jochen G. Raimann.[8] *[1]FMC Deutschland GmbH, Bad Homburg, Germany; [2]Fresenius Medical Care Argentina, buenos Aires, Argentina; [3]Fresenius Medical Care Asia Pacific, Hong Kong, China; [4]Fresenius Medical Care North America, Melrose, MA; [5]Maastricht University Medical Centre, Maastricht, Netherlands; [6]Maastricht University Medical Centre, Maastricht, Netherlands; [7]New York, NY; [8]Renal Research Institute, New York, NY; [9]Richard Bright Renal Unit, Bristol, United Kingdom; [10]University of California - Santa Barbara, Santa Barbara, CA; [11]Icahn School of Medicine at Mount Sinai, New York, NY. Group/Team: MONDO initiative.*

Background: Pre-dialysis serum sodium (SNa^+) is the main determinant of plasma osmolality. Whereas hyponatremia is associated with adverse outcomes in hemodialysis (HD) patients (pts), variations swings in SNa^+ may lead to fluid shifts between the extracellular and intracellular spaces and cell volume changes. The aim of the study was to explore the relationship between SNa^+, the rate of change (slope), and the SD of the residual (variability) of SNa+ with all cause of death.

Methods: All incident and prevalent pts from the MONDO initiative with at least 6 SNa+ measurements during baseline (1st year in HD) were selected. Follow-up defined as 2nd year on HD. Survival analysis were applied to study the effect of SNa+, slope and variability on event. Smoothing spline logistic regression models were used to explore the joint effect of (a) SNa^+ with variability, and (b) SNa^+ with slope on event. Additionally, time to event analysis were used to delineate the association of various demographic and clinical parameters with event.

Results: 15, 335 HD pts (63.2 years, 59% males, 24% diabetics) from Europe (10,907), West Asia (1,991), South America (283) and US (2,154) were included. Lower SNa^+, positive and negative slope, and higher variability associated with an increased the risk of event. Increased risk of death with higher variability and slopes appeared to be present at all levels of SNa^+, with apparently stronger effects for variability than slope (Figure 1). However, the relation between SNa+ variability and slopes with outcome lost significance after adjusted for confounders.

Conclusions: Our findings suggest that SNa^+ variability may constitute a novel prognostic indicator. Underlying pathological conditions may explain the relation between SNa^+ and outcome.

Modified Compression Bioimpedance in Edema Quantification in Patients on Hemodialysis

Amit P. Singh,[2] John J. Pitre,[1] Joseph L. Bull,[1] Leo Koziol,[2] William Weitzel,[3,2] Panduranga S. Rao.[2] *[1]Tulane University, New Orleans, LA; [2]University of Michigan Health System, Ann Arbor, MI; [3]VA Ann Arbor Health System, Ann Arbor, MI.*

Background: Quantification of edema in dialysis patients is subjective and problematic. Given the importance of fluid overload, objective measures are necessary.

Methods: We conducted a clinical study using bioimpedance and circumferential strain apparatus for quantification of lower extremity edema in hemodialysis patients. Eleven stable hemodialysis patients, 18-85 years of age, with varying grades of clinical edema participated. During their usual hemodialysis session, a series of compression cycles (30 seconds, 50mm Hg) were applied above one ankle using a blood pressure cuff. Bioimpedance and strain data were collected using the bioimpedance meter and plethysmograph, respectively. This procedure was repeated until the completion of the dialysis session.

Results: Using the strain data we calculated the volume of mobilized fluid during compression. Using the bioimpedance data we calculated the total volume of fluid underneath the cuff. The median volume of fluid estimate for each subject was used to normalize the volume of mobilized fluid obtained from the strain measurements. These data, along with the fit parameters for the strain data, were plotted as a function of the edema grades. Of the three strain fitting parameters (ε_0, $\varepsilon_\infty - \varepsilon_0$ *and* τ), the ANOVA revealed significant differences among edema grades for both the instantaneous strain ε_0 ($p < 2\times10^{-16}$) and the viscoelastic strain $\varepsilon_\infty - \varepsilon_0$ ($p < 2\times10^{-16}$). ANOVA also revealed significant differences among edema grades for the strain-based estimate of the volume of mobilized fluid V_f^m ($p < 2\times10^{-16}$); bioimpedance based total fluid volume ($p = < 2\times10^{-16}$) and relative volume of mobilized fluid ($p < 2\times10^{-16}$).

Conclusions: Using this novel technique in dialysis patients we demonstrated the potential to quantify mechanical characteristics of edema, ε_0, $\varepsilon_\infty - \varepsilon_0$ *and* τ, to better characterize peripheral edema.

Effect of Fluid Status on the Fat Mass Estimated by Bioimpedance in Hemodialysis Patients

Samer R. Abbas,[3] Stephan Thijssen,[3] Erik L. Penne,[1] Jochen G. Raimann,[3] Nathan W. Levin,[2] Peter Kotanko,[3,4] Fansan Zhu.[3] *[1]Medical Center Alkmaar, Alkmaar, Netherlands; [2]None, New York, NY; [3]Renal Research Institute, New York, NY; [4]Icahn School of Medicine at Mount Sinai, New York, NY.*

Background: This prospective study utilizes calf bioimpedance spectroscopy (cBIS) to guide the attainment of dry weight (DW_{cBIS}) in chronic hemodialysis (HD) patients. In the present research we evaluate whether fat mass is altered when DW_{cBIS} is attained.

Methods: Target post-HD weight was gradually reduced from baseline (BL) until DW_{cBIS} was achieved. DW_{cBIS} was defined as the presence of both flattening of the curve of extracellular resistance during HD and the attainment calf normalized resistivity (CNR) in the normal range (Zhu, Physiol Mea 2008). Extracellular (ECV), intracellular (ICV) volume and total body water (TBW) were measured using whole body bioimpedance spectroscopy (Hydra 4200). Fluid overload (FO), lean body mass (LBM), and fat mass (FM) were calculated according to a body composition model (Chamney, Am J Clin Nutr 2007).

Results: Twenty-eight patients (13 females; 7 diabetic; age 53.7±12 years) achieved DW_{cBIS} over a period of 43.8±30.1 days. On average 16±10 measurements per patient were required to attain DW_{cBIS}. Although significant decreases in body weight, CNR and ECV pre and post HD were observed, LBM and FM at DWcBIS did not differ significantly from BL (Table 1). ECV/TBW and FO were non-significantly higher at BL compared to DW_{cBIS} (Table 1).

Conclusions: This study showed that attainment of DW_{cBIS} did not affect fat mass.

Table 1

	Wt (kg)	CNR	ECV (L)	ECV/TBW	FO (kg)	LBM (kg)	Fat (kg)
Pre HD BL	78±15.8	14.2±2	16.9±2.6	0.48±0.05	1.8±3.2	34.7±15.5	31.2±16.3

p value	<0.0001	<0.0001	<0.001	0.1			

SA-PO770

Lower Blood Flow Rate in the Last Quarter of Hemodialysis May Protect Against Hypotension Rebecca Backenroth,[1,2] Dvora Rubinger,[1] Tasneem Kab,[3] Irit Mor yosef levi,[4] Dan Sapoznikov.[1] *[1]Hadassah U Med Center, Jerusalem, Israel; [2]Barzilai U Med Center, Ashkelon, Israel; [3]Hadassah u med center, Jerusalem, Israel; [4]Nephrology, Hadassah, Jerusalem, Israel.*

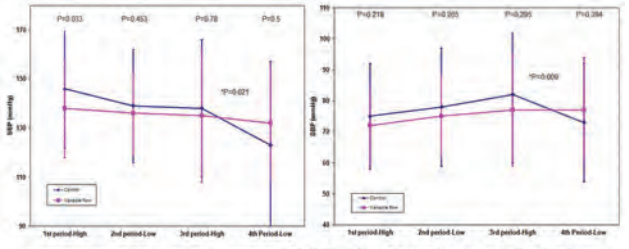
Background: In hemodialysis (HD), high blood flow rate (BFR) increases clearances and decreases clotting of the extracorporeal circuit. However, possible adverse effects are not well delineated.

Methods: A prospective crossover study compared the effects of higher vs lower BFR, with patients serving as their own controls. Consenting stable adults on chronic HD were studied for 2 sessions in random order usually a week apart. The control session, with 'high' constant BFR, 300-450 cc/min, and the variable flow session, alternating high then low, 250 cc/min BFR in 4 equal periods of the session. Continuous beat to beat BP and pulse were monitored noninvasively by Finometer ™, O2 saturation by pulse oximeter, and subjective wellbeing by questionnaires.

Results: Twelve patients in 24 HD sessions were studied. Baseline weight, pulse, interdialytic weight gain and UF rates were similar in the sessions but intial systolic BP (SBP) was higher in the control HD. In the control HD, SBP declined while the diastolic BP (DBP) declined only in the 4th quarter. The variable flow HD was similar until the last quarter, when lower BFR was associated with significant reversal of the decline of SBP and DBP, and a rise in DBP. Pulse increased insignificantly during both sessions. Autonomic parameters were similar except LFα (index of baroreflex sensitivity) which increased in the control, but decreased in the 4th, lower BFR period (p=0.03). Total peripheral resistance also differed only in the 4th period, when it decreased in the control, but increased in the variable BFR group. Stroke volume was significantly higher in the 1st period of low BFR, and cardiac output decreased in both sessions. SBP did not correlate with cardiac output. Subjective feelings and O2 sat were similar in both sessions.

Conclusions: Low BFR during the last quarter of HD seems to attenuate decreases in both SBP and DBP.

Funding: Clinical Revenue Support



Mean systolic and diastolic blood pressures (SBP) (DBP) ±SD. "High" and "Low" refer to the blood flow rate in the variable flow session. p - difference in means. *p - difference in slope between periods.

SA-PO771

Prediction of Residual Renal Function (RRF) in Hemodialysis (HD) and Hemodiafiltration (HDF) Maria-Eleni Roumelioti,[2] Christos Argyropoulos,[2] Mark L. Unruh,[2] V. Shane Pankratz.[1] *[1]UNM Health Sciences Center, Albuquerque, NM; [2]University of New Mexico, Albuquerque, NM.*

Background: RRF is associated with improved survival in HD patients but requires cumbersome urinary collections to measure. Beta-2 microglobulin, (B2M) has been proposed as measures of RRF, without the need for such collections. We validate the predialysis B2M from the first session of the week, as a predictor of RRF in pts receiving HD or HDF.

Methods: We simulated the distribution of the predialysis B2M concentration in a mixed cohort of pts (N=10,000) receiving HD or HDF at different levels of RRF using a recently described population kinetic (PopK) model for B2M (PLoS ONE10(6):e0129575). Logistic regression models were used to derive cutoffs of B2M predicting the RRF in this **development cohort (Dev)**. These models were then used to predict the Urea Clearance (as a measure of RRF) in a **validation cohort (Val)** of 350 actual patients receiving either HF or HDF (PLoS ONE 10(12): e0143813) in whom B2M had been measured. Characteristics of the Dev cohort were deliberately chosen to differ from the Val cohort to assess generalizability.

Results: Median (IQR) RRF in ml/min was 5 (2.5-7.5) in Dev & 0.61 (0.0-2.3 ml/min Urea Cr) in the Val. Median (IQR) B2M in ml/L was 18.9 (11.6-23.2) in Dev & 25.5 (19.5-32.1) in Val. **Sensitivity** (Sens), **Specificity** (Spec) were > 75%, while **AUCs** were >0.83 in both the Dev and Val cohorts [figure]. Median (IQR) of the optimal (AUC maximizing) B2M (in mg/L) cutoffs for RRF > 0ml/min & > 2 ml/min were 22.1 (20.0-23.2) & 19.5 (19.2-20.3) respectively in the Dev cohort. Sens/Spec of these cutoffs were 0.53/0.93 & 0.60/0.90 in the Val cohort.

Conclusions: PopK derived cutoffs of B2M predict with high accuracy RRF in pts on HD or HDF. These cutoff values are nearly identical to the values previously estimated in actual pts, attesting to the validity of the PopK model. Such cutoffs may have utility when implementing the KDOQI incremental dialysis guideline & as enrollment criterion in ESRD studies.

SA-PO772

Bedside BNP as a Marker of Overhydration in Hemodialysis Patients Jan Melin,[3] Magnus Lindberg,[2] Jenny Stenberg,[3] Hans Furuland.[1] *[1]University Hospital, Uppsala, Uppsala, Sweden; [2]University of Gävle, Gävle, Sweden; [3]University Hospital Uppsala, Uppsala, Sweden.*

Background: Management of hydration status in dialysis patients is a great challenge to nephrologists, and new tools to understand the hydration status (HS) are needed. The aim of this study was to investigate the usefulness of brain natriuretic peptide (BNP), analyzed bedside, as a marker of overhydration (OH) in hemodialysis (HD) patients.

Methods: We investigated the distribution of BNP, measured by Alere Triage® BNP Test, and analyzed the correlation between BNP and HS, defined by bioimpedance spectroscopy (BIS) in 64 HD patients. We assumed there would be a difference in HS between patients with high levels of BNP (h-BNP) and low levels of BNP (l-BNP) and choose an arbitrary cut off of 500 ng/ml, and then differences between the groups were tested for significance. HS, blood pressure (BP) and heart rate was measured, and BNP analyzed, before one mid-week dialysis session. Blood samples were also drawn for analysis of NT-proBNP and inflammatory markers. Demographic data, comorbidities, lab values and nutritional status were collected from medical records.

Results: A positive correlation was found between BNP and OH (r = 0.4), although many severely overhydrated patients had normal or just slightly elevated BNP. BNP levels were above 500 in 38 % (n=24) of the participants. The level of OH before dialysis was higher in the h-BNP group than in the l-BNP group. There was no difference in BP before or after dialysis, but patients in the h-BNP group were older, had lower muscle strength and lower Hemoglobin and Albumin levels compared to the l-BNP group.

Conclusions: A normal BNP does not rule out OH as defined by BIS in HD patients, on the other hand euvolemia was rare in patients with elevated BNP. This suggests that BNP might serve as a marker of OH in a subgroup of old and frail patients. In a further study we aim to investigate if the relationship between BNP, when elevated, and OH is reproducible at an individual level.

Funding: Private Foundation Support, Government Support - Non-U.S.

Difference between groups, high and low BNP

Variables	BNP < 500 (n = 40)	BNP > 500 (n = 24)	Level of significance

Government Support in the Development of Hemodialysis in County Level Hospitals in China Hua Liu,[2] Hongli Jiang.[1] *[1]Dialysis Center of First Affiliated Hospital of Medicine School, Xi?an Jiaotong University, Xi'an, Shaanxi, China; [2]First Affiliated Hospital of Medical College of Xi'an Jiaotong University, Xi'an, China.*

Background: In 2013, there were 88 hemodialysis center in Shaanxi province in China and all equipment and medical personnel could only meet the demand of about 22% ESRD patients. This paper will explore the role of government decision-making and financial support in the construction of hemodialysis center projects in county level hospitals in Shaanxi province in China after increasing investment in health care reform.

Methods: After 2013, the hemodialysis room construction project in county hospitals in Shaanxi province was carried out. Under the support of the government, we prepared the blood purification training materials and recorded teaching physicians and nurses in blood purification standard operating procedures, arranged 150 hours courses and 135 days clinical practice stage from 2013 to 2015 in four times. The effect of the training

course of the projects and the status of the hemodialysis center in the county hospital of Shaanxi province were analyzed retrospectively.

Results: From the May 14, 2013 to June 30, 2015, we held four consecutive training classes, training a total of 827 doctors, nurses and technicians. After the implementation of this project, the number of dialysis rooms increased by leaps and boundsin Shaanxi provinc. By the end of December 31, 2016, there were 66 new county hospital hemodialysis room throughout 57 counties, and there were 2068 new dialysis patients registered in national dialysis registration system, far higher than the previous year increasing level (more than 30%), also higher than increasing ratio of the world's new hemodialysis patients.

Conclusions: The project construction of the hospital hemodialysis room at the county level is the policy of the provincial government to improve the level of medical treatment in patients with chronic kidney disease. The government give a strong financial support in the purchase of equipment, personnel training and other aspects, which is convenient for patients with end-stage renal disease to obtain renal replacement therapy, improve the ability of hospital hemodialysis services and comprehensive treatment.

Patiens and hemodialysis room development by hemodialysis network reported in China from 2014 to 2016

	In 2014	In 2015	In 2016
numbers of hemodialysis patients	6350	6856	9170
the new MHD patients	833	770	2068
hemodialysis room in county hospital	30	40	89

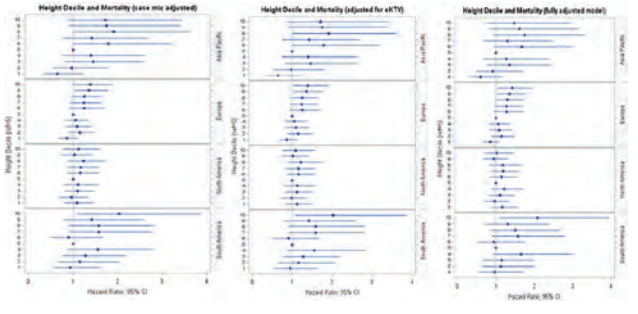
Heights of Hemodialysis Patients Are Associated with Outcomes: Results From the Monitoring Dialysis Outcomes (Mondo) Initiative Samir D. Patel,[10] Alice Topping,[10] Xiaoling Ye,[10] Bernard J. Canaud,[1] Cristina Marelli,[6] Adrian M. Guinsburg,[2] Xiaoqi Xu,[3] Albert J. Power,[4] Neill D. Duncan,[8] Jeroen Kooman,[9] Frank van der Sande,[9] Len A. Usvyat,[7] Yuedong Wang,[5] Peter Kotanko,[10] Jochen G. Raimann,[10] Paola Carioni.[1] *[1]FMC Deutschland GmbH, Bad Homburg, Germany; [2]Fresenius Medical Care, Moron, Argentina; [3]Fresenius Medical Care Asia Pacific, Hong Kong, China; [4]Richard Bright Renal Unit, Bristol, United Kingdom; [5]University of California - Santa Barbara, Santa Barbara, CA; [6]Fresenius Medical Care Argentina, buenos Aires, Argentina; [7]Fresenius Medical Care North America, Melrose, MA; [8]Imperial College Renal and Transplant Centre, London, United Kingdom; [9]Maastricht University Medical Centre, Maastricht, Netherlands; [10]Renal Research Institute, New York, NY.*

Background: In the general population taller people have better metabolic profiles and cardiovascular outcomes (Nelson NEJM 2015), a finding reversed in hemodialysis (HD) patients (pts) (Shapiro CJASN 2015, Elsayed JASN 2015). We studied this relationship in incident HD pts in the international MONDO database.

Methods: In this retrospective cohort study, we included incident HD pts commencing treatment between 01/01/2006 and 12/31/2010, and noted their outcome over 2.5 years following a 6 months baseline. Patients were stratified into deciles of their respective database population, [Asia-Pacific (AP), North (NA) and South America (SA), Europe (EU)], and by gender. Analysis was done using Cox regression with height decile 5 as reference. We constructed 3 different models: a simple case-mix adjusted model for age, gender, post-dialysis weight (Figure 1); the second model additionally including eKt/V (Figure 2); and a fully adjusted model further including albumin, interdialytic weight gain, phosphorus, and pre dialysis systolic blood pressure (Figure 3).

Results: We studied 23,353 pts (62 ± 15 years old, 42% females, body mass index 26 ±6 kg/m^2, 165 ± 10 cm tall). In the fully adjusted models, for SA we found a trend of increasing hazard ratio (HR) without significance among deciles > 5. In EU, deciles 8-10 had significantly increased HR. We observed no significant trend in AP and NA (Figure 3). The result remains materially identical in adjusted models.

Conclusions: Taller height associates with poorer outcomes for reasons yet to be elucidated. Trends we observed were not consistent between continents. Additional studies including body composition analysis may provide additional insight.



Forrest plots of height decile and mortality. Figure 1, Figure 2, Figure 3.

Dry Mouth with Hemodialysis Patients Results in Hypogeusia Miho Suzuki,[2] Ikuto Masakane.[1] *[1]Honcho-Yabuki Clinic, Yamagata, Japan; [2]Yabuki hospital, Yamagata, Japan.*

Background: Dry mouth is one of the causes of taste disorder and affects excessive intake of salt or decreased appetite. Dry mouth often occurs in hemodialysis (HD) patients. However, there have been few reports about dry mouth associated with taste disorder in HD patients. In this study, we examined salivation secretion and taste sensitivity in Maintenance HD patients.

Methods: Inclusion criteria were 46 HD patients who complained of dry mouth by symptomatic investigation and were recognized to have low taste sensitivity from the taste test results. 17 individuals (mean age; 67.9±9.1 yr, 10 men) agreed to enroll in the study. The subjects were divided by unstimulated whole salivation into Low Salivation (LS; 7 patients) and Normal Salivation (NS; 10 patients) groups. Taste sensitivity was determined by the filter paper disc method. Taste sensitivity of sweet, salt, sour and bitter tastes were evaluated. The sample with each taste has five levels of concentration. Low Taste Sensitivity was determined when patients were not able to recognize level three. Salt intake was determined by a 3-day food diary. These results were compared between the two groups by using a Student t-test or Mann-Whitney's U test.

Results: Of the low taste sensitivity patients 7 were categorized as LS and 9 were categorized as NS. Of the subjects that complained of taste disorder symptoms; 4 in the LS group complained of hypogeusia; and 6 in the NS group complained of hypogeusia, pantogeusia, heterogeusia and hemigeusia. Between the LS and NS groups respectively, the ages were (70.9 ± 7.3 vs 65.8 ± 10.1 yr p = 0.275), and the dialysis vintage was (114.9 ± 96.7 vs 75.8 ± 78.3 mth p = 0.353). The taste sensitivity of the four tastes showed no significant difference. But salt taste sensitivity (5.0 ± 1.8 vs 3.2 ± 1.7 points p = 0.088) tended to be lower in the LS group than the NS group. Salt intake showed no significant difference (6.3 g ± 2.0 vs 8.1 ± 2.1 g p = 0.096).

Conclusions: There are many causes & symptoms of taste disorders. Dry mouth tends to result in hypogeusia, especially in patients with less salt taste sensitivity. However, salt intake showed no significant difference between the LS and NS groups. Therefore, it cannot be determined that dry mouth results in a taste disorder which then results in an excessive intake of salt.

SA-PO776

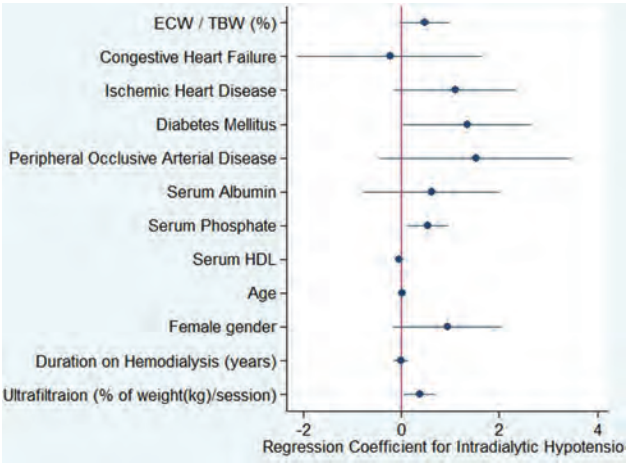
Muscle Mass Measured by Multi-Frequency Bioimpedance and Intradialytic Hypotension among Hemodialysis Patients Jong Cheol Jeong,[1] YOUNG-IL Choi,[2] Myoung-sung Kim,[3] MinJeong Lee,[1] Inwhee Park,[1] Gyu Tae Shin,[1] Heungsoo Kim.[1] *[1]Ajou University School of Medicine, Suwon, Republic of Korea; [2]Dr.Choi's Medical Clinc, SEOUL, Republic of Korea; [3]Myoung clinic, Ansan, Republic of Korea.*

Background: With the introduction of bio-impedance devices, more relevant and reproducible assessment have become possible. To find optimal bio-impedance indices to predict clinical outcomes, more data are needed.

Methods: Prevalent hemodialysis patients (duration of dialysis more than 3 months) were enrolled in three dialysis units. At baseline, clinical indices, physical assessment of volume status, arthropometry examination, NT-proBNP and cardiac indicies by chest PA were collected. At follow up, cardiac indices and clinical events including intradialytic hypotension, cardiovascular events, pulmonary edema were collected. Segmental bio-impedance assessments were performed at every assessment.

Results: Total 150 patients were enrolled. Mean age was 58.5 ± 14.1 years old. Female were 75 (50%). Modified Charlson comorbidity score, Tilburg frailty score, and PG-SGA were 3.9 ± 1.8, 3.3 ± 2.3, and 3.2 ± 4.2, respectively. Body mass index was 22.6 ± 3.3 kg/m^2. ECW/TBW was significantly correlated with cardiac index in positive direction. (spearman's rho 0.351, $p < 0.001$) ECW/TBW also showed significant correlation with NT-proBNP. (spearman's rho 0.384, $p < 0.001$). However, higher ECW/TBW was reported to be associated with intradialytic hypotension in the multivariable logistic regression models. (Odds ratio (OR) 1.627, 95% confidence interval (C.I.) 0.985 – 2.687, $p = 0.058$) (Figure 1). Skeletal muscle index was negatively associated with ECW/TBW. (spearman's rho -0.416, $p < 0.001$) Skeletal muscle index was better predictor for intradialytic hypotension than NT-proBNP (AUC comparison of NT-proBNP vs. skeletal muscle index; 0.721 vs. 0.506, $p = 0.003$).

Conclusions: Reduced skeletal muscle mass was associated with frequent intradialytic hypotension. Optimal values of ECW/TBW, as other than index as inversed reflection of muscle mass, still need to be validated with clinical outcomes.



SA-PO777

Psychological Distress in Dialysis-Dependent CKD Syed S. Zaidi,[1] Andrew Nixon,[1,2] Judi M. Todd,[1] Dawn Brannigan,[1] John Anderton,[1] Mark Brady,[1] Ajay P. Dhaygude.[1] *[1]Lancashire Teaching Hospitals NHS Foundation Trust, Preston, United Kingdom; [2]University of Manchester, Manchester, United Kingdom.*

Background: The burden of chronic kidney disease (CKD) and renal replacement therapy results in a high prevalence of psychological distress. It is not routine practice to screen for psychological distress in patients with CKD. The Distress Thermometer (DT) is a screening tool for psychological distress that has been validated in the renal population. Our aims were to establish healthcare provider ability to perceive patient psychological distress and to assess factors that are associated with psychological distress in those with dialysis-dependent CKD.

Methods: One-hundred patients with dialysis-dependent CKD were recruited. Patient age-modified Charlson Comorbidity Index (CCI) and WHO performance status were assessed. Dialysis unit nursing staff assessed patient psychological distress using the DT. Patients completed the DT on the same day as the nurse assessment. A DT cut off score of ≥7 was used to define severe levels of psychological distress. The correlation between nurse and patient DT scores was assessed using Pearson's correlation coefficient. Linear regression was performed to assess the magnitude of associations. A p value of <0.05 was considered statistically significant.

Results: Mean age was 63.19 years (SD: 14.18) with 58 male patients. Median time on haemodialysis was 38 months (IQR 16.25 to 66.75). Mean CCI score was 5.56 (SD: 1.97). The prevalence of WHO score ≥3 was 37%. The prevalence of severe psychological distress was 29%. Mean nurse DT score was 4.34 (SD: 2.69) and mean patient DT score was 4.32 (SD: 3.37). There was a weak to moderate correlation between the nurse and patient DT scores (r=0.50, p= 0.00, 95% CI 0.32-0.65). After adjusting for age, gender, dialysis vintage and CCI, only WHO score was associated with patient DT score. Each 1 point increase in WHO score was associated with an increase in patient DT score by 0.91 (p=0.01, 95% CI 0.27-1.55).

Conclusions: Psychological distress is highly prevalent in those with dialysis-dependent CKD. Psychological distress is associated with performance status; however, it is not associated with multimorbidity. Healthcare provider perceptions of patient psychological distress do not correlate strongly with patient reported psychological distress. Therefore, patients should be offered the opportunity to complete a psychological distress screening tool, such as the DT.

SA-PO778

The Association Between Tobacco Use and Intradialytic Hemodynamics in Hemodialysis Mark T. Sonderman, Peter N. Van Buren. *UT Southwestern Medical Center, Dallas, TX.*

Background: Extreme changes in intradialytic blood pressure are associated with poor outcomes in hemodialysis patients, but the overall effect of traditional cardiovascular risk factors on these outcomes is poorly understood. We sought to explore the effect of lifetime tobacco use on vascular hemodynamics during dialysis.

Methods: We determined smoking status among a group of hypertensive hemodialysis (HD) patients concurrently enrolled in a cross-sectional study. We compared differences in pre, post, and intradialytic change in systolic blood pressure (SBP), total peripheral resistance index (TPRI), and cardiac index (CI) in subjects defined as never smokers or smokers (current or former) using unpaired t-tests and multivariable linear regression controlling for ultrafiltration rate, diabetes, baseline hemodynamics, and other baseline characteristics.

Results: The pre and post dialysis hemodynamics are shown in Table 1. The ΔTPRI was -582 dynes/sec/cm2/m2 in smokers and 102 dynes/sec/cm2/m2 in non-smokers (p-value = 0.003). The ΔCI was 0.249 L/min/m2 in smokers and -0.063 L/min/m2 in non-smokers (p-value = 0.02). The ΔSBP was -14.5 mmHg in smokers and -10.3 mmHg in non-smokers (p-value = 0.63). In multivariable linear regression, there was an independent association between smoking and ΔTPRI (p=0.012) with an average reduction of 522 dynes/sec/cm2/m2 in ΔTPRI in HD patients with a history of tobacco use.

Conclusions: Hemodialysis patients with a smoking history have reductions in intradialytic TPRI compared to non-smokers although overall BP changes were not different. Further research needs to be done to identify the role of smoking and smoking cessation on intradialytic hemodynamics.

Funding: NIDDK Support

Hemodynamic Values Before and After Dialysis

	Smokers			Never Smokers			
Variable	Pre	Post	Delta	Pre	Post	Delta	p-value
SBP	153 (21.0)	139 (23.0)	-14.5 (29.1)	158 (17.7)	147 (21.7)	-10.3 (31.5)	0.63
TPRI	3320 (972)	2740 (640)	-582 (799)	2920 (703)	3030 (1010)	102 (834)	0.003
Cardiac Index	2.91 (0.647)	3.16 (0.521)	0.249 (0.459)	3.05 (0.577)	2.99 (0.702)	-0.063 (0.486)	0.02

The p-value compares the delta between the two groups.

The data are presented as box plots which indicate the 5th, 25th, 50th, 75th, and 95th percentiles.

Patient Characteristics Associated with the In-Center Hemodialysis Consumer Assessment of Healthcare Providers and Systems (ICH CAHPS) Scores Taimur Dad,[2] Hocine Tighiouart,[2] Megan Grobert,[1] Eduardo K. Lacson,[2,1] Klemens B. Meyer,[2] Dana Miskulin,[2] Daniel E. Weiner,[2] Michelle M. Richardson.[2] *[1]Dialysis Clinic Inc, Boston, MA; [2]Tufts Medical Center, Boston, MA.*

Background: The In-Center Hemodialysis Consumer Assessment of Healthcare Providers and Systems (ICH CAHPS) Survey is a mandatory assessment of patient experience of ICH patients. To better understand performance on this quality metric, we evaluated patient characteristics associated with high ICH CAHPS scores.

Methods: Cross-sectional analysis of ICH CAHPS scores in 2012 to all ICH patients in Dialysis Clinic, Inc (DCI) facilities. Eligibility criteria determined by AHRQ included ≥ 18 years old and received dialysis at the current facility for ≥ 3 months. Measures include patient-level demographic, clinical, laboratory, and functional characteristics. Outcomes include "top box" scores for the three global rating scores for the nephrologist, dialysis facility staff, and dialysis facility and three composite scores 'Nephrologists' Communication and Caring' (Comm), 'Quality of Dialysis Center Care and Operations' (Qual), and 'Providing Information to Patients' (Info). "Top box" was defined by AHRQ as ≥8 for global rating scores (scale 0-10 with 10 being the best) and either "Always" (from Always, Usually, Sometimes, Never) or "Yes" (from Yes, No) answer choice to questions within each composite.

Results: Among 11,055 eligible patients, 4,514 (41%) returned the survey or completed it by phone. In random intercept multivariable logistic models which accounted for dialysis facility effect, older age and lower education were consistently associated with higher odds of top box scores for all three global ratings. Among composite outcomes, higher Kt/V (Comm), lower education (Qual), and being active on the transplant list (Info) were associated with higher odds of top box scores. Shortened treatments were associated with lower odds for a top box score for all global ratings and the Comm composite. Results were similar after imputing missing predictor data.

Conclusions: Older age and lower educational level were associated with higher global rating scores while higher Kt/V, lower educational level, and being active on the kidney transplant list were associated with higher composite scores. Our findings raise concern about dialysis facility scores being influenced by patient case-mix with associated expectations of care experience.

The Standardised Outcomes in Nephrology-Haemodialysis (SONG-HD) Consensus Workshop on Establishing a Core Outcome Measure for Fatigue in Patients on Haemodialysis Angela Ju,[3] Mark L. Unruh,[2] Jonathan C. Craig,[4] Allison Tong.[1] *[1]The University of Sydney, Sydney, NSW, Australia; [2]University of New Mexico, Los Ranchos, NM; [3]University of Sydney, Sydney, NSW, Australia; [4]University of Sydney/Children's Hospital, Sydney, NSW, Australia.*

Background: Fatigue is a critically important outcome for patients on haemodialysis but is infrequently and inconsistently reported across trials and observational studies, which probably reflects the lack of suitable measures that are feasible and psychometrically robust to use in this setting.

Methods: At an international consensus workshop, 56 (15 patients/caregivers; 42 health professionals) participated from nine different countries in six facilitated breakout groups. All discussions were transcribed and analysed thematically

Results: Four themes were identified. *Drawing attention to a distinct and all-encompassing symptom* was explicitly recognising fatigue as a multifaceted symptom that is unique to haemodialysis. *Emphasising the pervasive impact of fatigue on life participation* confirmed the importance of addressing patient concerns about consequences of fatigue such as being limited in their ability to do usual activities such as work and hobbies, and justified the focus on assessing this restriction. *Ensuring meaningfulness* of the measure was advocated to facilitate treatment decision-making for both patients and clinicians. *Minimising burden of administration* meant that the measure should be simple, short, without imposing additional burden given the high level of fatigue in the haemodialysis population. These support a proposed core outcome measure that asks patients about the extent to which fatigue limits participation in usual activities.

Conclusions: Patients, caregivers and health professionals supported the need for a simple, short, and meaningful core outcome measure that focuses on the impact of fatigue on life participation to be used in haemodialysis trials.

SA-PO781

Measurement of Fluid Shifts during 15 Minutes of Standing Using Bioimpedance in Hemodialysis Patients and Healthy Subjects Xia Tao,[1] Fansan Zhu,[1] Ohnmar Thwin,[1] Priscila Preciado,[1] Laura Rosales,[1] Stephan Thijssen,[1] Peter Kotanko.[1,2] *[1]Renal Research Institute, New York, NY; [2]Icahn School of Medicine at Mount Sinai, New York, NY.*

Background: The InBody 770 bioimpedance device allows measurements of fluid status and body composition. Due to gravity, body fluid can shift from the trunk to the legs while standing. The aim of this study was to investigate if gravity-induced fluid shifts produce detectable changes in fluid distribution and if the magnitude of fluid shifts differs between hemodialysis (HD) patients and healthy subjects (HS).

Methods: We studied ten HD patients (7 males, age 58.1±12 years), pre and post HD, and 12 HS (7 females, age 33.3±5.6 years). Two measurements were performed 15 minutes apart in a standing position with the InBody 770 (InBody USA, Cerritos, CA, USA). Extracellular (ECW), intracellular (ICW), and total body water (TBW), ECW in the right and left leg (ECW_{RL}; ECW_{LL}) and the trunk (ECW_T) were recorded. ECW/TBW ratio was calculated with measurements at the start of observation period. Repeated measurements were compared by paired t-test. Unpaired t-test was used to compare patients to HS for ECW/TBW ratio.

Results: During the 15-minute observation period, no significant change in TBW, ICW, or total and trunk ECW occurred. Leg ECW increased significantly for both patients and healthy subjects. In HD patients, the observations above were true both pre and post HD (average fluid removal on HD: 2.2 kg). Pre-HD ECW/TBW differed significantly from post-HD in patients and from HS.

Conclusions: Fifteen minutes of standing did not produce measurable changes in whole body ECW or TBW. However, leg ECW did increase significantly over this period, and this was true in healthy subjects, HD patients before dialysis, and HD patients after fluid removal.

Funding: Commercial Support - Fresenius medical care/ Renal Research Institute LLC

Table 1: The differences (Δ) were calculated as the respective fluid compartment changes over a period of 15 minutes.

SA-PO782

Osteocytic Perilacunar/Canalicular Turnover in Dialysis Patients with High and Low Serum PTH Levels Aiji Yajima,[1] Ken Tsuchiya,[2] Kosaku Nitta.[2] *[1]Indiana University, Indianapolis, IN; [2]Tokyo Women's Medical University, Shinjuku-ku, Japan.*

Background: Osteocytic perilacunar/canalicular turnover in hemodialysis (HD) patients has not yet been reported, despite its particular relationship to bone and mineral metabolism in these patients. Under these circumstances, we were prompted to investigate osteocytic perilacunar/canalicular turnover in CKD patients.

Methods: Osteocyte lacunae in lamellar bone and woven bone were classified as eroded surface-, osteoid surface-, and quiescent surface-predominant osteocyte lacunae (ES-Lc, OS-Lc, QS-Lc, respectively) in HD patients with high or low parathyroid hormone (PTH) levels and control subjects without CKD.

Results: While the number of ES-Lc per unit bone volume (N.ES-Lc/B.Ar) was higher than N.OS-Lc/B.Ar in all groups [high-PTH (P<0.001) -, low-PTH (P=0.002) -, and control (P<0.001)], N.ES-Lc/B.Ar was higher in the high-PTH group than in the low-PTH (P<0.001) and control groups (P<0.001). The total volume of ES-Lc per unit bone volume (ES-Lc.Ar/B.Ar) was greater than OS-Lc.Ar/B.Ar in the high PTH (1.2 ± 0.4 vs. 0.5 ± 1.0 %, P<0.001) and the low-PTH groups (0.6 ± 0.3 vs. 0.1 ± 0.2 %, P<0.001). N.ES-Lc/B.Ar was higher in woven bone than in lamellar bone (P<0.001). MS/BS obtained from both groups were greater than that in the control group (1.15 ± 1.19 vs. 0.51 ± 0.38 %, P=0.039 and 0.92 ± 0.43 vs. 0.51 ± 0.38 %, P=0.016, respectively). Moreover, we could validate the shapes of the lacunar walls by backscattered electron microscopy.

Conclusions: Osteocytic perilacunar/canalicular turnover depends, at least in parts, on serum PTH level. Thus, attention should be paid to bone loss from the viewpoint of osteocytic parilacunar/canalicular turnover in HD patients. **Acknowledgment-**We acknowledge Professor David B. Burr for analyses of the bone histomorphometric parameters and capturing of the images of osteocyte lacunae under the backscattered electron microscope. And we also acknowledge Dr. Keith W. Condon for his excellent technique to make bone samples for the observation by electron microscopy.

Sleep Disorders in ESRD Claire Kennedy,[3,4] Thomas Kane,[2] Peter J. Conlon.[1] *[1]Beaumont Hospital, Dublin 9, Co Dublin, Ireland; [2]Department of Respiratory and Sleep Medicine, Beaumont Hospital, Dublin 9, Dublin 9, Ireland; [3]Department of Nephrology, Beaumont Hospital, Dublin, Ireland; [4]Royal College of Surgeons in Ireland, Dublin, Ireland.*

Background: Sleep disturbance may be overlooked in patients with ESRD due to competing medical issues, as well as a perception that it is difficult to study and frustrating to manage. We aimed to study sleep quality in an ESRD cohort using subjective and objective tools, and to assess the impact of renal replacement therapy (RRT) modality change on sleep disturbance.

Methods: A detailed assessment of sleep quality was performed in an unselected cohort of dialysis patients using several validated subjective tools as well as unattended home polysomnography (PSG) and/or wrist actigraphy. Repeat assessment was performed in those that switched RRT modality.

Results: Baseline interviews were performed in 33 patients. The majority reported poor sleep quality (54.5%, n=18), troublesome restless legs syndrome (RLS; 54.5%; n=18) and reduced quality of life (QOL) most marked in the fatigue and general health perception domains. Screening for depression identified one patient with possible mild depression. PSG (n=19) and actigraphy (n=14) confirmed high rates of sleep fragmentation and disordered sleep architecture across all dialysis modalities. PSG identified periodic limb movement (PLM) disorder in 42% (n=8) and sleep apnoea (apnea-hypopnea index >5) in 58% (n=11). Four patients were medicated for severe PLM with good effect; CPAP was initiated in one patient with severe obstructive sleep apnoea with marked clinical improvement. There were six RRT modality changes. Three were transplanted with improved self-reported sleep quality, fatigue and RLS at 6 months; serial PSG (n=2) showed reduced sleep apnea and PLM, with increased sleep efficiency. Three switched from conventional to nocturnal home hemodialysis (NHHD); again this led to better self-reported sleep quality and fatigue scores. Repeat PSG (performed on and off NHHD at one and six months) demonstrated reduced PLM and increased sleep efficiency, with the improvement most marked on the on-dialysis nights.

Conclusions: This cohort of dialysis patients had poor sleep quality and reduced quality of life without features of depression. Simple therapeutic interventions, made on the basis of home PSG, made a big clinical difference. NHHD and transplantation improved sleep quality. Unattended home PSG and actigraphy were well tolerated, including by those on nocturnal dialysis.

SA-PO784

Quality of Sexual Life Is More Associated with Mental Aspect of Quality of Life Rather Than Physical among ESRD Patients Nien-Chen Li,[1] Norma J. Ofsthun,[2] Franklin W. Maddux,[1] Nwamaka D. Eneanya.[3] *[1]Fresenius Medical Care, Waltham, MA; [2]Fresenius Medical Care North America, Waltham, MA; [3]Massachusetts General Hospital, Boston, MA.*

Background: In the Kidney Disease Quality of Life Short Form (KDQOL-SF) survey, there is an item that specifically investigates quality of sexual life (QSL). Few studies have demonstrated associations of QSL with different subscales featured in the KDQOL-SF. We sought to elucidate the relationship of QSL with overall QOL among ESRD patients.

Methods: Between 1/1/2014 and 8/31/2016, we administered KDQOL surveys to 184,986 patients aged between 18 to 85 with ESRD. QSL was ascertained by analyzing the item "How much does kidney disease bother you in your sex life?" with responses ranging from "Not at all" to "Extremely bothered". To investigate the associations between QSL and overall QOL, two methods were used: 1) correlational analysis between the QSL item and all other items in KDQOL, and 2) correlational analysis between the QSL item and all 5 composite subscales derived from KDQOL.

Results: Among the sample cohort, the mean age at the time of survey was 60.8 (±14.0) years. Fifty-seven percent were male, 60% white race, and 41% married. Thirty-four percent of all patients indicated that their kidney disease bothered their sex life. QSL was more correlated with "emotional" or "mental" rather than "physical" items. For example, r=0.27 for "I feel frustrated dealing with my kidney disease", but r=0.13 for "moderate activities" For composite subscales, sex life was correlated with the effects of kidney disease subscale (after removing the sex item) by 0.48, followed by the symptom subscale (0.34), burden of kidney disease subscale (0.33), mental component summary (0.30), and physical component summary (0.19). All correlations had a p value <.001.

Conclusions: We demonstrated that QSL was more associated with mental (rather than physical) well-being among dialysis patients. To improve QSL among patients with ESRD, psychological evaluations and treatments should be prioritized.

Intradialytic Laughter Therapy: A Qualitative Study Paul N. Bennett, Brigitte Schiller, Christine Kalife, John H. Vo. *Satellite Healthcare, San Jose, CA.*

Background: Hemodialysis patients experience poor physical function and increased anxiety and depression. Intradialytic Laughter Therapy is a group therapy that can be performed while patients are on hemodialysis. Laughter Therapy combines elements of physical activity, intentional laughter, controlled deep breathing and meditation. Laughter Therapy has been shown to increase exercise in the facial, chest, abdominal and skeletal muscles, reduce stress, reduce anxiety and counteract depressive symptoms in non-dialysis patients. The aim of this study was to explore patients' and staff perceptions of an Intradialytic Laughter Therapy program.

Methods: Intradialytic Laughter Therapy was delivered in two separate regional US hemodialysis clinics consisting of 30 minute sessions during dialysis, once per week for 3 months. Patients and clinical hemodialysis staff from the two clinics were surveyed and then interviewed using semi-structured interviews immediately following the 3 month program of Intradialytic Laughter Therapy. Content analysis of survey free text and interview transcript data identified coded items that were categorized into themes.

Results: 58 patients and 25 clinical hemodialysis staff were surveyed and interviewed. The four major themes emerging from the survey interview data were: (1) dialysis is boring and depressing, (2) laughter improved mood, health and wellbeing, (3) improved connections and community and (4) not for everyone. Laughter therapy made people feel happy, and helped them forget about their problems and the boredom of dialysis. Laughter therapy brought people together and establish comradery improving the rapport between staff and patients. Although Laughter Therapy was embraced by most patients those patients who felt indifferent still recommended continuing laughter therapy for the benefit of other patients and staff who they knew enjoyed the Laughter Therapy.

Conclusions: Intradialytic Laughter Therapy is a safe, complementary therapy that can be used during hemodialysis to improve interpersonal interaction, help build group identity, solidarity, and cohesiveness and increase intradialytic physical activity. Laughter Therapy has been shown to be a positive therapy and can be seen as an important element to improve patient and staff experience in US hemodialysis clinics.

Quality of Sexual Life in ESRD Patients Nien-Chen Li,[1] Norma J. Ofsthun,[2] Franklin W. Maddux,[1] Nwamaka D. Eneanya.[3] *[1]Fresenius Medical Care, Waltham, MA; [2]Fresenius Medical Care North America, Waltham, MA; [3]Massachusetts General Hospital, Boston, MA.*

Background: Sexual dysfunction is a highly prevalent problem for patients (pts) undergoing dialysis. This study investigated associations of QSL with quality of life (QOL) for different ESRD modalities.

Methods: In Jan14-Aug16, we administered KDQOL surveys to ascertain the effect of kidney disease on quality of sexual life (QSL) (scaled from "not at all bothered" to "extremely bothered") among a national cohort of dialysis patients, The sample consisted of 184,986 prevalent pts aged 18-85. Logistic model was used to derive odds ratios (ORs) of bothered sexual life (SexL) for age, gender, race, marital status, dialysis modality (PD vs. HD), QOL (physical component summary [PCS] and mental component summary [MCS]). Since demographics were not matched between PD and HD pts, the model was weighted by propensity scores.

Results: Mean age at survey was 60.8 (±14.0) yr; 57% males; 60% Whites; and 41% married. Pts aged 30-64 were most bothered in SexL with OR=1.32 (95% CL 1.23-1.41, p<.001) and 1.95 (1.90-1.99, p<.001) when compared to those aged 18-29 and 65-85, respectively. Males had 2.5X higher odds of having bothersome SexL than women (p<.001). Married pts were 60% more likely to have bothersome SexL than unmarried (p<.001). PD pts were 46% more likely to be bothered in SexL than HD pts (p<.001). For every 1 SD reduction in PCS and MCS, the odds of having bothered SexL increased by 39% and 72%.

Conclusions: We demonstrated that PD pts were more subject to lower QSL than HD pts. Lower QSL was associated with lower QOL physically and mentally. Male middle-aged, and married pts had the most bothersome QSL. Sexual educational programs and interventions should be developed to improve QSL for ESRD pts.

A Six Month Program of Intradialytic Exercise Is Effective in Reducing Length of Hospital Stay in Hemodialysis Patients Daniel S. March,[1] Charlotte E. Grantham,[1] Matthew P. Graham-Brown,[2] Hannah M. Young,[2] Nicola Cooper,[1] James Burton.[1] *[1]University of Leicester, Leicester, United Kingdom; [2]University of Leicester and University Hospitals of Leicester NHS Trust, Leicester, United Kingdom.*

Background: Hemodialysis (HD) patients have a greater risk for hospital admission than the general population with a longer length of in-patient stay (LOS). Intradialytic exercise (IDE) programs have shown improvements in patient related outcomes but there is little evidence regarding the utilisation of health services or cost effectiveness of such programs.

Methods: We performed a retrospective analysis on a subset of 35 patients enrolled in a randomised controlled trial investigating the effect of IDE on cardiac structure and function. The IDE group (n=14) performed 6 months of cycling exercise during HD for 30 mins thrice weekly. Usual care was continued for the control group (n=21). In addition to demographic data, hospital admissions (elective and non-elective stay), and LOS were collected from patient's medical records for 6 months (6M) pre (baseline), 6M during and 6M post IDE.

Results: Hospital admissions in the exercise group stayed the same over the length of the study, there was a small reduction in hospital admissions in the control group for 6M during and 6M post IDE (Table 1). There was a small reduction (11%) in LOS for the control group during the 6M IDE period compared to 6M pre. However, for the exercise group there was a 73% reduction in LOS (3.3 days) during the 6M IDE, which regressed towards baseline for the 6M post period.

Conclusions: We have shown a 3 d reduction in LOS in HD patients while participating in a program of IDE. Based on the current estimates, an additional day of in-patient care costs the UK NHS around £373. An annual reduction of in-hospital care of 3 d for each of the 23,000 UK HD patients would amount to a cost saving of ~£25.7m for the UK health economy.

Total Hospital admissions and length of stays for patients

	6M pre	6M during	6M post
	Hospital Admissions		
Control	1.5 ± 1.5	1.0 ± 1.4 (-33%)	1.3 ± 1.8 (-13%)
IDE	0.6 ± 0.9	0.6 ± 0.9 (0%)	0.6 ± 0.9 (0%)
	Length of Stay		
Control	8.0 ± 17.1	7.1 ± 18.4 (-11%)	7.8 ± 12.0 (-2%)
IDE	4.5 ± 8.9	1.2 ± 1.7 (-73%)	3.4 ± 6.7 (-24%)

Mean ± SD (% change from 6M pre)

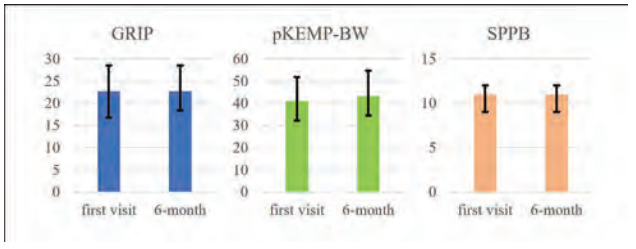
Resistance Training Improves Muscle Strength and Maintained Physical Performance in Patients with Maintenance Hemodialysis Yoshifumi Moriiyama,[2] Sae Aratani,[3] Masahiko Hara,[4] Hideaki Ishikawa.[1] *[1]Konan Kosei Hospital, Konan, Japan; [2]Nagoya kyoritsu hospital, Nagoya, Japan; [3]Nippon Medical School Hospital, Tokyo, Japan; [4]Osaka City University Graduate School of Medicine, Osaka, Japan.*

Background: It is reported that reduced muscle strength and physical performance are prevalent conditions in patients with maintenance hemodialysis, and deleterious changes in these parameters are associated with elevated mortality.

Methods: We provided 306 patients with 6-month resistance training program during hemodialysis. Primary outcome measures included muscle strength measured by handgrip (mean of right and left), percent knee extension muscle power to body weight (pKEMP-BW; mean of right and left), and physical performance measured by short physical performance battery (SPPB). Differences of these variables during 6-month were compared using Wilcoxon signed rank test.

Results: Median age was 71 (quartile 64-77) years old, 160 patients (52.2%) were men, and median dry weight was 54.5 (47.5-62.0) kg. During the 6-month, handgrip showed a slight increase in lower quartile from 22.8 (16.8-28.5) kg to 22.8 (18.3-28.5) kg (p<0.001), pKEMP-BW showed significant increase from 41.0 (32.0-51.8) % to 43.1 (34.4-54.7) % (p<0.001), and SPPB did not change the median and quartile values from 11.0 (9.0-12.0) to 11.0 (9.0-12.0) (Figure).

Conclusions: Resistance training improved muscle strength and maintained physical performance in patients with maintenance hemodialysis. We speculate that resistance training has a potential to prevent progression of sarcopenia and frailty in patients with maintenance hemodialysis.



SA-PO789

Multicenter, Prospective, Randomized, Crossover Trial to Demonstrate the Benefits of Hemodialysis without Acetate (with Citrate): ABC-Treat Study Patricia De Sequera,[1] Rafael Perez-Garcia,[1] Manuel Molina.[2] *[1]Hospital Infanta Leonor, Madrid, Spain; [2]H Santa Lucia, Murcia, Spain. Group/Team: Spanish ABC-treat group study.*

Background: Dialysis fluid, essential element in hemodialysis, is manufactured in situ by the monitors mixing 3 basic components: treated water, bicarbonate concentrate and acid concentrate. We have 2 types of acid concentrate: acetate (A) and citrate (C). **Objective:** To evaluate the impact of HD with C on calcium metabolism, acid base status, inflammation, coagulation and hemodynamic stability compared to HD with A.

Methods: Multicenter, prospective, randomized and crossover study, 32 weeks, 16 with 3mmol/l A (SoftPac®) and 16 with 1mmol/l C (Select BagCitrate®). Inclusion criteria: adults in HD for at least 3 months by arteriovenous fistula, and sign informed consent. Exclusion criteria: allergy or intolerance to citrate, intercurrent inflammatory diseases, significant cognitive impairment. Epidemiological, dialysis, and biochemical data were collected. Visual clotting scores of the dialyser and venous chambers were quantified.

Results: 53 patients were included, 44(83%) males, average age:64(16,5) years, dialysis technique HD/HDF: 18(34%)/35(66%). Mean values of the dialysis parameters: Blood flow: 392,8(48,2) ml/min; kt: 53,5(8,2) L, infusion volume in HDF: 26,9(3,7) L, dialysate bicarbonate concentrations: 31,5(1,6) mmol/l. Results Of the 32 patients who completed the study on 03/31/2017 in table. Coagulation scores from either chambers and dialyser, as well as the number of hypotension episodes recorded during the sessions were lower with the C (p=0.00). We did not find differences neither in the inflammatory parameters measured with C-reactive protein and IL-6, nor in the preHD bicarbonate values.

Conclusions: Dialysis with C modifies most phosphocalcic metabolism parameters, not only acutely as previously described, but also in the long term, and decreases/avoids postdialysis alkalaemia. We have found lower coagulation scores and arterial hypotension episodes with C.

Risks and Benefits of Novel Oral Anticoagulants across the Spectrum of CKD among Patients with Atrial Fibrillation Jung-Im Shin,[1] Alex Secora,[1] Josef Coresh,[1] Alex R. Chang,[2] Morgan Grams.[1] *[1]Johns Hopkins University, Baltimore, MD; [2]Geisinger Medical Center, Danville, PA.*

Background: The relative safety of novel oral anticoagulants (NOACs) vs. warfarin for treatment of atrial fibrillation (AF) in patients with chronic kidney disease (CKD) in real-world settings is unknown. The objective of the study was to evaluate risks and benefits of NOACs in comparison with warfarin across a range of estimated glomerular filtration rate (eGFR).

Methods: We analyzed a cohort of 3,206 patients with AF who used NOACs (Apixaban, Rivaroxaban, or Dabigatran) and a 1:1 propensity-score matched cohort of 3,206 warfarin users between October 2010 and January 2017 in the Geisinger Health System. We estimated the incidence rates of bleeding and ischemic stroke, stratified by G-stage of CKD.

Results: Mean baseline age of the study population was 73.3 years, 46.6% were women, and mean eGFR was 68.5 ml/min/1.73 m^2. There were 1,181 bleeding events, 466 ischemic strokes, and 310 deaths among 6,412 patients with 7,391 person-years (PYs) of follow-up. The incidence rates of bleeding (NOACs vs. warfarin) were 17.4 vs. 16.9 per 100 PYs among those with eGFR≥60, 25.2 vs. 19.0 among those with eGFR 30-59, and 38.1 vs. 30.4 for eGFR<30 ml/min/1.73 m^2, respectively (Figure 1). The incidence rates of ischemic stroke were 6.0 vs. 6.0, 8.8 vs. 7.5, and 9.2 vs. 10.6 for those with eGFR≥60, eGFR 30-59, and eGFR<30 ml/min/1.73 m^2, respectively. Similar findings were observed when each drug was analyzed individually. Among the 122 NOACs users with eGFR<30, 27.8% were not prescribed with renal dose adjustment.

Conclusions: In real-world settings, patients with CKD on NOACs for treatment of AF appeared to experience bleeding events more frequently than those on warfarin. Further large-scale studies are warranted to confirm our descriptive findings.

Cardiac Output Changes Relate to Ultrafiltration Volume during Intermittent Hemodialysis and to Pre-HD Intravascular Volume Assessed by Inferior Vena Cava Ultrasound Collapsibility in ICU Patients Matthew Kaptein,[2,3] Christopher Nguyen,[1] John Kaptein,[3] Elaine Kaptein.[3] *[1]Keck School of Medicine of USC, Los Angeles, CA; [2]Loma Linda University Medical Center, Loma Linda, CA; [3]LAC+USC Medical Center, Los Angeles, CA.*

Background: The goal of volume management is to optimize intravascular volume and maximize cardiac output (CO). CO tends to increase after volume administration in volume depleted patients[1], to increase with UF in volume overloaded ESRD patients[2,3], and to decrease with UF in ESRD patients prone to intradialytic hypotension[4].

Methods: We retrospectively studied 12 ICU patients in 29 intermittent HD (IHD) encounters who had relative intravascular volume assessed by respiratory changes in inferior vena cava diameter within 24 hours prior to IHD/UF, and CO assessed by thermodilution before and after IHD/UF. IVC Collapsibility Index (CI) = (IVCmax-IVCmin)/IVCmax *100%. CO change >10% was considered significant.

Results: For encounters with IVC CI <10% (volume overload), UF -1.6 to -2.6L was associated with increased CO (+14 to +66%) [A]. Larger (-3.0 to -3.2L) [B] or minimal (-0.75 to +0.2L) [C] UF was associated with decreased CO (-15 to -22%). With IVC CI >30% (volume depleted) volume given during IHD may increase CO [D], while UF (-2.4 to -3.0L) may decrease CO (-28 to -44%) [E]. With IVC CI of 10 to 30%, volume removal (-1.4 to -2.8L) may decrease CO (-4 to -20%) [F].

Conclusions: Changes in CO with respect to IVC CI and net volume change with IHD/UF (Fig 1a) may be consistent with changes in position along the Frank Starling curve (Fig 1b), assuming that relative intravascular volume is a primary determinant of IVC CI and CO. These data are consistent with IVC CI being an indicator of relative intravascular volume, and provide empiric evidence that “appropriate” volume removal can improve CO in ICU patients. Reference PMID: 1) 28261499, 2) 8420299, 3) 12059009, 4) 27539225

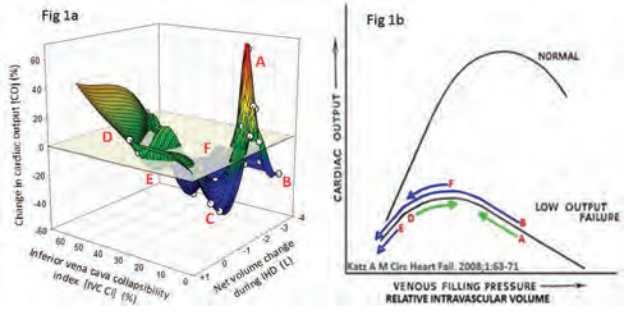

Fig 1a: 3D mesh plot of relationships among change in CO with IHD/UF, intravascular volume assessed by IVC CI before IHD, and volume change during IHD. (O) - individual encounters. Letters indicate different response patterns. Fig 1b: Frank Starling curve with response patterns.

Individual-Level Changes in Interdialytic Weight Gain and Blood Pressure before Dialysis Treatment Are Associated with Same-Day Extreme Heat Events within Northeastern US Cities Alice Topping,[3] Richard V. Remigio,[4] Jochen G. Raimann,[3] Peter Kotanko,[3] Franklin W. Maddux,[2] Patrick Kinney.[1] *[1]Boston University School of Public Health, Boston, MA; [2]Fresenius Medical Care, Waltham, MA; [3]Renal Research Institute, New York, NY; [4]University of Maryland, College Park, Washington, DC.*

Background: In previous work, we have observed the effect of seasonal changes on interdialytic weight gain (IDWG) and pre-treatment blood pressure among hemodialysis (HD) patients. We sought to understand this seasonal effect at a finer temporal resolution by joining averaged daily ambient weather data with individual-level patient data. We focused on patients residing within northeastern United States cities.

Methods: Clinical data were extracted from Fresenius Medical Care-North America (FMC-NA) database for HD patients in Boston (N=1439), New York (N=2241), and Philadelphia (N=3762) between 2001 and 2012. Using weather data from the National Oceanic and Atmospheric Agency (NOAA), we defined a heat wave event as average ambient air temprature in the 99th percentile for each city. We applied linear mixed-effects regression modeling to estimate the effect of same-day heat wave event exposures on IDWG and, systolic blood pressure (pre-SBP), and diastolic blood pressure (pre-DBP) for patients in each city.

Results: All three cities demonstrated associations between same-day heat wave events and IDWG percentage. When compared to non-heat wave events, individual-level IDWG percentage can decrease up to 0.34 % on average (Figure 1a). Same-day heat wave effects on blood pressure demonstrated associations for all three cities. When compared to non-heat events, pre-SBP and pre-DBP can decrease up to 3.28 mmHg and 1.45 mmHg on average, respectively (Figure 1b,c).

Conclusions: Same-day heat wave exposures demonstrated a consistent effect on IDWG percentage and blood pressure among individual patients in the northeastern region of the USA. Our preliminary findings demonstrate a potential relationship between outdoor heat events and important clinical measures in hemodialysis patients. Further work is needed to account for possible regional-specific variation related to these clinical measures.

SA-PO793

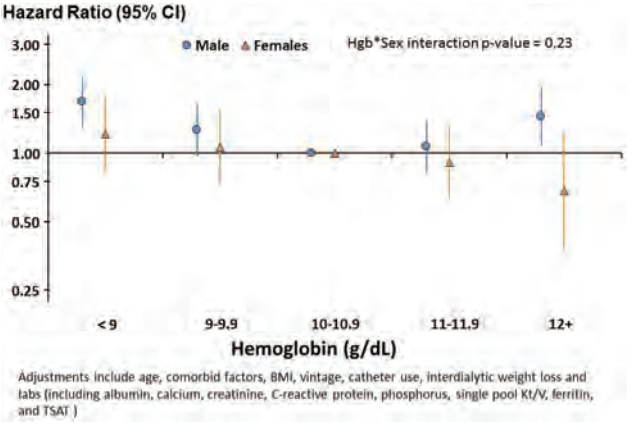
Evaluation of Gender Differences in the Association between Hemoglobin and Mortality Among Hemodialysed Patients in the JDOPPS Norio Hanafusa,[1,5] Charlotte Tu,[2] Keith McCullough,[2] Brian Bieber,[2] Ronald L. Pisoni,[2] Bruce M. Robinson,[2] Takeshi Hasegawa,[3,5] Masaomi Nangaku.[4,5] *[1]Department of Blood Purification, Tokyo Women's Medical University, Tokyo, Japan; [2]Arbor Research Collaborative for Health, Ann Arbor, MI; [3]Division of Nephrology, Department of Medicine, Showa University Fujigaoka Hospital, Yokohama, Japan; [4]Division of Nephrology and Endocrinology, the University of Tokyo School of Medicine, Tokyo, Japan; [5]Anemia Working Group, the Japan Dialysis Outcomes and Practice Patterns Study, Tokyo, Japan.*

Background: Lower hemoglobin (Hb) levels can be permissible among female patients without kidney diseases. Little is known about the gender-specific anemia management in hemodialysis (HD) patients.

Methods: We studied the gender differences in the association between baseline or time-varying Hb values in five categories and all-cause mortality on 6,891 patients in phases 3-5 (2005-2015) of Japan Dialysis Outcomes and Practice Patterns Study (JDOPPS). The associations were investigated by Cox proportional hazard models, with different levels of adjustment. The interaction between gender and hemoglobin's effect on mortality was analyzed using likelihood ratio tests. Several sensitivity analyses were performed, including time-dependent 0-90-day-lagged models and models stratified by vintage and by patient age.

Results: During the median follow-up of 2.58 years, 781 patients died. In the baseline Hb models without lag, a "U-shaped" association (Figure) was observed only in male patients (sex*Hb interaction p=0.23). Similar associations were seen in the lagged time-dependent models. Stratified analyses showed that patients with vintage >1 year or age <75 years exhibited trends similar to the entire population.

Conclusions: The association between Hb and survival might differ between genders in Japanese HD patients. Only male patients showed a "U-shaped" association between Hb and survival, while a moderate linear relationship was observed in females. The detailed investigations in the male patients with higher hemoglobin levels might lead to better understanding of the gender differences in anemia management and of anemia management in whole dialysis population as well.



Adjusted hazard ratio of all-cause mortality, by baseline hemoglobin and gender

SA-PO794

Endogenous Erythropoietin and Requirement of Erythropoietin Supplementation in Hemodialysis Patients Laura Sola, Susana B. Gonzalez, Juan C. Diaz, Veronica Miranda, Laura C. Fajardo, Ricardo A. Hermo. *CASMU-IAMPP, Montevideo, Uruguay.*

Background: Anemia is frequent in hemodialysis (HD) patients (Pts) and is associated to increased morbidity and mortality, being the main cause decreased erythropoietin (EPO) production. The objective of this study is to measure endogenous EPO (EPOe), and asses its relationship with hemoglobin (Hb) and required dose of erythropoietin supplementation (EPOsup) in HD Pts.

Methods: EPOe was measured in HD Pts older than 18 years on treatment in the HD Unit of CASMU on February 2017. Were excluded Pts with evident bleeding, neoplasia, acute infection or hospitalization in the previous month. Data was registered regarding gender, age, and residual renal function (RRF) (creatinine clearance when diuresis ≥300 ml/day) EPOe and Hb were measured after 1 week without EPOsup, in midweek HD, with Advia 2010, Siemens. EPOe was considered low when <4.3, normal value 4.3 to 29 and high >29 mUI/ml. EPO dose was considered as UI/Kg/week, and its response as Hb/EPO dose Quantitative data was expressed as mean and standard deviation or median and interquartile range (IQ), and compared by t test or ANOVA, and categorical measures expressed by percentage and compared by chi square. Significant differences were considered with p values <0.05.

Results: We studied 134 Pts, 83 men (61.9%), median age 70 (IQ 60-79) years, 44 diabetics (32.8%), HD vintage 28 months (IQ 14-49). Diuresis in 54 Pts was 800 (IQ 500-1350) ml/day, with RRF 6,4 (IQ 2,8-9,3) ml/min. Median EPOe was 9.4 (6.6-13.7) mUI/ml. Low EPOe in 10 (7.5%), normal in 116 (86.5%), and high in 8 Pts (6.0%). Pts who did not received EPOsup (19) not differ regarding mean age, HD vintage or EPOe with those with EPOsup. Hb levels were significantly higher in those Pts without EPOsup (12.4±1.1 vs 11.1±1.1 g/dL). EPO categories did not differ regarding age, gender, diabetes, Hb levels or EPO dose. Higher EPOe levels were significantly associated to higher vintage (low EPOe 36.7 ± 23.5, normal EPOe 35.7 ± 41.4 and high EPOe 77.6 ± 70.6 months).

Conclusions: Unexpectedly only 7.5% of the Pts had low EPOe, even though normal levels are inadequate in anemic Pts. Higher EPOe in Pts with longer dialysis vintage may suggest others sources for EPOe besides kidneys in these Pts.

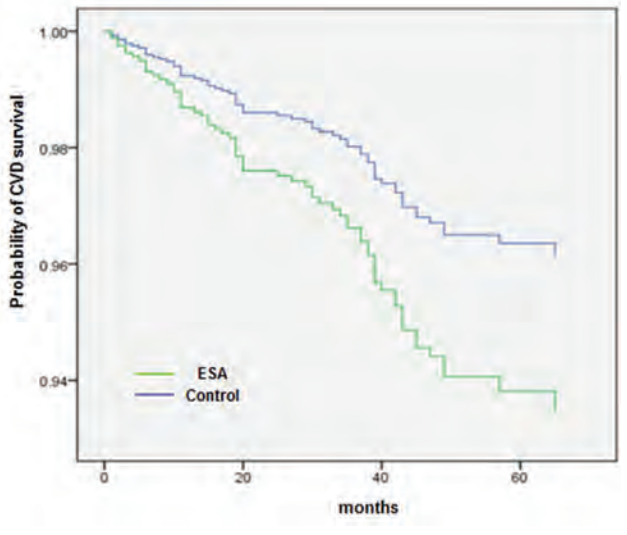
Safety of Erythropoietin Administration among ESRD Patients Jong hoon Lee,[1] Byung ha Chung,[1] Cheol Whee Park,[4] Chul Woo Yang,[3] Yong-Soo Kim,[5] Bumsoon Choi.[2] *[1]Seoul St. Mary hospital, Seoul, Republic of Korea; [2]Division of Nephrology, Department of Internal Medicine, Seoul, Republic of Korea; [3]Seoul St. Mary's Hospital, Seoul, Republic of Korea; [4]The Catholic University of Korea, Seoul, Republic of Korea; [5]The Catholic University of Korea College of Medicine, Seoul, Republic of Korea.*

Background: Erythropoietin (EPO) has been used to care for anemia in CKD patients. Concerns about the administration of EPO include CVD events and tumor progression, but definite associations were not fully identified. We performed the study to validate safety of EPO administration among ESRD patients.

Methods: 3432 ESRD patients were included to a prospective observational study in Clinical Research Center for ESRD registry. The patients were divided into HD group and PD group by dialysis methods. A dose of EPO, IV iron administration and serum Hb levels, CVD and cancer mortality were collected in the registry. Analyses were conducted to estimate hazard ratio(HR) for the EPO administration, dose of EPO and Hb levels with mortality of CVD and cancer.

Results: The mortality rate of CVD was 1.71% in HD group and 1.94% in PD group. CVD mortality was increased by EPO administration in PD group (HR 1.72, p=0.04). But the mortality has no correlation with EPO dose and Hb level. Any factor did not relate to CVD mortality in HD group. The mortality rate of cancer in ESRD patients was 0.94% in HD group and 0.78% in PD group. Hb level, EPO administration and dose were not associated with cancer mortality in both groups. In multivariate risk factor analysis, the mortality of CVD was associated to diabetes (p<0.01) and age (p<0.01) in both groups. However, the mortality of cancer was not associated with any factor.

Conclusions: EPO administration was associated with an increase of CVD mortality in PD patients. Diabetes and age were independent risk factors of CVD mortality. On the other hand, the mortality of cancer in ESRD patients was not associated with EPO administration.



Cardiovascular disease survival among peritoneal dialysis patients

SA-PO796

The Impact of Dose of ESA and Iron on the Risk of Adverse Events in Hemodialysis Patients Takahiro Kuragano,[2] Takeshi Nakanishi.[1] *[1]Hyogo College of Mediicne, Nishinomiya, Japan; [2]Internal Medicine Division of Kidney and Dialysis, Nishinomiya, Japan.*

Background: Anemia treatment with higher doses of ESA in patients with maintenance hemodialysis(MHD) might increase the risk of cardiovascular disease(CVD). On the other hand, higher doses of iron might cause iron overload, which can induce oxidative stress and CVD. The effects of the dosage balance of ESA and iron on the adverse events of MHD patients have not been well established.

Methods: This work was a prospective observational multicenter study over a period of 3 years in 1095 patients on MHD. The patients were divided into 4 groups according to the dose of ESA (high ESA (≥3000 IU/week), low ESA) and intravenous iron (high iron (≥15 mg/week), and low iron). Furthermore, in another analysis, the patients were divided into 4 groups according to the dose of ESA and iron storage (high ferritin (≥50 ng/mL), and low ferritin). A time-dependent Cox hazard model was applied to evaluate the association between patient groups and adverse events.

Results: *Doses of ESA and iron:* There was no significant difference in CVD risk between low ESA/low iron and high ESA/low iron. However, the CVD risks for high ESA/high iron (HR: 2.6, P=0.03) and low ESA/high iron (HR: 3.1, P=0.01) were significantly higher than that for low ESA/low iron. The risk of death for high ESA/high iron was significantly (HR: 2.8, P=0.04) higher than for low ESA/low iron. *Dose of ESA according to iron storage:* There was no significant difference in CVD risk between low ESA/low ferritin and high ESA/low ferritin. However, the CVD risks for low ESA/high ferritin (HR: 3.3, P=0.01) and high ESA/high ferritin (HR: 3.3, P=0.01) were significantly higher than that for low ESA/low ferritin. The risk of death for high ESA/high ferritin was significantly (HR: 3.1, P=0.01) higher than that for low ESA/low ferritin.

Conclusions: We found that high doses of ESA and iron were significantly associated with higher risks of CVD and death. Regardless of ESA dose, a higher dose of iron was significantly associated with a higher risk of CVD. Interestingly, patients with iron deficiency treated with a high dose of ESA were not necessarily at high risk of CVD. We concluded that a higher dose of iron for improving the responsiveness to ESA did not necessarily attenuate this risk of CVD and death.

SA-PO797

Association between Resistance to Erythropoiesis-Stimulating Agents and Carnitine Profile in Patients on Maintenance Hemodialysis Daigo Kamei,[2] Ken Tsuchiya,[1] Kosaku Nitta.[1] *[1]Blood Purification, Tokyo Women's Medical University, Shinjuku-ku, Japan; [2]Blood purification, Tokyo Women's University, Tokyo, Japan.*

Background: Patients on dialysis are in a chronic carnitine-deficient state. This condition may be associated with abnormalities in fatty acid and organic acid metabolism; however, the details are unknown. We investigated the association between carnitine profiles before and after dialysis and the erythropoiesis-stimulating agent (ESA) resistance index (ERI), which is a significant prognostic factor in patients on maintenance hemodialysis.

Methods: cross-sectional study. We measured the carnitine profile of 79 patients on maintenance hemodialysis before and after dialysis using liquid chromatography-tandem mass spectrometry (LC-MS/MS). The associations between the ERI and pre-dialysis carnitine profile, removal rate of various carnitines, and previously-reported ERI-related factors were investigated. Significant factors were determined with stepwise multiple regression analysis and validated with the bootstrap method. SPSS version 22.0 was used for analysis, and P<0.05 was considered statistically significant.

Results: The removal rate of long-chain acylcarnitine with dialysis was lower than that of short-chain or medium-chain acylcarnitines. Stepwise multiple regression analysis (n=79) demonstrated that 3-hydroxy isovalerylcarnitine (C5-OH, P<0.001, β= -0.469) and stearoylcarnitine (C18, P<0.001, β= 0.390) were independent significant factors (R^2= 0.239) of ERI. The bootstrap method similarly indicated these two to be significant factors.

Conclusions: ERI was positively correlated with long-chain C18 acylcarnitine and was negatively correlated with short-chain C5-OH acylcarnitine. C5-OH and C18 acylcarnitines at baseline might be contributing factors in distinguishing responders from nonresponders after L-carnitine administration.

SA-PO798

Hemoglobin Level and Dose of Erythropoietin Stimulating Agent Depending on Hemoglobin Measurement Day Soo Ya Bae, Chung Hee Baek, Su-Kil Park, Hyosang Kim. *Asan Medical Center, University of Ulsan College of Medicine, SEOUL, Republic of Korea.*

Background: Hemoglobin (Hb) variability is frequently observed in end stage renal disease (ESRD) patients. There have been many discussions over true functional Hb in ESRD patients without any confirmative conclusion. Optimal dosing of Erythropoietin Stimulating Agent (ESA) based on true Hb level is important, because high dose ESA is known to be related to poor outcomes with increased health care expenditure. We investigated changes in Hb level and erythropoietin stimulating agent (ESA) dose depending on the change of Hb measurement day in maintenance hemodialysis (HD) patients

Methods: The day for predialysis Hb measurement was changed from days after long interdialytic period (Monday or Tuesday) to midweek days (Wednesday or Thursday) in Asan Medical Center in September 2013. We reviewed baseline clinical characteristics, laboratory data including Hb, dose of ESA, dose of intravenous (IV) iron, and parameters related to HD for two years before and after the change of Hb measurement day in 92 patients receiving maintenance HD.

Results: Mean age of patients was 61.6 ± 12.1, and diabetes mellitus was the leading cause of ESRD (52.2 %). Mean Hb level was 10.71 ± 0.06 g/dL a year before the change of Hb measurement day, 10.78 ± 0.47 g/dL a year after the change (p=0.105). Mean ESA dose was 175.36 ± 72.47 μg darbepoietin alfa per month, 163.65 ± 83.95 μg per month, before and after the change, respectively (p=0.022). Mean IV iron dose was 6.32 ± 4.89 ample (100 mg Fe3+/1 ample) iron hydroxide sucrose per year, 4.47 ± 5.02 ample per year, before and after the change, respectively (p<0.001). Mean interdialytic weight gain was 2.81 ± 0.82 kg and 1.99 ± 0.61 kg, before and after the change, respectively (p<0.001). The number of patients without achievement of target Hb requiring higher dose of ESA was decreased from 8 to 2, before and after the change respectively.

Conclusions: Significant decrease in the ESA and IV iron dose was observed without change in Hb level after midweek predialysis Hb measurement. Midweek predialysis Hb level would be better criterion for ESA dosing.

SA-PO799

Association of Predialysis ESA Anemia Treatment with Mortality after Dialysis Initiation James B. Wetmore,[5] Suying Li,[4] Heng Yan,[4] Hairong Xu,[2] Marvin V. Sinsakul,[1] Yi Peng,[4] Jiannong Liu,[3] David T. Gilbertson.[4] *[1]AstraZeneca, Bethesda, MD; [2]Astrazeneca, Westlake Village, CA; [3]Minneapolis Medical Research Foundation, Minneapolis, MN; [4]Chronic Disease Research Group, Minneapolis, MN; [5]Hennepin County Medical Center, Minneapolis, MN.*

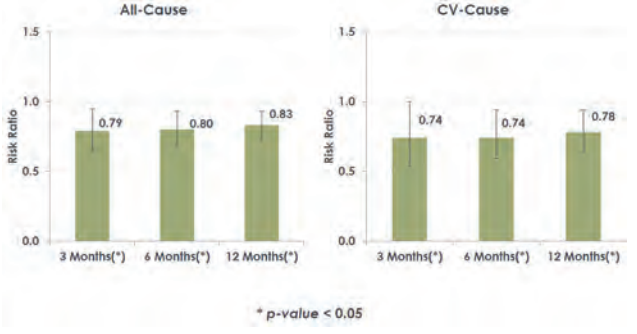
Background: Whether treatment of anemia in the setting of CKD prior to hemodialysis (HD) initiation may reduce post-initiation mortality is unknown.

Methods: Patients who initiated HD between April 1, 2012 and June 30, 2013 were identified from USRDS end-stage renal disease (ESRD) and pre-ESRD files. Hemoglobin (Hb) measurements at HD initiation and at least one other measurement in the subsequent 3-months, in the absence of transfusion, were required. Patients who either never had anemia (defined as Hb ≥ 9.0 g/dL) in the absence of treatment or those who had persistent post-initiation anemia despite treatment were eliminated. Patients who were consistently well-treated (Hb ≥ 9.0 g/dL) with ESAs were retained and compared with patients who appeared to have untreated or ineffectively-treated anemia prior to HD initiation, provided the latter responded to ESAs after initiation. Cox PH models, adjusted for patients' demographics and comorbidities, were used to calculate the hazard ratio of all-cause and cardiovascular (CV) mortality after HD initiation.

Results: The study sample was comprised of 3662 consistently well-treated patients and 4461 patients in the compared group. Adjusted risks of outcomes are shown in the Figure. All-cause mortality was significantly less for the consistently well-treated patients at 3 (HR 0.79, 95% CIs 0.65-0.95), 6 (HR 0.80, 95% CIs 0.69-0.93), and 12 (HR 0.83, 0.73 – 0.93) months. A similar pattern was observed for CV mortality at 3 (HR 0.74, 95% CIs 0.54-1.00), 6 (HR 0.74, 95% CIs, 0.59-0.94) and 12 (HR 0.78, 95% CIs 0.64-0.94) months.

Conclusions: Failure to achieve Hb ≥ 9.0 g/dL through lack of treatment in the predialysis period may represent missed treatment opportunity to reduce mortality after HD initiation.

Funding: Commercial Support - AstraZeneca



Risk of all-cause and cardiovascular mortality in patients with consistently well-treated predialysis anemia (Hb at least 9.0 g/dL) compared to those patients who were not adequately treated but who later proved to be treatable after dialysis initiation.

Anemia Management in Hemodialysis Patients – Is Six-Weekly Monitoring of Hemoglobin Sufficient? Abdullah A. Alaryni, M. Khaled Shamseddin, Frances Macleod, Eduard A. Iliescu. *Kingston General Hospital, Kingston, ON, Canada.*

Background: The KDIGO guidelines recommend monitoring of hemoglobin (Hb) in hemodialysis patients (HD pts.) at least monthly (not graded). Canadian HD programs vary from every 4 to 6-weeks and protocols exist for both schedules. Our centre changed from monthly to every 6 weeks in March, 2014. The objective of this QI report is to examine the volume of CBC measurements, costs, and proportion of pts. with Hb on target before and after the change.

Methods: This is a retrospective study of prevalent HD pts. in South-Eastern Ontario including all in-centre, satellite and home HD. The primary variables were the number of CBCs performed (obtained from EMR) during the 252 days before and 252 days after Mar. 24, 2014 and the associated costs (CDN $ 8.27/CBC Ontario Provincial Fee Schedule). The 252 day equal periods represent exactly 8 complete monthly cycles and 6 complete 6-weekly cycles before and after the change. The proportion of pts. with Hb on target (100 – 120 g/L) was assessed for a longer period of 2 yrs. before and after the change to assess long term outcomes.

Results: The profile of HD pts. is 430 - 440 total, 46 % in-centre, 43 % satellite, 11 % home HD, majority Caucasian, mean age 66 yr., 44 % female, 46 % DM, and 45 % with CVC. The CBC numbers and costs decreased overall but more in satellite than in in-centre pts (Table 1). The proportion of patients with Hb on target 2 years before and after were similar, 60 and 60.5 % respectively.

Conclusions: The results of this study suggest that anemia management in HD pts. results in similar outcomes with CBC measured every 6 weeks as with monthly with reduced cost. The reduction in CBCs was lower in in-centre pts. who had more CBCs measured between the routine bloodwork likely due to higher acuity and overall this is rational use of more frequent testing in sicker pts. The results of this study provide a regional perspective as this is the only HD program in the region, but may not be generalizable to HD programs with different population characteristics.

Table 1.

	Monthly Cycles	6-Weekly Cycles	Reduction/Savings
In-Centre (# CBC)	2194	1995	199
Satellites (# CBC)	1605	1275	330
Total (# CBC)	3799	3270	529
Cost (CDN $)	31,417.73	27,042.90	4,374.83

SA-PO801

Definition and Validation of a Novel Metric to Assess Erythropoiesis Stimulating Agent Response in Hemodialysis Patients Calvin J. Meaney,[4] Spinel Karas,[2] Ben Robinson,[4] Jamie L. Gaesser,[3] Alan Forrest,[6] Wojciech Krzyzanski,[3] Mandip Panesar,[1] Gauri G. Rao.[5] *[1]Williamsville, NY; [2]The University of North Carolina, Durham, NC; [3]University at Buffalo, Glen Mills, PA; [4]University at Buffalo School of Pharmacy and Pharmaceutical Sciences, Buffalo, NY; [5]University of North Carolina, Chapel Hill, NC; [6]University of North Carolina Eshelman School of Pharmacy, Chapel Hill, NC.*

Background: Erythropoiesis stimulating agents (ESA) are the primary treatment of anemia in end-stage renal disease (ESRD) patients. Hemoglobin variability in and out of a narrow target range is common and associated with higher mortality and/or morbidity. More robust metrics of ESA response are needed to define optimal dosing and association to clinical outcomes.

Methods: In this cross-sectional, single-center, retrospective study, 49 ESRD patients on hemodialysis were followed for 12 months. To quantify the excursion of hemoglobin outside the target range (10-12g/dl), the area-under-the-curve of hemoglobin versus time over a 12-month period (AUC-HGB) was calculated using the trapezoidal rule. Patients were categorized into 4 responder groups based on AUC-HGB quartiles. Comparative analysis of demographic and clinical characteristics between responder groups was performed using Chi-square and Kruskal Wallis tests as appropriate. Spearman correlations between AUC-HGB, erythropoietin resistance index (ERI) and time within therapeutic range (TTR) were performed.

Results: There were no significant differences in demographics, laboratory, or dialysis parameters between responder groups except hemoglobin and ESA dose. The mean age was 58.0±13.1 years, 59% were male and 69% were African-American. Mean hemoglobin was 10.4±0.58g/dl (range 6.0-13.6g/dl). The median (range) AUC-HGBs for each group were: 4.45 (0-20) g x year/dL in the excellent responder group; 48.2 (26-65) g x year/dL in the good responder group; 101 (76-109) g x year/dL in the fair responder group; and 201 (123-528) g x year/dL in the poor responder group. There was a negative correlation with AUC-HGB and TTR (r=-0.93, p<0.001) and hemoglobin concentration (r=-0.85, p<0.01), while there was a positive correlation with AUC-HGB and ERI (r=0.70, p<0.001). The poor response group received higher median ESA dose (160 U/kg/week) compared to the excellent response group (68.8 U/kg/week, p<0.001) with a similar number of ESA dose changes between the groups. Over 2 years of follow-up, 5 patients died, of which 3 were in the poor response group.

Conclusions: AUC-HGB is a valid metric of ESA response in the hemodialysis population and may serve as a better marker of ESA response compared to conventional metrics.

GX-E2 versus CERA for Anemia in Patients Receiving Maintenance Peritoneal Dialysis: A Phase 2, Randomized, Multi-Center, Active-Comparator, Dose-Finding Safety and Efficacy Study E un jeong Ko,[1] Byung ha Chung,[1] Sug kyun Shin,[2] Hyung Wook Kim,[3] Byung chul Shin,[4] Seok Joon Shin,[5] Hyeong cheon Park,[6] Young Sun Kang,[7] Sang-Ho Lee,[8] Ho Cheol Song,[5] Su Hyun Kim,[9] Ki Young Na,[10] Young-Il Jo,[11] Won Kim,[12] Eun Young Seong,[13] Yong-Lim Kim,[14] Minkyu Heo,[15] Jungwon Woo,[15] Chul Woo Yang.[1] *[1]Seoul St. Mary's Hospital, Seoul, Republic of Korea; [2]Ilsan Hospital NHIS, Gyeonggi, Republic of Korea; [3]St. Vincent's Hospital, Gyeonggi, Republic of Korea; [4]Chosun University, Gwangju, Republic of Korea; [5]Incheon St. Mary's Hospital, Gyeonggi, Republic of Korea; [6]Gangnam Severance Hospital, Yonsei University College of Medicine, Seoul, Republic of Korea; [7]Korea University Medical College Ansan Hospital, Gyeonggi, Republic of Korea; [8]Kyung Hee University Hospital, Seoul, Republic of Korea; [9]Chung-Ang University Hospital, Seoul, Republic of Korea; [10]Seoul National University Bundang Hospital, Gyeonggi, Republic of Korea; [11]Konkuk University Hospital, Seoul, Republic of Korea; [12]Chobuk National Univeristy Medical School, Jeonju, Republic of Korea; [13]Pusan National University Hospital, Busan, Republic of Korea; [14]Kyungpook National University Hospital, Daegu, Republic of Korea; [15]Genexine, Inc., Seongnam-si, Republic of Korea.*

Background: GX-E2 is hybrid Fc (hyFc)-fused long-acting recombinant human erythropoietin. We conducted a phase 2, randomized, active-comparator, safety and efficacy study in patients with anemia receiving maintenance peritoneal dialysis.

Methods: Patients with a stable end-stage renal disease treated with peritoneal dialysis were included. In Part A, a dose-finding study was conducted in 60 subjects with 4-week treatment of six different dosage of GX-E2. In Part B, 12-week treatment was conducted in 72 individuals with two selected doses of GX-E2 based on the Part A results, and with methoxy polyethylene glycol-epoetin β (CERA) (0.6 μg/kg bi-weekly). Primary endpoint was mean hemoglobin change from baseline to the end of treatment.

Results: In Part A, mean Hb level was significantly increased after 4 weeks GX-E2 administration and mean Hb changes from baseline were 0.6±1.3 g/dL in 3 μg/kg, 1.3±1.1 g/dL in 5 μg/kg, and 1.4±1.0 g/dL in 8 μg/kg bi-weekly. In Part B, participants were randomly assigned to 3 groups, treated bi-weekly with 5 μg/kg, 8 μg/kg of GX-E2 and 0.6 μg/kg of CERA. Mean Hb level changes after 12 weeks GX-E2 administration were 2.2±1.3 g/dL in 5 μg/kg, 3.1±1.1 g/dL in 8 μg/kg, and 1.7±1.4 g/dL in CERA, GX-E2 showed comparable or better outcome compared to CERA (p-values for each 0.233, <0.001). No safety issues were observed.

Conclusions: In this phase 2 study of anemia treatment in patients with end-stage renal disease on maintenance peritoneal dialysis, GX-E2 was well-tolerated and effectively maintained Hb levels.(grant number: HI14C1038)

SA-PO803

Epoetin Alfa and Darbepoetin Alfa: A Cross-Sectional Study Comparing Doses According to Administration Intervals Marie-Eve Dupuis,[5] Caroline Lamarche,[4] Robert Z. Bell,[1] Katherine Desforges,[3] Laurence Lepage,[2] Vincent Pichette,[5] Jean-Philippe Lafrance,[4] Michel Vallee.[4] *[1]Centre de recherche Hopital Maisonneuve-Rosemont, St. Lambert, QC, Canada; [2]Hopital Maisonneuve Rosemont, Montreal, QC, Canada; [3]Maisonneuve-Rosemont Hospital, Montréal, QC, Canada; [4]None, Montreal, QC, Canada; [5]Université de Montréal, Montréal, QC, Canada.*

Background: Anemia is a common problem among patients with chronic kidney disease. Erythropoiesis stimulating agents (ESA) are frequently used to maintain haemoglobin between 95-115 g/L. Multiple studies suggest that longer intervals than those recommended in the product monographs of these ESA can be effective. Most of these studies were done in non dialysis patients. Fewer studies were done with population in hemodialysis, peritoneal dialysis and in transplanted patients.

Methods: In this retrospective, single center, cross-sectional study, we compared the dose, reported in IU/kg/week, between groups defined by the interval at which patients received ESA (more than once a week (G0), once a week (G1), once every other week (G2), once every three weeks (G3), once every 4 weeks (G4) and once every more than 4 weeks (G5). Charts of all patients receiving an ASE at a stable dose for at least three months and followed in either the pre-dialysis, hemodialysis, peritoneal dialysis and transplant clinic were reviewed.

Results: Five hundred and ninety four patients were included. One hundred and twenty-two patients (22%) were on epoetin alfa and 462 (78%) were on darbepoetin alfa. The mean dose/kg/week was less when a longer interval was used: the mean dose/kg/week) was 247 in G0, 195 in G1, 82 in G3, 67 in G3, 33 in G4 and 28 in G5 ($p<0.0001$). In the epoetin subgroup, the mean dose/kg/week was 256 in G0, 124 in G1, 52 in G2, 37 in G3, 19 in G4, 17 in G6 ($p<0.0001$). In the darbepoetin subgroup, the mean dose/kg/week was 162 in G0, 228 in G1, 86 in G2, 71 in G3, 35 in G4, 33 in G5 ($P>0.0001$).

Conclusions: Doses were significantly lower in the longer interval groups, suggesting that longer intervals are efficient to maintain haemoglobin in the desired target in a large population of patients with chronic kidney disease. The mean dose remained smaller in the longer intervals when comparing both ESA types, however, the mean dose was generally less in the epoetin group compared to the darbepoetin group. A selection bias might explain some of the differences between groups. Nonetheless, using longer intervals seem possible in a significant number of patients. Since longer intervals are more acceptable to patients and are more cost effective, this approach might be favourable.

SA-PO804

Conversion from Epoetin Alfa to Darbepoetin Alfa in HD: Optimized Dose Conversion Algorithm and Hb Stability Dongyang Shang,[1] Alex Yang,[1] Shijie Chen,[1] Steven Chang,[1] Sheila Doss-McQuitty,[1] Brigitte Schiller.[1,2] *[1]Satellite Healthcare, San Jose, CA; [2]Stanford University, Palo Alto, CA, CA.*

Background: Previous conversion experiences from thrice weekly epoetin to once weekly darbepoetin resulted in inconsistent outcomes when using the conversion table in the prescribing information (PI). This study tested an improved conversion algorithm and assessed the accuracy through achieved target hemoglobin (Hb), Hb stability and speed to reach Hb stability.

Methods: This is a prospective, controlled, open-label, multi-center interventional trial. Data from 5643 in-center HD patients from 54 dialysis centers from January 2016 to May 2017 are presented. Conversion occurred from June 2016 to February 2017. Doses were adjusted monthly to achieve a target Hb of 10 to 11.4 g/dL. Hb values were measured monthly for the 4 months before conversion, 1 month during the conversion, and up to 4 months after conversion. Hb consistency was defined as an increase or decrease of ≤ 3% in the percentage of patients in each Hb category.

Results: The improved conversion table increases the number of dose categories, resulting in doses that overall are 8.8 times more closely aligned with the optimal dosing curve than the current PI. The distribution of patients (n=4634) treated with darbepoetin for 4 months reaching the target Hb 10.0-11.4 g/dL is clinically and statistically similar to pre-conversion. Within 2 months of conversion 54% of patients reached target Hb, similar to the month prior to conversion.

Conclusions: In this real-world dosing conversion study switching from epoetin to darbepoetin, the improved conversion table reduces the risk of initial under-dosing and shortens the duration of time before patients achieve stable Hb. Appropriate therapeutic conversion provides more accurate darbepoetin dosing based on patients' ESA needs.

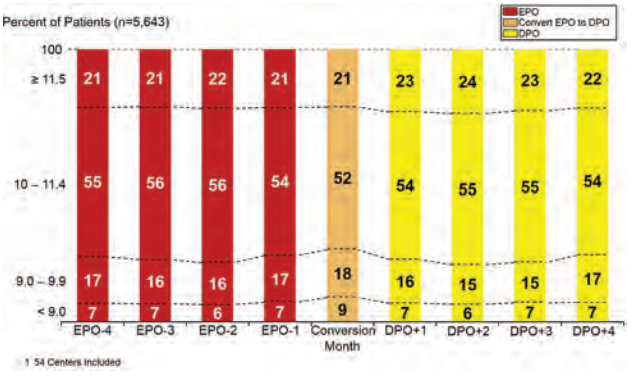

Figure: Hb Stability During Darbepotin Conversion[1] – Proportion of Converted Patients by Hb Ranges from January 2016 to May 2017

SA-PO805

Levels of the EPO-Responsive Hormone Erythroferrone in Mice and Humans with CKD Mark R. Hanudel,[1] Maxime Rappaport,[1] Victoria R. Gabayan,[2] Isidro B. Salusky,[1] Tomas Ganz,[2] Elizabeta Nemeth.[2] *[1]Department of Pediatrics, David Geffen School of Medicine at UCLA, Los Angeles, CA; [2]Department of Medicine, David Geffen School of Medicine at UCLA, Los Angeles, CA.*

Background: We previously demonstrated that, in mice with normal kidney function, erythropoietin (EPO) stimulates erythroblasts to secrete the hormone erythroferrone (ERFE), which acts to suppress production of the iron-regulatory hormone hepcidin. ERFE-mediated hepcidin suppression increases iron availability for RBC production. ERFE has not been assessed in humans or in the setting of CKD.

Methods: We measured serum ERFE levels in wild type mice, with and without adenine diet-induced CKD, after administration of a single EPO dose. We also measured serum ERFE in adults with normal kidney function after EPO treatment, as well as in 161 adult and pediatric healthy controls, 82 adult and pediatric non-dialysis CKD patients, and 101 adult and pediatric dialysis patients.

Results: In mice with normal kidney function, serum ERFE levels, undetectable at baseline, increased in response to EPO, peaking 6h post-injection. In mice with CKD, serum ERFE levels increased to a similar degree, but peaked later, at 24h post-injection. In both groups, serum hepcidin was decreased at 48h. In four adults with normal kidney function injected with a single EPO dose, serum ERFE increased 2.2-fold from baseline by 48-72h post injection. Concurrently, serum hepcidin levels decreased 2.3-fold from baseline by 48-72h hours post injection. Median serum ERFE did not differ between non-dialysis CKD and control patients (6.1 vs. 7.8 ng/ml), but was significantly elevated in dialysis patients (15.7 ng/ml, $p<0.05$). In the non-dialysis CKD patients, serum EPO correlated positively with ERFE (Spearman $r=0.59$, $p<0.001$), but ERFE did not correlate with hepcidin. Hepcidin correlated with TSAT (Spearman $r=0.34$, $p=0.004$), but not with CRP or eGFR. Similarly, in the dialysis patients, rhEPO dose correlated positively with ERFE (Spearman $r=0.44$, $p<0.001$), but ERFE did not significantly correlate with hepcidin. Hepcidin did not correlate with TSAT or CRP.

Conclusions: In humans with normal kidney function, EPO administration increases ERFE and suppresses hepcidin. In CKD patients, ERFE correlates with serum EPO or rhEPO dose, but not hepcidin. These data suggest that ERFE is responsive to EPO in humans and mice regardless of kidney function, but that regulation of hepcidin in CKD is multifactorial, masking the hepcidin suppressive effects of ERFE.

SA-PO806

Impact of Intra-Venous Ferric-Sucrose Hydroxide on Mortality in HD: MEDIAL Iron Cohort ECHO (MICE Study) Victorio Menoyo,[2] Malik Touam,[4] Pierre-Yves Durand,[1] A. Testa.[3] *[1]ECHO, VANNES, France; 2HEMODIALYSiS, ECHO, NANTES, France; 3ECHO NANTES, NANTES, France; 4Necker Hospital, Paris, France. Group/Team: MEDIAL STUDY GROUP.*

Background: Intraveinous iron is the main complement to Erythropoiesis Stimulant Agent (ESA) treatment for HD patients. Ferric Sucrose Hydroxide (HFS) is one of this. Previous retrospective studies have shown the potential toxicity of HSF, and have report increased mortality above some monthly dose. We aimed to study the toxicity of HSF, and to precize its relationship with this markers.

Methods: Medical Iron Cohort ECHO is a multicenter cohort of HD patients coming from 49 HD french centers. All incident patients were included from year 2005 to 2015. Data were retrospectively analyzed. Iron injections, ESA, hemoglobin and other biological data were recorded in a single database : MEDIAL. Statistical analysis used

a non-parametric test for exceedances of the Ferritin, TSAT and CRP standards as well as kt/V <1.3. We considered the usual demographics and diabetes. We have defined 4 subgroups according to the dose of HFS: A: <100 mg / month; B: 100-200 mg / month; C: 200-300 mg / month; D: 300-400 mg / month; E:> 400 mg / month. The proportional risk regression survival analysis (Cox model) was performed using the STATISTICA software.

Results: 1,370 patients were included. The average follow-up was 41.5 months. 481 deaths occured during the study period. It was a very strong relationship between mortality and HFS dose above 200 mg / month. (P <0.0000) The stratified analysis showed that this relationship was dose-dependent and the effect appears above a dose of 100 mg / month of HFS. Although there was no significant difference between subgroups A, B, C, there was a trend towards it. There was no significant relationship between mortality and Ferritin or TSAT blood levels. There was no significant difference between the 5 groups regarding the received ESA dose or hemoglobin. Gender and diabetes were not linked to mortality, while other independent factors appeared to be significant: age at onset of dialysis, albuminemia, CRP and kt/V <1.3.

Conclusions: This study suggests that intraveinous HFS in HD patients could be toxic, probably for doses considered to be low toxicity to date. Ferritin and TSAT blood levels are not good markers for HSF toxicity. Advanced age at the start of ESRD, undernutrition, inflammatory status, or poor dialysis dose are significant markers linked to mortality. Further prospective studies are required to confirm these results.

SA-PO807

Serum Concentration of Non-Transferrin Bound Iron in Hemodialysis Patients Is Increased after Oral Iron Administration Noriko Saito,[4] Kazuhide Saito,[6] Tetsuo Morioka,[3] Hisaki Shimada,[4] Kozo Ikarashi,[3] Yutaka Tsubata,[5] Taiji Sasagawa,[3] Katsuya Ikuta,[1] Yutaka Kohgo,[2] Shigeru Miyazaki.[3] *[1]Asahikawa Medical University, Asahikawa, Japan; [2]International University of Health and Welfare, Nasushiobara, Japan; [3]Shinraku-en Hospital, Niigata, Japan; [4]Shinraku-en hospital, Niigata, Japan; [5]Shinrakuen hospital, Niigata city, Japan; [6]Niigata University, Niigata, Japan.*

Background: Non-transferrin bound iron (NTBI), which appears in serum in iron overload, is thought to cause organ damage through free radical production. We reported NTBI was increased after intravenous iron administration (IVIA) in hemodialysis (HD) patients (ASN2016), on the other hand, their kinetics after oral iron administration(OIA) is unknown. Aim of this study is to assess the kinetics of NTBI concentration after OIA in HD patients.

Methods: 16 HD patients without any iron load within 4 weeks, whose Hb<12g/dl, ferritin<100ng/ml and CRP<1.0mg/dl, were enrolled. They received oral ferrous sulfate 105mg at the start of HD session. We evaluated the following markers before and at 1,2,3,4 and 48 hours(hr) after OIA : NTBI, Hepcidin-25(HPC), high sensitive CRP(hsCRP), 8-oxo-2'-dehydroguanosin, serum iron, transferrin saturation(TSAT), transferrin(Tf), ferritin, soluble Tf receptor and standard hematological parameters. NTBI was measured by recently described reliable method(Clin Chim Acta437:129-135, 2014). 4 HD patients without OIA were also enrolled as control.

Results: 1. Fe before OIA was 30(24-49)μg/dl and significantly increased to 45(27-57)μg/dl at 1hr and reached the peak level of 272(104-320)μg/dl at 4hr and then decreased to 52(34-81)μg/dl at 48hr (Medians(interquartile range)). 2. TSAT before OIA was 12(7-17)%, significantly increased to 24(17-39)% at 2hr, reached the peak level of 70(34-80)% at 4hr and decreased to 17(14-26)% at 48hr. 3. NTBI before OIA was 0.02(0-0.10) μM and significantly increased to 0.15(0.03-0.56)μM at 4hr and decreased to 0.02(0-0.07) at 48hr. 4. NTBI at 4hr after OIA correlated with TSAT at 4hr(r=0.894,p<0.001). 5. The predictor of NTBI 4hr after OIA was percentage of hypochromic red cells (%HypoHe) before OIA by stepwise analysis (β=0.548, p=0.028, R2=0.3) 6. Ferritin before OIA was 16(15-29) ng/ml and significantly increased to 35(19-48)ng/ml at 48hr. HPC was unchanged during 48hr. 7. In control patients TSAT, NTBI and ferritin were not changed during 48hr.

Conclusions: TSAT and NTBI significantly increased at 2hr and 4hr after OIA, respectively and both peaked at 4hr. %HypoHe before OIA was negative predictor of NTBI at 4hr. Clinical significance of NTBI increment after OIA should be further examined.

SA-PO808

Evaluating Iron Overload in Haemodialysis Patients with MRI T2* Benjamin Elyan,[1] Kenneth Mangion,[1,2] Samantha F. Cockburn,[1] Patrick B. Mark,[1] Elaine Rutherford.[1,2] *[1]Institute of Cardiovascular and Medical Sciences, University of Glasgow, Glasgow, United Kingdom; [2]Cardiology and Imaging Group, British Heart Foundation Glasgow Cardiovascular Research Centre, University of Glasgow, Glasgow, United Kingdom.*

Background: Intravenous iron is commonly prescribed to hemodialysis (HD) patients but optimal dosing is not established and iron overload is a clinical concern. MRI derived non-contrast T2* time is used to screen for cardiac and liver iron overload in other clinical groups, such as thalassemia - the lower the T2* time, the greater the degree of iron overload. T2* has not been studied in HD patients. We hypothesised that T2* in HD patients would differ from matched healthy volunteers (HVs) and that T2* in HD patients may correlate with their total cumulative intravenous iron doses.

Methods: 22 incident HD patients and 26 age and sex matched HVs were enrolled. Participants underwent a 3.0T MRI scan (Siemens Verio). T2* images were blindly analysed offline using Medis analysis software (QMaps) placing regions of interest in the myocardial septum and the liver. Statistical analysis was done using SPSS (version 22).

Results: Liver and myocardial septal T2* times were higher in HD patients (Table 1). Septal T2* times in HD patients negatively correlated with cumulative iron dose (R^2 = -0.49 p= 0.017) (Figure 1). Liver T2* times also negatively correlated with cumulative iron dose (R^2 = -0.46 p 0.028).

Conclusions: T2* times in septal and liver tissues are higher in incident HD patients compared with HVs, suggesting that HD patients do not have overt signs of iron overload early on. However, greater cumulative iron doses correlated with lower T2* times in HD patients. Imaging signs of iron overload may develop in patients established on HD for longer. Further research should explore the longitudinal affects of cumulative iron dose on T2 * times.

Effects of Adult Erythropoietin Dosing Regimens on Pediatric Dosing Practice: Findings from North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) Sarah A. Twichell,[3] Elizabeth A. Hunt,[3] Karen Martz,[2] Michael J. Somers.[1] *[1]Boston Children's Hospital, Boston, MA; [2]NAPRTCS, Rockville, MD; [3]University of Vermont Children's Hospital, Burlington, VT.*

Background: Development of recombinant erythropoietin (epo) led to declines in anemia among hemodialysis (HD) patients, but studies showed more morbidity in adult HD patients with a 'normal' hemoglobin (hgb) level, so 2008 adult guidelines recommended target hgb <11.5 gm/dL. Adult guidelines are often applied to pediatric dialysis patients, though increased morbidity with higher hgb levels has not been demonstrated in children. We evaluated transfusions and anemia among pediatric HD patients before and after adult anemia guideline implementation.

Methods: We performed a retrospective analysis of children in the NAPRTCS database, a voluntary, prospective registry of children with end stage renal disease. We assessed transfusions, anemia, epo dosing, and hospitalizations in 3 time periods: baseline (2003-2007), implementation (2008-2011) and post-implementation (2012-2016). Children were included once in the earliest period enrolled.

Results: 1,199 children enrolled in the NAPRTCS HD registry during the study period (54.7% male, median age 13.4 years). Children in post-implementation were significantly younger than children in baseline and implementation. 12.8% of patients had transfusions in baseline, 19.6% in implementation (p=0.008 vs. baseline), and 17.4% in post-implementation (p=0.08 vs. baseline). Mean hgb 6 months after HD start was 11.8 gm/dL in baseline, 11.1 gm/dL in implementation (p<0.001 compared with baseline) and 11 gm/dL in post-implementation (p<0.02 compared with baseline). Median epo dosing 6 months after starting HD was 211 u/kg/week in baseline, 131 u/kg/week in implementation, and 142 u/kg/week in post-implementation. 6 months after starting dialysis, 42.7% of children were hospitalized in baseline, 43.4% in implementation, and 46.5% in post-implementation. The rate of anemia (hgb <10) 6 months after starting dialysis was 17.4% in baseline, 23.5% in implementation, and 23.8% in post-implementation.

Conclusions: With implementation of adult epo dosing guidelines, epo dosing was lower, anemia rate increased, transfusion rate increased, and mean hgb levels decreased among NAPRTCS participants. There was no significant difference in hospitalization rates before and after guidelines. Further study of safe target hgb levels among pediatric HD patients is warranted.

Iron Supplementation for Hemodialysis Patients: Less Oxidative Stress by Oral Ferric Citrate Hydrate as Compared to Intravenous Saccharated Ferric Oxide Masaaki Nakayama,[6] Yoshihiro Tani,[4] Wan-Jun Zhu,[6] Keitaro Yokoyama,[1] Masafumi Fukagawa,[7] Takashi Akiba,[5] Myles S. Wolf,[2] Hideki N. Hirakata.[3] *[1]Division of Nephrology and Hypertension, Department of Internal Medicine, The Jikei University School of Medicine, Tokyo, Japan; [2]Duke University, Durham, NC; [3]Fukuoka Renal Clinic, Fukuoka City, Japan; [4]Fukushima Medical University, Fukushima, Japan; [5]Sekikawa Hospital, Tokyo, Japan; [6]Tohoku University, Tohoku University Hospital, Sendai City, Japan; [7]Tokai University School of Medicine, Isehara, Japan.*

Background: Orally dosed ferric citrate hydrate (FC) corrects renal anemia in patients on hemodialysis (HD), suggesting a need for exploration of the biological differences in effects of iron supplementation using different routes of administration. To address this issue, the present study compared oral FC with intravenous saccharated ferric oxide (FO) in stable HD patients.

Methods: Six patients received 3 consecutive protocols in the first HD session of the week in a fasting state: nothing given, as control (C); oral load of FC (480 mg iron), and 5 minutes of intravenous FO (40 mg iron). Iron dynamics and biological impact on redox-inflammation status during the study (6 hours) were examined.

Results: Significant increases in serum iron and transferrin saturation (TSAT) were seen with both FC and FO. Regarding total iron-binding capacity, no changes were found in FC, whereas significant increases were seen in FO, despite the lower serum iron levels in FO, suggesting appearance of nontransferrin-binding iron (NTBI). This is suggested by the significant changes of NTBI/serum Iron ratio (%) in FO, but not in FC (Fig). Compared to C, increases were seen in serum myeloperoxidase (oxidative marker) with accompanying significant decreases in thioredoxin (anti-oxidant) in FO, whereas no changes were found in FC. While ratio of intact- to c-terminal FGF23 at 4 hours after starting HD were significantly higher with FO, as compared with C or FC.

Conclusions: Oral FC differs from intravenous FO in areas such as transferrin-binding capacity, NTBI generation, induction of oxidative stress, and FGF23 metabolism. Oral FC may have benefits in terms of iron supplementation for anemia associated with chronic kidney disease.

SA-PO811

A 29-Day Safety, Efficacy, and Pharmacodynamic Study of a Hypoxia-Inducible Factor Prolyl Hydroxylase Inhibitor, Daprodustat, Administered TIW in Anemic Subjects on Hemodialysis (HD) Christine K. Bailey,[2] Stephen Caltabiano,[2] Alexander R. Cobitz,[2] Chun Huang,[2] Kelly M. Mahar,[2] Vickas Patel,[2] Steven Zeig.[1] *[1]Pines Clinical Research, Inc., Hollywood, FL; [2]GlaxoSmithKline, Collegeville, PA.*

Background: This randomized, double-blind, placebo (PBO)-controlled study (funded by GSK) examined the relationship between daprodustat TIW dosing and hemoglobin (Hgb) level and safety over 29 days in 103 subjects on HD ≥ 3 times weekly and who were previously receiving a stable dose of an erythropoiesis-stimulating agent (ESA).

Methods: Subjects with baseline Hgb of 9.0–11.5 g/dL discontinued ESAs and were randomized to receive daprodustat 10, 15, 25, or 30 mg TIW or PBO.

Results: Mean baseline Hgb was 10.6 g/dL for all randomized subjects. Switching from an ESA to daprodustat produced dose-dependent mean changes in Hgb (g/dL) from baseline and maximum EPO after 29 days (**Table**). Day 29 pre-dose EPO levels were near or below baseline values, indicating no accumulation of EPO after daprodustat TIW treatment. At Day 29, mean hepcidin levels were reduced from baseline in a dose-dependent manner by an overall mean of 11.7% in subjects in the combined daprodustat group compared with a mean increase of 27.8% in the PBO group. Daprodustat was generally well tolerated, with an adverse event profile consistent with the HD population. No new safety concerns were identified. Based on the TIW dose-response relationship in this study and the QD dose-response relationship in the prior study PHI113633, each characterized by a Bayesian Emax model, the dose conversion ratio between QD to TIW dosing of daprodustat was ~ 2.0 across the dose range.

Conclusions: These data inform the Hgb dose-response relationship of daprodustat in anemic HD subjects who were switched from a stable dose of ESA and treated with daprodustat TIW for 29 days. Daprodustat TIW treatment reduced hepcidin levels and increased plasma EPO levels in a dose-dependent manner. These data support future longer-term clinical studies in patients on HD to further explore daprodustat TIW to treat anemia of CKD.

SA-PO812

Intravenous Regular Administration of 40mg Iron a Month Might Reduce Hemoglobin Variability of Hemodialysis Patients in Japan Tatsuo Tsukamoto. *Kitano Hospital, The Tazuke Kofukai Medical Research Institute, Osaka, Japan.*

Background: Japanese hemodialysis patients show relatively lower ferritin level than that of other countries, although their TSATs (transferrin saturation) are more than 20%. I have measured iron loss by iron contents of residual blood in the blood tubing set and dialyzer, and estimated that 500mg of iron would be lost by routine hemodialysis procedure in Japan (Am J Nephrol 2016,43,32-38). In this study, I show here the stable iron status as well as hemoglobin (Hb) level by regular administration of 40mg iron a month. Moreover, I demonstrate the reduction of Hb variability by the supplementary protocol.

Methods: 157 patients of Otowa Memorial Hospital were enrolled after informed consent. Men were consisted in 64.7%, and the mean age was 69.2±13.5 (m±SD). 40.4% was diabetic. 40mg of iron (saccharated ferric oxide) was intravenously administered once a month after hemodialysis session. Hb, TSAT, and ferritin were monitored every month before and after the regular iron supplementation. Hb variability was counted in each patient by the Fishbane's method described in the previous paper (Kidney International 2005,68, 1337-1343). ERI (erythropoiesis resistance index) was also calculated with human recombinant erythropoietin (rHuEPO) dose in a month divided by Hb and body weight (dry weight). Erythropoiesis-stimulating agents (ESAs) used in this study were rHuEPO, darbepoetin-a (DA), and continuous erythropoietin receptor activator (CERA). DA was converted to 200U, and CERA was 240U of rHuEPO, respectively. The dose of ESA was determined by an attending physician along the Japanese guideline for renal anemia in chronic kidney disease 2008.

Results: Hb levels kept from 11.2±1.0g/dL at the beginning to 10.9±1.0g/dL after 12 months. TSAT and ferritin did not change from 26.3±12.2% and 88.9±86ng/mL to 25.7±9.9% and 77.6±94.6ng/mL, respectively. ERI changed from 40.5±36.1 to 39.6±32.6. Although iron status and ERI did not changed significantly, Hb variability reduced from 120 times per 6 months before the regular iron administration to 98 times after 6 months and 81 times after 1 year.

Conclusions: Intravenous regular administration of 40mg iron a month might reduce hemoglobin variability of hemodialysis patients without significant change of iron status In Japan.

Pharmacokinetics of Ferric Pyrophosphate Citrate (Triferic®) in Pediatric CKD-5HD Patients Raymond D. Pratt, Ajay Gupta. *Rockwell Medical Inc, Wixom, MI. Group/Team: RMFPC-11 Study Group.*

Background: Triferic (FPC) is a carbohydrate-free complex iron salt with a MW ~1300 Daltons. FPC is approved as an iron replacement product to maintain hemoglobin in adult patients receiving chronic hemodialysis. Triferic rapidly transfers across the dialyzer membrane, donates iron directly to transferrin, and is cleared from the circulation with a half-life of 2 to 4 hr. The current study examined the pharmacokinetics (PK) of Triferic administered via dialysate and intravenously (IV) to pediatric hemodialysis patients.

Methods: This was an open-label, two period single dose study conducted in 22 CKD-5HD patients between ages 1 and 17 years. Each patient received 2 treatments in sequential order. Blood was drawn for serum iron profile at defined times for PK analysis. The treatments were Triferic 0.07 mg Fe/kg IV into the post-dialyzer blood line (FPC-IV) and Triferic 2 mM (110 mg Fe/L) via HD (FPC-HD). HD was conducted for 3-4 hours and IV infusions were administered during HD. An estimate of iron delivered at the dialysis session was calculated by using partial AUC based on the IV dose.

Results: A total of 22 subjects, age range 1-17 years were enrolled. PK data are available on 21 subjects. There was greater inter-individual variability and lower peak iron levels in the younger age group patients. FPC-HD showed a similar intradialytic and post-dialysis iron profile as FPC-IV in all age groups. The results of mean intradialytic change in serum Fe with HD and IV, and average dose administered via HD (Fe HD) are presented below: Non-compartmental analysis showed that FPC was rapidly cleared with a t½ of approximately 2 hr. FPC was well tolerated with no drug related adverse effects noted.

Conclusions: This study shows that FPC iron can be delivered to pediatric CKD5HD patients either intravenously when using solid bicarbonate cartridge or bag system, or via the dialysate. FPC was well tolerated. The results suggest that IV administration in patients below age 12 be started at 0.1 mg Fe/kg and increased as needed to achieve a post HD target TSAT of around 75%.

Funding: Commercial Support - Rockwell Medical Inc.

Iron Parameters after FPC via Dialysate or IV

Age yr.	N	ΔsFe HD µg/dL (SD)	ΔTSAT %	$TSAT_{Max}$ %	Fe HD Dose mg	Fe HD Dose mg/kg	$TSAT_{max}$ IV
1-5	3	55.5 (26.2)	17.3	34.3	1.47	0.08	34.7
6-11	2	73.5 (9.2)	25.3	52.5	1.67	0.06	43.8
12-17	16	189.9 (58.5)	59.1	87.3	4.97	0.09	61.6

Labile Plasma Iron for the Early Detection of Iron Overload in ESRD Alon Benaya,[4] Itzchak N. Slotki,[3] Linda Shavit,[2] Jolanta Malyszko.[1] *[1]Medical University, Bialystok, Poland; [2]Shaare Zedek Medical Center, Jerusalem, Israel; [3]Share Zedek Medical Center, Jerusalem, Israel; [4]shaare zedek, Jerusalem, Israel.*

Background: The increased usage of intravenous iron (IVI) in hemodialysis patients during recent years has led to increasing concern over the potential development of iron overload (IO). Current methods for detecting iron overload, transferrin saturation (TSAT) and serum ferritin are neither sensitive nor specific. Labile plasma iron (LPI) represents a component of non-transferrin bound iron that is both redox active and chelatable and may be a more accurate indicator of impending iron overload. We studied whether LPI measured using the FeROS LPI detecting system (Aferrix) can serve as an early indicator of impending IO in hemodialysis patients.

Methods: Chronic hemodialysis patients from two medical centers in Israel and Poland who received IVI were included. Demographic data, cause of ESRD, comorbidities, medications and the following laboratory parameters were recorded: Hb, serum iron, transferrin, TSAT, ferritin. LPI was measured before and 48 hours after a single IV administration of either iron sucrose 100 mg, iron gluconate 62.5 mg, iron (III)-hydroxide dextran complex 100 mg. A test result of 0.6 units of LPI or more indicated a potential for iron-mediated production of reactive oxygen species in the sample.

Results: 111 hemodialysis patients, aged 64 ± 15, were included in the study. 90 patients received iron sucrose, 14 iron gluconate and 7 iron dextran at mean monthly doses of 233 ± 133 mg; LPI was negative in all patients prior to IVI, but became positive post administration in 4 patients, all of whom received iron sucrose. Three of these were diabetic, had TSAT <30% and ferritin <360 ng/ml and received monthly iron doses of 400-500 mg.

Conclusions: Doses of IVI routinely used in chronic hemodialysis patients appear to be safe. However, higher monthly doses may be associated with detectable LPI post administration, even in the absence of currently used laboratory parameters of IO.

SA-PO815

Low-Dose Iron Treatment and Erythropoiesis Efficiency in Hemodialysis Patients with Anemia Treated by Erythropoiesis-Stimulating Agents Tadashi Kuji,[1] Shota Suzuki,[2] Tetsuya Fujikawa.[3] *[1]Yokodai Central Clinic, Yokohama, Kanagawa, Japan; [2]Yokohama City University, Yokohama, Kanagawa, Japan; [3]Yokohama National University, Yokohama, Kanagawa, Japan.*

Background: Anemia is a common comorbidity and is a major cause of morbidity and mortality among hemodialysis (HD) patients. Iron deficiency is a major cause of resistance to erythropoiesis-stimulating agents (ESA) therapy; however, excessive iron has toxic effects including oxidative stress. Even standard-dose parental iron supplementation causes oxidative stress due to free iron in the blood, therefore low-dose iron is desirable to reduce the free iron release for optimal prognosis. We aimed to investigate whether low-dose iron supplementation is as effective for erythropoiesis as standard-dose iron supplementation.

Methods: A randomized, controlled, parallel-group study was performed for six months. One hundred and two patients were randomized to receive 20mg intravenous elemental iron per week (Low-dose iron group: n = 53) or 40 mg intravenous elemental iron doses per week (Standard-dose iron group: n = 49). Ferritin and transferrin saturation were measured at two-month intervals. Iron was administered for two months when HD patients showed iron deficiency (transferrin saturation < 20% and ferritin < 100ng/ml). ESA resistance index was defined as the weekly weight-adjusted dose of ESA divided by hemoglobin concentration.

Results: No significant differences in baseline characteristics except systolic blood pressure were evident between the two groups. The mean numbers of two-month long iron supplementation were 0.74 ± 0.83 in low-dose iron group and 0.49 ± 0.56 in standard-dose iron group. Mean Hb levels during the evaluation period of 6 months were 10.5 ± 0.4 g/dL in the low-dose iron group and 10.4 ± 0.4 g/dL in the standard-dose iron group (p = 0.315). There was a tendency toward low ESA dose in the low-dose iron group compared to the standard-dose iron group (4116.1 ± 2170.4 IU/week vs. 4935.1 ± 1792.8 IU/week, p = 0.079). There was a trend towards decrease in ferritin levels in low-dose iron group compared with the standard-dose iron group (-36.4±50.5 ng/mL vs. -11.8 ± 65.2 ng/mL, p = 0.073). Reticulocyte hemoglobin levels (newly synthesized hemoglobin) and ESA resistance index were not significantly different between the two groups.

Conclusions: Low-dose iron treatment suppresses ferritin levels, but does not decrease hemoglobin levels and reticulocyte hemoglobin levels or does not increase required ESA dose.

SA-PO816

Link between Iron Deficiency and Thrombocytosis in Dialysis Patients – Are ADPKD Patients Different? Felix Nadrowitz,[1] Klaus Stahl,[2] Bernhard M. Schmidt,[1] Gero D. von Gersdorff,[4] Katherine Rascher,[4] Hermann G. Haller,[1] Roland Schmitt.[3] *[1]Hannover Medical School, Hannover, Germany; [2]MHH, Hannover, Germany; [3]Medizinische Hochschule Hannover, Hannover, Germany; [4]University Hospital Cologne, Cologne, Germany.*

Background: Secondary thrombocytosis has been reported in iron deficiency (ID) anemia. Maintenance hemodialysis (MHD) patients with adult polycystic kidney disease (ADPKD) often receive low iron supplementation due to their spontaneously high hemoglobin levels. We analyzed a possible correlation between ID and platelet count in MHD ADPKD and non-ADPKD patients.

Methods: We conducted a multi-center cohort study with 2387 ADPKD and 30923 non-ADPKD patients. Data between 2008 and 2015 were extracted from over 190 outpatient hemodialysis centers from the institutional KfH quality registry. Multivariable correlation as well as multivariable linear regression analysis with thrombocyte count and parameters of iron status were performed. To correct for inflammation dependent changes laboratory measurements were only included when CRP was in the normal range.

Results: While mean transferrin saturation (TSAT) in ADPKD patients indicated ID (16.6 ± 7.4 %), mean ferritin was not in the ID range (544.8 ± 416.9 ng/ml). Mean absolute thrombocyte count in the ADPKD cohort was 202.2 ± 65.0 $x10^3/\mu l$. A correlation coefficient of -0.12859 implicated a statistically significant, but minor negative correlation of thrombocytes with TSAT. In non-ADPKD MHD patients mean TSAT was 17.9 ± 9.6 % and mean ferritin was 631.6 ± 446.2 ng/ml. Mean platelet count was 216.5 ± 73.7 $x10^3/\mu l$ with a likewise significant, but small negative correlation coefficient to TSAT (-0.11974). Only an extremely low TSAT (< 2%) was associated with platelet counts above the upper limit of normal.

Conclusions: In MHD patients with ADPKD we could not find a relevant correlation of TSAT and platelet count. This was not different from non-ADPKD patients. Our study demonstrates that common degrees of ID in ADPKD and non-ADPKD patients on MHD do not result in thrombocytosis.

SA-PO817

Efficient Hemoglobin Maintenance Levels Are Achieved by Relatively Lower Levels of Serum Ferritin and Moderate Transferrin Saturation in Hemodialysis Patients Chie Ogawa,[2] Ken Tsuchiya,[1] Fumiyoshi Kanda,[2] Kunimi Maeda.[2] *[1]Department of Blood Purification, Tokyo Women's Medical University, Shinjuku-ku, Japan; [2]Maeda Institute of Renal Research, Kawasaki, Japan.*

Background: The optimal iron levels for patients on hemodialysis (HD) are currently unknown. However, excessive iron intake can lead to oxidative stress or impair the efficiency of its use. To identify the optimal iron content for patients on HD, we investigated the relationship between hemoglobin (Hb) level and iron status in patients on HD.

Methods: 208 HD-outpatients treated with recombinant human erythropoietin (rHuEPO) were followed up from July 2006 to June 2007. The doses of rHuEPO and low-dose iron supplement were adjusted to maintain a Hb level of 10–11 g/dL, according to the Japanese guidelines. Hepcidin 25 (Hep 25) was measured at baseline measured using LC-MS/MS assay. Using the mean values for a 1-year period, the relationships among Hb, s-ft levels, and TSAT levels were investigated based on a receiver operating characteristic curve (ROC) and a logistic regression model. In addition, the correlations among s-ft, TSAT, and Hep25 levels were analyzed by Pearson product–moment correlation coefficient.

Results: By ROC, the cutoff point of s-ft and TSAT levels with a Hb ≥10 g/dL showed <90 ng/mL and ≥20%. Upon logistic regression model analysis with a Hb ≥ 10 g/dL set as the endpoint, the odds ratios relative to a group with s-ft ≥ 90 ng/mL and TSAT < 20% revealed that the group with s-ft < 90 ng/mL and TSAT ≥ 20% had the highest ratio: 46.75 (95% CI: 10.89–200.70, p < 0.001). Hep 25 exhibited a strong positive correlation with s-ft [r = 0.78 (95% CI: 0.72–0.83, p < 0.001)] and a weak positive correlation with TSAT [r = 0.18 (95% CI: 0.04–0.31, p = 0.010)].

Conclusions: In this study, the iron status showing s-ft < 90 ng/mL and TSAT ≥ 20% was optimal in HD patients receiving rHuEPO for anemia therapy. This result indicates that the threshold values for the optimal iron status may be lower than those currently recommended in the guidelines for iron level management.

SA-PO818

A Prospective Study Examining the Contribution to Renal Anemia Treatment of Ferric Citrate Hydrate, an Iron-Based Oral Phosphate Binder, in Hemodialysis Patients with Hyperphosphatemia: ASTRIO Study Keitaro Yokoyama,[1] Masafumi Fukagawa,[6] Takashi Akiba,[4] Masaaki Nakayama,[5] Koji Hanaki,[3] Ito Kyoko,[7] Hideki N. Hirakata.[2] *[1]Division of Nephrology and Hypertension, Department of Internal Medicine, The Jikei University School of Medicine, Tokyo, Japan; [2]Fukuoka Renal Clinic, Fukuoka City, Japan; [3]JAPAN TOBACCO INC., Tokyo, Japan; [4]Sekikawa Hospital, Tokyo, Japan; [5]Tohoku University, Tohoku University Hospital, Sendai City, Japan; [6]Tokai University School of Medicine, Isehara, Japan; [7]Torii Pharmaceutical Co., Ltd, Tokyo, Japan.*

Background: We conducted a prospective study examining the contribution to renal anemia treatment of Ferric citrate hydrate (FC) compared with non-iron-based oral phosphate binders (Control), in HD patients with hyperphosphatemia undergoing ESA therapy.

Methods: The study was designed as a multicenter, open-label, active-controlled, randomized, parallel-arm comparison study. HD patients who had been used non-iron-based oral phosphate binders were randomized to FC group (n=45) or Control group (n=48). In FC group, previous treatment was discontinued at registration and switched to FC, and continued for 24 weeks. In Control group, previous treatment was continued. Serum P and Hb were controlled in the target ranges of 3.5 to 6.0 mg/dL and 10.0 to 12.0 g/dL, respectively. We have evaluated the doses of ESA and IV iron.

Results: Mean changes in ESA dose (IU/week) from baseline to end of treatment (EOT) were –1211.8±3609.5 in FC group and 1195.5±6662.8 in Control group. It was significantly lower in FC group than Control group (p=0.0386). Cumulative dose of IV iron from baseline to Week 24 was also significantly lower in FC group than Control group (p=0.0065). Other parameters are shown in the table.

Conclusions: We confirmed that FC decreased doses of ESA and IV iron. We also confirmed the differences of ERI, MCV, RDW and FGF23 between FC group and Control group. It was considered iron supplementation by FC was done in functional manner. FC is expected to contribute to renal anemia treatment and hematopoietic.

Parameter	FC group (N=40) Change (from baseline to EOT)	Control group (N=42) Change (from baseline to EOT)	Adjusted Mean Difference (FC minus Control)	p-value
Serum P (mg/dL)	0.24	-0.17	0.55	0.0643
Hb (g/dL)	0.45	0.34	0.17	0.5065
TSAT (%)	8.6	0.5	9.0	0.0005
Serum ferritin (ng/mL)	79.0	2.9	79.5	<0.0001

Predictive Hierarchical Modeling of Determinants of Outcomes of Anemia Management with Binocrit®, a Biosimilar Epoetin Alfa, in the Hemodialysis Setting (MONITOR-CKD5 Study) Frank Dellanna,[1] David Goldsmith,[2] Johannes F. Mann,[3] Philippe Zaoui,[4] Christian Combe,[5] Andriy Krendyukov,[6] Ivo Abraham,[7] Karen Macdonald.[8] *[1]MVZ DaVita Rhein-Ruhr GmbH, Duesseldorf, Germany; [2]Guy's & St. Thomas' NHS Foundation Trust, Great Maze Pond, United Kingdom; [3]KfH Nierenzentrum, München, Germany; [4]Clinic of Nephrology Chu Grenoble, Grenoble, France; [5]CHU de Bordeaux, Bordeaux, France; [6]Sandoz Biopharmaceuticals, Holzkirchen, Germany; [7]University of Arizona, Tucson, AZ; [8]Matrix 45, Tucson, AZ.*

Background: The European observational MONITOR-CKD5 study demonstrated the real-world effectiveness of Binocrit® in renal anaemia. Patients treated for up to 24 months showed stable dosing patterns and stable hemoglobin (Hb) outcomes. Predictive hierarchical modeling was applied to identify determinants of outcomes of interest.

Methods: A subset of 484 patients with complete 24-month data was used to investigate pre-specified potential determinants of the following outcomes: (1) mean Hb of last 4 visits, estimated using Wald test (hierarchical linear regression); risk for (2) chronic hyporesponsiveness, (3) overnight hospitalization, (4) thromboembolic events (TEE), (5) mortality. Risks were estimated using adjusted odds ratios (OR; hierarchical logistic regression). The intraclass correlation coefficient (ICC) quantified the proportion of variance in outcome attributable to a center class effect.

Results: The following determinants were retained for each outcome of interest at p<0.05. For mean Hb of last 4 visits (ICC=0.0477): age (+0.0067g/dL per 1 year over mean); chronic infection or inflammatory disease at baseline (-0.3395g/dL if present); Kt/V≥1.2 at baseline (+0.3181g/dL if present). For risk of chronic hyporesponsiveness (ICC=0.1599): chronic infection or inflammatory disease at baseline (OR=3.055). For risk of hospitalization (ICC=0.2349): no determinants retained despite ICC. For TEE risk (ICC=0.0550): serum albumin ≥3g/dL (OR=0.396); Kt/V≥1.2 at baseline (OR=0.455); age (per 1 year of age over mean, OR=1.021). For overall mortality (ICC=0.1156): deficient iron status (OR=2.354); Kt/V≥1.2 at baseline (OR=0.316); age (per 1 year over mean, OR=1.064).

Conclusions: In hemodialysis patients receiving Binocrit® for 2 years, determinants of positive Hb outcome included Kt/V≥1.2 and serum albumin ≥3g/dL. The presence of chronic infection or inflammatory disease and deficient iron status were predictive of poorer Hb outcomes. Age was associated positively with Hb levels, but negatively with TEE and mortality risk. Consistent with findings from the DOPPS and ESAM observational studies, all determinants except for age are clinically modifiable or manageable.

Development and Validation of a Transfusion Risk Score David T. Gilbertson,[3] Heng Yan,[3] Hairong Xu,[2] Marvin V. Sinsakul,[1] Yi Peng,[3] James B. Wetmore,[5] Jiannong Liu,[4] Suying Li.[3] *[1]AstraZeneca, Bethesda, MD; [2]Astrazeneca, Westlake Village, CA; [3]Chronic Disease Research Group, Minneapolis, MN; [4]Minneapolis Medical Research Foundation, Minneapolis, MN; [5]Hennepin County Medical Center, Minneapolis, MN.*

Background: Following changes to CMS payment for dialysis services in Jan 2011 and the ESA label revision 6 months later, a decline in hemoglobin (Hb) levels and an increase in transfusions were observed in dialysis patients. Transfusions have decreased from their 2012 peak, and transfusion avoidance is the preferable option in dialysis patients. We sought to develop a predictive model for transfusions using comorbidity, markers of inflammation, previous transfusion, vitamin D use, IV iron use, ESA dose, Hb, ferritin and TSAT.

Methods: USRDS/Crownweb data from 2012-13 were used for model development. Point prevalent hemodialysis (HD) patients on 11/1/12 with ≥ 6 months Medicare A/B coverage and mean Hb < 10 g/dL were included. Aug-Oct were used to assess anemia-related variables (Hb, ESA, TSAT, ferritin, IV iron use, vitamin D, and transfusion), and May-Oct were used to assess comorbidity from claims. Logistic regression with Lasso for variable selection was used to predict transfusion during the next 3 months. For model validation, similar cohort construction was used, with point prevalent HD patients on 8/1/13.

Results: Variables retained in the final model included Hb, ESA dose, ferritin, TSAT, IV iron, vitamin D, prior transfusion, and interactions of these variables. In the validation dataset, a calibration plot showed good agreement between observed/predicted transfusions (Figure): *c*-statistic = 0.74.

Conclusions: The addition of ferritin and TSAT, along with inflammatory comorbidities, aided in prediction of transfusions in patients with Hb levels < 10 g/dL. Optimal anemia management strategies involve balancing CV risk on the high end of Hb and ESA exposure with transfusion risk on the low end. The ability to identify patients at risk for transfusion may lead to improved anemia management and outcomes.

SA-PO821

Association of Hepcidin with Anemia Parameters in Incident Dialysis Patients: Difference between Dialysis Modalities Jeong hoon Lim,[1] Jong-Hak Lee,[2] Man-hoon Han,[1] Kyu Yeun Kim,[1] Hee-Yeon Jung,[1] Ji-Young Choi,[1] Jang-Hee Cho,[1] Chan-Duck Kim,[1] Sun-Hee Park,[1] Yong-Lim Kim.[1] *[1]Kyungpook National University Hospital, Daegu, Republic of Korea; [2]Daegu Fatima Hospital, Daegu, Republic of Korea.*

Background: Hepcidin has been considered to be a key regulator of iron homeostasis in recent years. However, its relationships to other variables are not well understood. This study aimed to evaluate association of serum hepcidin level with iron parameters and other clinical parameters, especially according to dialysis modality, in end-stage renal disease (ESRD) patients.

Methods: A total of 110 incident dialysis patients, 68 on peritoneal dialysis (PD) and 42 on hemodialysis (HD), were prospectively followed up for 6 months. Serum hepcidin level was measured by a commercial ELISA kit (DRG Instruments, Marburg, Germany) at baseline and 6 months after initiation of dialysis. The relationship of hepcidin to clinical parameters was investigated using linear regression models.

Results: Serum hepcidin levels significantly increased in initial 6 month after start of dialysis. PD group showed higher hemoglobin after 6 months dialysis than HD group, in spite of less use of erythropoiesis-stimulating agents during study period. In multivariate regression model, independent predictors of serum hepcidin were aspartate transaminase (ß=21.359, *p*=0.003), ferritin (ß=0.056, *p*=0.008), transferrin saturation (ß=0.644, *p*=0.009), and phosphate (ß=6.946, *p*=0.001) in incident ESRD patients. At 6 month after initiating dialysis, serum hepcidin was independently predicted by urine volume (ß=–0.008, *p*=0.043), alanine transaminase (ß=12.091, *p*=0.008), ferritin (ß=0.051, *p*<0.001), and total iron binding capacity (TIBC) (ß=–0.191, *p*=0.002) in all patients, whereas by ferritin (ß=0.056, *p*<0.001) and TIBC (ß=–0.184, *p*=0.023) in PD patients, and urine volume (ß=–0.021, *p*=0.004), ferritin (ß=0.048, *p*=0.095), and TIBC (ß=–0.225, *p*=0.015) in HD patients.

Conclusions: Serum hepcidin was differentially associated with anemia parameter between PD and HD patients. Urine volume was an independent predictor of hepcidin in incident HD patients. It suggests preservation of urine volume may be important to reduce hepcidin concentration in incident HD patients.

SA-PO822

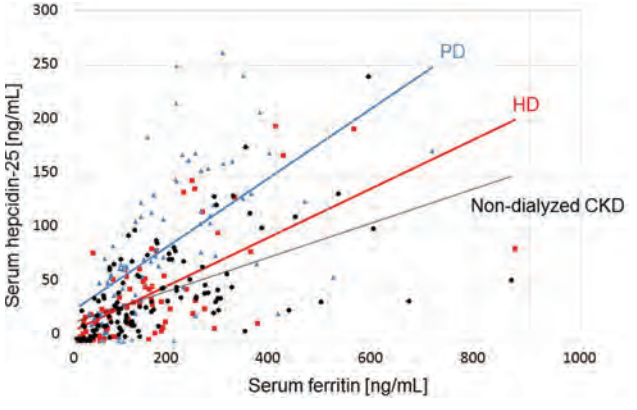
Difference in the Hepcidin/Ferritin Ratio among Non-Dialyzed CKD Patients, and Patients on Hemodialysis and Peritoneal Dialysis Takahito Niikura,[1] Yukio Maruyama,[1] Satomi Nakashima,[1] Nanae Matsuo,[1] Yudo Tanno,[1] Ichiro Ohkido,[1] Keitaro Yokoyama,[1] Hiroyasu Yamamoto,[1,2] Takashi Yokoo.[1] *[1]Division of Nephrology and Hypertension, Department of Internal Medicine, The Jikei University School of Medicine, Tokyo, Japan; [2]Department of Internal Medicine, Atsugi City Hospital, Atsugi, Japan.*

Background: The level of hepcidin, a key mediator of iron homeostasis, generally increases in patients with chronic kidney disease (CKD), attributable to inflammation or a decline in the glomerular filtration rate (GFR). Although the hepcidin/ferritin ratio is used in hepatic disorders (e.g., viral and autoimmune hepatitis) and hematological disease (e.g., hereditary hemochromatosis and thalassemia), its role in renal patients have never been investigated. We evaluated the hepcidin/ferritin ratio in non-dialyzed CKD patients, and in those undergoing hemodialysis (HD) or peritoneal dialysis (PD); we also used this ratio to explore iron homeostasis in CKD patients.

Methods: We recruited 285 CKD patients (117 non-dialyzed CKD patients, 80 HD patients, and 88 PD patients) and measured the levels of serum hepcidin-25, ferritin and markers of kidney disease. Serum hepcidin-25 levels were assessed via liquid chromatography/tandem mass spectrometry.

Results: The serum hepcidin-25 level was elevated in all CKD patients, and was significantly higher in PD than non-dialyzed CKD and HD patients (68.6 [0.4–262] vs. 32.8 [0.7–240] vs. 25.9 [0.4–196] ng/mL, p < 0.01). The serum hepcidin-25 level correlated positively with that of serum ferritin in all CKD patients, whereas the hepcidin/ferritin ratio was higher in PD patients than in other CKD patients.

Conclusions: PD patients exhibited a higher serum hepcidin-25 level and the hepcidin/ferritin ratio than did non-dialyzed CKD and HD patients. Several factors unique to PD patients, such as continuous peritoneal stimulus by the dialysate, and subclinical inflammation and infection, may explain the high hepcidin/ferritin ratio in such patients.



SA-PO823

Determinants of Hepcidin/Ferritin Ratio in Patients Undergoing Maintenance Hemodialysis Takahiro Kuragano, Takeshi Nakanishi. *Hyogo College of Mediicne, Nishinomiya, Japan.*

Background: Hepcidin is the key regulator of iron absorption. Although low serum levels of hepcidin allow iron uptake in patients with iron deficiency, an imbalance of hepcidin and iron storage might be associated with iron overload. As iron containing phosphate binder has expanded the clinical use in chronic kidney disease patients, intestinal iron absorption should be properly evaluated.

Methods: Study design: Cross sectional study. Subjects: 317 patients undergoing maintenance hemodialysis (MHD). We measured the blood levels of Hb, ferritin, transferrin saturation (TSAT), body mass index (BMI), total protein, albumin, high-sensitivity (h) CRP, int-PTH, creatinine (Cr), urea nitrogen (UN), β 2-microglobulin (β2MG), and hepcidin-25. The Mann-Whitney U test and least absolute shrinkage and selection operator (LASSO) analysis were applied to evaluate the association between the hepcidin/ferritin ratio and the clinical parameters.

Results: According to the Mann-Whitney U test, the hepcidin-25/ferritin ratio in patients with diabetes (0.34± 0.33) was significantly (P<0.05) higher than in patients without diabetes (0.27± 0.3). In LASSO analysis, higher albumin (0.06), higher int-PTH (0.03), higher Cr (0.03), higher dose of intravenous iron administration (0.01) and diabetes (0.09) were identified as significant determinants of a higher hepcidin-25/ferritin ratio. In the patients with higher CRP levels (≥0.3 mg/dL), higher ferritin (19.64), higher int-PTH (1.76), and male (0.36) were selected as the significant predictors of higher serum levels of hepcidin-25, male sex (0.11), diabetes (0.13), lower TSAT (-0.01), and lower BMI (-0.03) were selected as significant predictors of a higher hepcidin-25/ferritin ratio.

Conclusions: In this study, we found that in MHD patients, the hepcidin/ferritin ratio is significantly associated with patient characteristics such as nutritional condition, diabetes, sex, and hyperparathyroidism. Furthermore, in MHD patients with inflammation, iron dysutilization (low TSAT), malnutrition (low BMI), and diabetes are significantly associated with the higher hepcidin-25/ferritin ratio. The imbalance of hepcidin and ferritin might cause increased iron absorption and iron overload, and thus iron supplementation for these patients should be performed carefully.

SA-PO824

Randomised Controlled Trial of Intravenous Iron versus Increased Erythropoietin in Haemodialysis Anaemia Sarah Hildebrand, Neill D. Duncan, Frederick W. Tam, Damien Ashby. *Imperial College Renal and Transplant Centre, London, United Kingdom.*

Background: Anaemia in haemodialysis patients is treated with both erythropoietin and intravenous iron, but response rates are suboptimal, and treatment thresholds remain controversial. Despite poor reliability, traditional iron indices such as ferritin are usually used to guide treatment choices, whilst the relative effectiveness of the two available treatments has never been compared in a randomised trial.

Methods: Stable haemodialysis patients who became moderately anaemic (Hb 90-104g/l) on routine testing with non-extreme ferritin (100-800ng/l) were randomly allocated to treatment with either intravenous iron (1g divided over 5 consecutive sessions, IVFE group) or increased erythropoietin (starting 3000unit/week or median increase 50%, EPO group). No further treatment was given for 2 months.

Results: In 194 patients followed for up to 18 months (2438 patient-months observed), there were 160 anaemia episodes with completed randomisation and follow-up (mean age 63, 71% male). Intravenous iron and increased erythropoietin were equally effective: a positive haemoglobin response (increase by at least 5g/l by 2 months) was observed in 54/76 IVFE patients, and 62/84 EPO patients (71.1 vs 73.8%, p=0.7). Factors predictive of treatment response were assessed in both groups. In the IVFE group, compared to non-responders, those achieving Hb response had lower hepcidin (101 vs 143ng/ml, p=0.031), lower mean cell volume (90.6 vs 94.5, p=0.034) and lower reticulocyte Hb (33.8 vs 35.5, p=0.047). In the EPO group only low CRP was predictive of a positive response (13.5 vs 28.6, p=0.038). Ferritin was not predictive of response in either group (p=0.9 and 0.2 respectively). Weaker associations with response were found for gender, B12 levels, previous erythropoietin dose and warfarin use.

Conclusions: Intravenous iron and erythropoietin are equally effective in the majority of haemodialysis patients who become anaemic. Ferritin does not predict treatment response, but hepcidin and several established biomarkers do: in combination they could be used in an evidence-based protocol with improved response rates.

The Effect of Ferric Citrate on IV Iron, ESA Utilization, and Laboratory Parameters in Real-World Dialysis Practice Csaba P. Kovesdy,[3] Christopher G. Rowan,[1] Bryce Foote,[2] Luke S. Acree,[2] Leslie A. Meltzer,[2] Robin Lewinter.[2] *[1]COHRDATA, Santa Monica, CA; [2]Keryx Biopharmaceuticals, Boston, MA; [3]University of Tennessee Health Science Center, Memphis, TN.*

Background: Ferric Citrate (FC) is an iron-based phosphate (P) binder approved for control of serum P in patients (pts) with CKD on dialysis. We retrospectively evaluated changes in healthcare resource utilization (HRU) and laboratory parameters before and after FC initiation in typical dialysis practice.

Methods: FC users were identified between 1/2015-7/2016 from a large U.S. dialysis provider. HRU and lab data were ascertained for continuous FC users in 4 sequential periods (1 pre and 3 post-FC initiation; 3 months each). We determined mean change and mean % change for each post-FC period vs. pre-FC (baseline). Mean change was analyzed using Students t-test for paired data.

Results: 2,395 FC initiators were included (mean age 54 years, 50% female, 43% black race). Median dialysis vintage was 3.5 years (mean 4.6 years) and 9% were phosphate binder naive. Mean follow-up for continuous FC users was 104 days. At baseline, P management in these patients was suboptimal as only 25% of pts had P <5.5 mg/dL. P significantly decreased within 1 month (mean change -0.26 mg/dL, *P*<0.001), and 40% had P <5.5 mg/dL by 6 months. At 3, 6 and 9 months post-FC (compared to pre-FC),

we observed small but statistically significant mean increases in hemoglobin, transferrin saturation (TSAT) and ferritin despite decreases in cumulative IV iron and ESA dose (all $P<0.05$). At 3-6 months post-FC (vs. pre-FC), the mean reduction in cumulative IV iron and ESA administration was -130 mg ($P<0.001$) and -17,127 IU ($P<0.001$), respectively. The Figure depicts mean % change for each HRU and lab parameter.

Conclusions: Despite significant reductions in IV iron and ESA utilization, hemoglobin and iron parameters improved within 3 months of FC initiation in pts on dialysis. Additionally, serum P control improved significantly in this patient population.

SA-PO826

Patterns of Anemia Management and Response in the Predialysis Period James B. Wetmore,[4] Heng Yan,[3] David T. Gilbertson,[3] Hairong Xu,[2] Marvin V. Sinsakul,[1] Yi Peng,[3] Jiannong Liu,[5] Suying Li.[3] *[1]AstraZeneca, Bethesda, MD; [2]Astrazeneca, Westlake Village, CA; [3]Chronic Disease Research Group, Minneapolis, MN; [4]Hennepin County Medical Center, Minneapolis, MN; [5]Minneapolis Medical Research Foundation, Minneapolis, MN.*

Background: The management of anemia in the predialysis period has not been fully described.

Methods: We used USRDS ESRD and pre-ESRD files to study patients initiating hemodialysis (HD) between April 1, 2012 and June 30, 2013. Patients had to have a hemoglobin (Hb) measurement at HD initiation and at least one other measurement in the 3 months after, in the absence of a blood transfusion. Patients were divided into those with predialysis Hb ≥ 9.0 g/dL and those <9.0 g/dL. Percent of patients receiving ESAs and associated Hb levels before and after dialysis initiation were reported.

Results: Of 20,454 patients, 15,599 (76%) had predialysis Hb ≥ 9.0 g/dL. Of those with Hb ≥ 9.0 g/dL, 11,694 (75%) did not require ESAs; mean predialysis Hb was 10.4 ± 1.1 g/dL. The remaining 25% required ESAs, attaining a predialysis Hb level of 10.3 ± 0.9 g/dL. Of 4855 (24% of the total) who had predialysis Hb <9.0 g/dL, only 1293 of these (27%) received ESAs; mean predialysis Hb was 8.2 ± 0.7 g/dL; the remainder (73%) with Hb < 9.0 g/dL did not receive ESAs and had a predialysis Hb level of 8.2 ± 0.8 g/dL. Only 183 (4%) proved poorly responsive to ESAs after initiation, with Hb increasing from 7.9 ± 1.1 g/dL (predialysis) to only 8.5 ± 0.7 g/dL (postinititiation). Of the 4461 (92%) who responded to ESAs after initiation, Hb increased markedly from 8.2 g/dL (predialysis) to 10.9 ± 1.2 g/dL (postinitiation).

Conclusions: One quarter of patients had predialysis Hb < 9.0 g/dL, of whom only one-quarter received ESAs. Since only 1 in 20 patients with Hb < 9.0 g/dL subsequently proved to be poorly responsive to ESAs after initiation, the vast majority of patients with predialysis Hb <9.0 g/dL appear to have been "rescuable" from anemia, suggesting that opportunities to effectively treat predialysis anemia are being missed.

SA-PO827

Roxadustat Treatment of CKD Anemia Is Not Influenced by Inflammation Lynda Szczech,[3] Anatole Besarab,[4] Khalil G. Saikali,[1] Lona Poole,[5] Gopal Saha,[2] Thomas B. Neff.[3] *[1]FibroGen, Inc., San Francisco, CA; [2]FibroGen Inc, San Francisco, CA; [3]FibroGen, Inc., San Francisco, CA; [4]FibroGen, Inc., San Francisco, CA; [5]Fibrogen, Inc, San Francisco, CA.*

Background: The efficacy of ESAs in the treatment of anemia is diminished in inflammation. The hypoxia-inducible factor prolyl hydroxylase inhibitor roxadustat is being developed for treatment of CKD anemia. This analysis of Phase 2 studies was undertaken to explore the efficacy of roxadustat in non-dialysis-dependent (NDD) and dialysis-dependent (DD) CKD patients with and without inflammation.

Methods: Data from five completed Phase 2 studies in NDD- and DD-CKD patients in both anemia correction and conversion of patients already treated for anemia were analyzed in this *post hoc* analysis. Among studies, roxadustat doses, study duration, and comparator (placebo or epoetin alfa) varied. Baseline (BL) hemoglobin (Hb) and change from BL (CFB) were summarized in the efficacy-evaluable populations among patient subgroups with BL CRP ≤ and > ULN (4.9 mg/L).

Results: A total of 234 NDD-CKD and 262 DD-CKD subjects were treated in these studies. Mean CFB in Hb with roxadustat versus comparator was summarized by study and inflammatory state. Roxadustat-driven erythropoiesis, at similar doses, is clinically similar in inflamed versus non-inflamed NDD-CKD and DD-CKD subjects. In all studies, BL CRP correlated with hepcidin and roxadustat significantly reduced hepcidin in a dose-dependent fashion.

Conclusions: Roxadustat corrected and maintained Hb similarly in NDD-CKD and DD-CKD subjects both with and without inflammation, in contrast to ESA comparators, for which inflamed subjects had a less robust response. Phase 3 trials are currently underway to further establish the efficacy and safety of roxadustat.

Funding: Commercial Support - FibroGen

Hemoglobin CFB among subgroups defined by inflammatory status

Study	Treatment (N)	Baseline CRP(mg/L)	Baseline Hb(g/dL)	Change from Baseline in Hb noninflamed subgroup	Change from Baseline in Hb inflamed subgroup

Relationship between History of Coronary Heart Disease at Dialysis Initiation and Onset of Events Associated with Heart Disease: A Propensity-Matched Analysis of a Prospective Cohort Study Daijo Inaguma,[3] Shigehisa Koide,[2] Kazuo Takahashi,[1] Hiroki Hayashi,[1] Midori Hasegawa,[2] Yukio Yuzawa.[2] *[1]Fujita Health University School of Medicine, Toyoake, Japan; [2]Fujita Health University School of Medicine, Aichi, Japan; [3]Nephrology, Fujita Health University School of Medicine, Toyoake, Japan.*

Background: Few studies have reported serial observations during dialysis initiation and maintenance. Therefore, we examined whether the incidence of heart disease events during maintenance dialysis differed between CKD patients with and without a history of coronary heart disease (CHD) at dialysis initiation.

Methods: The subjects were patients in the 17 centers participating in the Aichi Cohort Study of Prognosis in Patients Newly Initiated into Dialysis (AICOPP) from October 2011 to September 2013. We excluded 9 patients whose outcomes were unknown, as determined by a survey conducted at the end of March 2015. Thus, we enrolled 1,515 subjects into the study. We classified patients into 2 groups according to the history of CHD (i.e., a CHD group and a non-CHD group). Propensity scores (PS) represented the probability of being assigned to a group with or without a history of CHD. Onset of heart disease events and associated mortality and all-cause mortality were compared in PS-matched patients by using the log-rank test for Kaplan-Meier curves. Factors contributing to heart disease events were examined using stepwise multivariate Cox proportional hazards analysis.

Results: There were 254 patients in each group after PS-matching. During observation, heart disease events occurred in 85 patients (33.5%) in the CHD group and 48 (18.9%) patients in the non-CHD group. The incidence was significantly higher in the CHD group ($p < 0.001$). Heart disease-related death occurred in 27 patients (18.9%) in the CHD group and 12 (10.6%) in the non-CHD group ($p = 0.014$). All-cause death occurred in 70 patients (27.6%) in the CHD group and 47 (18.5%) in the non-CHD group ($p = 0.026$). The CHD group was associated with higher incidence of heart disease events (vs. the non-CHD group, HR = 1.75, 95% CI = 1.16-2.64). In addition, comorbidities such as diabetes mellitus (HR = 1.77), low body mass index (HR = 0.92), and low serum high-density lipoprotein cholesterol (/ 10mg/dL, HR = 0.86), were associated with higher incidence of events.

Conclusions: History of CHD at dialysis initiation was associated with a higher incidence of heart disease events and mortality and all-cause mortality.

SA-PO829

Trends and Outcomes of Surgical versus Transcatheter Aortic Valve Replacement in Patients on Maintenance Dialysis Priti Poojary,[1] Aparna Saha,[1] Shanti N. Patel,[2] Neha Debnath,[1] Kinsuk Chauhan,[1] Steven G. Coca,[1] Girish N. Nadkarni,[1] Lili Chan.[1] *[1]Icahn School of Medicine at Mount Sinai, New York, NY; [2]Maimonides Medical Center, New York, NY.*

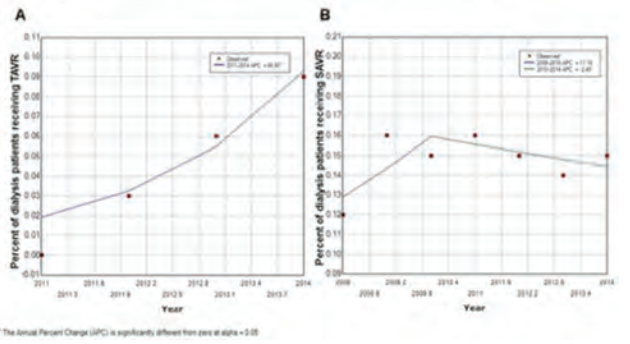
Background: The prevalence of aortic stenosis in maintenance dialysis patients is high (28-55%). Dialysis patients generally have high operative risk for surgical aortic valve replacement (SAVR). While transcatheter aortic valve replacement (TAVR) in high-risk patients is associated with better survival in clinical trials, dialysis patients are generally excluded from these studies. We sought to assess outcomes and trends of SAVR vs. TAVR in dialysis patients from a nationally representative database

Methods: Utilizing the National Inpatient Sample from 2008 – 2014, hospitalizations in dialysis patients for SAVR and TAVR were identified utilizing ICD-9-CM codes. TAVR patients were propensity matched with SAVR patients on demographics, hospital type, primary payer type, income, and Charlson comorbidity index

Results: The proportion of dialysis patients receiving SAVR procedures increased from 2008–2010 (annual percentage change(APC) of 11), then declined from 2010-2014(APC of -2). The proportion of dialysis patients receiving TAVR has significantly increased over time (APC of 69) (Figure 1). Prior to propensity matching, patients in the TAVR group were older(75 vs. 63 years, P<0.001), more likely to be white(67% vs 40%, P<0.001), and more likely to be female(40% vs. 31%, P<0.001). After matching, SAVR was associated with a longer length of stay (18 vs. 10 days, P<.001) and higher cost (76,450 vs. 67,510, P=0.05). TAVR was associated with lower odds for in-hospital mortality [OR 0.46 (95% CI 0.24-0.91)]

Conclusions: TAVR in dialysis patients is increasing and is associated with lower in-hospital mortality. The decreasing trend in SAVR suggests that these patients are now getting TAVRs instead. Patients who are getting TAVRs have different demographics from those getting SAVR. Further investigation is needed to identify reasons for gender and racial differences and evaluation of long-term outcomes between SAVR and TAVR

Figure 1: Trends in proportion of dialysis patients receiving (A) TAVR and (B) SAVR



SA-PO830

Effect of Sodium Thiosulfate on Arterial Stiffness in ESRD Patients Undergoing Chronic Hemodialysis: A Randomized Controlled Trial Donlawat Saengpanit,[1] Monchai Siribumrungwong,[2] Paweena Susantitaphong,[1] Pisut Katavetin,[1] Somchai Eiam-Ong,[1] Kriang Tungsanga,[1] Visith Sitprija,[3] Kearkiat Praditpornsilpa.[1] *[1]King Chulalongkorn Memorial Hospital, Thai Red Cross Society and Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand; [2]Lerdsin Hospital, Bangkok, Thailand; [3]Queen Saovabha Memorial Institute, Bangkok, Thailand.*

Background: End-stage renal disease (ESRD) patients undergoing chronic hemodialysis (HD) have an extremely poor cardiovascular outcome. Arterial stiffness (AS), a strong independent predictor of survival in HD patients, is related to vascular calcification (VC). Intravenous (IV) sodium thiosulfate (STS) can prevent VC in animal studies and delay progression of VC in HD patients, likely by cationic chelating and antioxidant properties. The effect of STS on AS has not been assessed in this patient population. This study is the first to evaluate the efficacy of STS on AS in HD patients.

Methods: We enrolled 50 HD patients with AS measured by Cardio-Ankle Vascular Index (CAVI ≥ 8) into an open-label, randomized controlled trial. Patients were allocated to receive IV STS 12.5 gram during the last hour of HD twice weekly for 24 weeks (n=24) or usual care (control; n=26). CAVI, hemodynamics, and biochemical parameters were determined at baseline, 12 weeks and after 24 weeks. (Thai Clinical Trials Registry ID: 20160814001)

Results: All baseline parameters including CAVI (IV STS, 9.33 ± 0.87 vs. control, 9.34 ± 0.94) were comparable. Twenty-four weeks of twice weekly IV STS slightly lowered AS but insignificantly when compared with the control group (mean difference of the change of CAVI between STS and control was -0.53; 95% CI -1.07, 0.02; P = 0.17). Significant improvement of AS was observed in those without diabetes mellitus (DM) (P<0.05). There were no significant changes in hemodynamic parameters in both groups. No significant changes in serum calcium, phosphate, calcium-phosphate product, intact parathyroid hormone, and 25-OH vitamin D levels at baseline and after 24 weeks in both groups were observed. High-sensitivity C-reactive protein was slightly but not significantly decreased in IV STS treated group than the control group. After STS treatment, anion gap significantly increased from baseline (P<0.05).

Conclusions: Intradialytic STS treatment has a trend toward improvement in AS measured by CAVI in HD patients. The subgroup results which demonstrated that ESRD patients without DM are affected differently by STS treatment are interesting and require further study for confirmation.

The Effect of Far Infrared Therapy on Peripheral Artery Disease in Hemodialysis Patients Chih-Ching Lin.[1,2] *[1]Division of Nephrology, Department of Medicine, Taipei Veterans General Hospital, Taipei City, Taiwan; [2]School of Medicine, National Yang Ming University, Taipei, Taiwan.*

Background: In hemodialysis (HD) patients, peripheral artery disease (PAD) remains a critical cardiovascular complication which is usually diagnosed by ankle brachial index (ABI). Far infrared therapy improves access flow of vascular access but the effect on PAD in HD patients is still unknown.

Methods: We enrolled 198 maintenance HD patients in this study. PAD was defined as ABI ≤ 0.90. Only PAD patients received WS TY101 FIR emitter (Firapy) for 40 minutes during each HD session, three times weekly for six months. The ABI was measured for bilateral lower extremities for 4 times [pre-dialytic timing (0 minute) and 40 minutes after the initiation of HD session at both day 0 and 6 months after the FIR therapy].

Results: Fifty-one out of 198 patients had PAD. In comparison with the period without FIR therapy in the 51 PAD patients, 6 months of FIR therapy significantly improved the ABI of right/ left side for 0 minute (from 0.77±0.19 to 0.81±0.20, P=0.027/0.79±0.20 to 0.81±0.17, P=0.049), 40 minutes during HD (from 0.73±0.23 to 0.83±0.19, P<0.001/ from 0.77±0.21 to 0.83±0.18, P<0.001) and incremental change between 0 and 40 minutes (from -0.04±0.14 to 0.02±0.13, P= 0.007/ from -0.02±0.13 to 0.02±0.14, P=0.012) respectively.

Conclusions: We demonstrate 40 minutes of FIR therapy three times weekly for 6 months improved ABI of both lower extremities, thus providing a new strategy for the treatment of PAD in HD patients.

Effect of Physical Training on Echocardiographic Parameters during Hemodialysis: A Randomized Clinical Trial Gabriela J. Abundis Mora,[3] Guillermo Garcia-Garcia,[1] Daniel Murillo brambila,[1] Monica C. Jimenez cornejo,[3] Karina Renoirte,[2] Jonathan Chavez.[2] *[1]Hospital Civil De Guadalajara, University of Guadalajara, Guadalajara, Mexico; [2]Hospital Civil de Guadalajara, Guadalajara, Mexico; [3]Hospital Civil de Guadalajara "Fray Antonio Alcalde", Guadalajara, Mexico.*

Background: Patients on HD reduce their motor capacity over the time. It has been shown that physical training programs in HD are a safe intervention that positively impacts patients quality of life with positive effects on peak oxygen consumption, endothelial function and arterial stiffness index. Our objective was to evaluate the effect of a physical activity program with ergonomic bicycle during HD on the echocardiographic parameters of patients with conventional HD

Methods: Randomized, controled, unblinded clinical trial in prevalent HD patients, from september 2015 to may 2016, ≧18 years old. Patients with amputation of lower limbs, motor sequelae of cerebral vascular event and patients with vascular accesses in the lower extremities were excluded. Pre-dialysis biochemical test and echocardiographic parameters were taken at 0, 4 and 8 months. The intervention group included 14 pts who performed 135 min per week of moderate intensity exercise with ergonomic bicycle for a period of 35 weeks. SPSS software version 2.0 was used.

Results: 28 pts, average age 41 years, male (64%), HD vintage of 26 months. No difference was found in gender distribution, hereditary history, BMI, HbA1c, progression of CKD or hemodialysis time between the 2 groups. In the intervention group there was an increase in deceleration time with a baseline value of 157 ms to 220 ms at 8 months, with a statistically significant result which was not observed in the control group. In the control group, there was an increase in PSAP with an initial value of 35 mmHg, which increased to 44.5 mmHg, with a statistically significant result. Comparisons of biochemical level did not show statistically significant changes between both groups at 8 months of follow-up

Conclusions: HD pts with physical activity with an ergonomic bicycle for an 8-month period, compared against patients who did not perform physical activity, increased the deceleration time and did not increase PSAP. Intradialytic aerobic exercise is a feasible way to improve the myocardial function of HD pts, however, the design of new studies is required to further explore the impact of this intervention on other vascular function markers and to determine whether or not it reduces cardiovascular morbidity and mortality observed in patients with CKD.

SA-PO833

Dietary N-3 Polyunsaturated Fatty Acids (PUFA) Intake and Mortality in Adults on Hemodialysis: The DIET-HD Multinational Cohort Study Valeria M. Saglimbene,[1,4] Germaine Wong,[1,5] Jonathan C. Craig,[2] Jorgen B. Hegbrant,[3] Giovanni F. Strippoli.[6,3] *[1]Sydney School of Public Health, University of Sydney, Sydney, NSW, Australia; [2]University of Sydney/ Children's Hospital, Sydney, NSW, Australia; [3]Diaverum Medical-Scientific Office, Lund, Sweden; [4]Diaverum Medical-Scientific Office, Lund, Sweden; [5]Centre for Kidney Research, Children's Hospital at Westmead, Sydney, NSW, Australia; [6]University of Bari, Bari, Italy. Group/Team: For DIET-HD investigators.*

Background: N-3 PUFA are protective factors for cardiovascular risk in the general population. However their role in hemodialysis patients, in whom the pathogenesis of cardiovascular disease is different, is uncertain.

Methods: The DIET-HD study is a prospective cohort study (January 2014-January 2016) in 9757 adults treated with hemodialysis in Europe and South America. The dietary N-3 PUFA intake was measured at baseline using the validated GA²LEN Food Frequency Questionnaire. Adjusted cox regression analyses clustered by country were conducted to evaluate the association between dietary N-3 PUFA intake and cardiovascular and all-cause mortality.

Results: During a median follow up of 1.5 years (8108 person-years), there were 1214 deaths of which 515 were attributable to cardiovascular causes. Compared to patients with the lowest dietary N-3 PUFA intake (<0.37 g/wk), the hazard ratios (95% confidence intervals) for cardiovascular mortality among patients in the middle (0.37 to <1.8 g/wk) and highest (≥1.8 g/wk) tertiles of N-3 PUFA were 0.80 (0.64 to 1.00) and 1.13 (0.88 to 1.45), respectively; the hazard ratios for all-cause mortality were 0.95 (0.82 to 1.09) and 1.08 (0.92 to 1.28), respectively. Only one third of the study population consumed sufficient N-3 PUFA (at least 1.75 g/wk) as recommended for primary cardiovascular prevention, and less than 10% as recommended for secondary prevention (7-14 g/wk).

Conclusions: Dietary N-3 PUFA intake was not associated with cardiovascular or all-cause mortality in patients on hemodialysis. The possibility that higher dose N-3 PUFA, reached from supplementation, might mitigate cardiovascular risk has not been excluded.

SA-PO834

Initiation of Hemodialysis Is Associated with Altered Protein Composition of High-Density Lipoprotein Ke Wang,[2] Cassianne Robinson-Cohen,[2] Andrew N. Hoofnagle,[2] Bryan R. Kestenbaum,[2] The HFM Study Group.[1] *[1]NIDDK, Bethesda, MD; [2]University of Washington, Seattle, WA.*

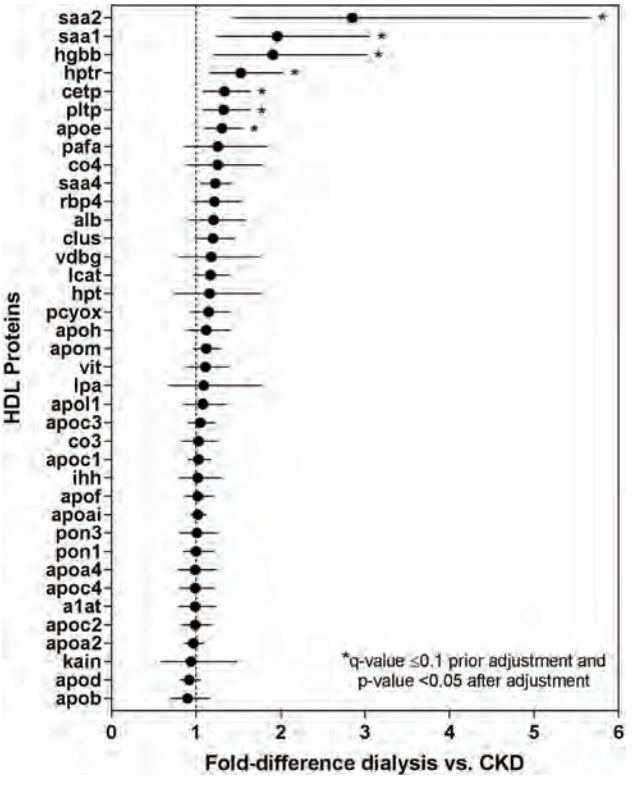
Background: High-density lipoprotein cholesterol (HDL-C) is composed of lipids and proteins that play important roles in cardiovascular disease development. The protein composition of HDL-C is altered in chronic dialysis patients compared to healthy controls. However, such differences conflate potential effects of kidney disease with those of dialysis procedures. We compared HDL-C associated proteins in patients recently initiating hemodialysis to those of patients with advanced chronic kidney disease (CKD).

Methods: We used liquid chromatography-mass spectrometry to quantify 38 HDL-C proteins in participants from the Hemodialysis Fistula Maturation (HFM) Study. We used linear regression to compare differences in log-transformed HDL-C proteins between 110 CKD patients awaiting dialysis (mean estimated GFR 12.8 ml/min/1.73m²) to 143 patients who initiated dialysis within the previous year. We used a q-value false discovery rate threshold of ≤0.1 to select candidate proteins that differed by dialysis status. We adjusted for age, race, gender, diabetes, body mass, smoking, prior cardiovascular disease, and statin use.

Results: Eight HDL-C associated proteins met the specified false discovery rate threshold for statistical significance (Figure). After covariate adjustment, seven of these proteins remained statistically significant at the p<0.05 level with minimal changes in effect sizes.

Conclusions: HDL-C associated proteins in pathways of inflammation and thrombosis are higher among recently initiated hemodialysis patients compared to those with late stage CKD. These findings suggest that the hemodialysis procedure itself may provoke adverse metabolic changes.

Funding: NIDDK Support



Differences in HDL-C proteins by dialysis status.

Increased Risk of Mortality, Major Cardiovascular Adverse Events, and Major Bleeding Outcomes Associated with Non-Steroidal Anti-Inflammatory Drugs in Patients with ESRD Hyung Ah Jo,[3] Seokwoo Park,[1] Hajeong Lee,[2] Dong Ki Kim.[3] *[1]SEOUL, SEoul, Republic of Korea; [2]Seoul National University College of Medicine, Seoul, Republic of Korea; [3]Seoul National University Hospital, Jong ro Gu, SEoul, Republic of Korea.*

Background: Many epidemiologic and randomized controlled studies have shown that non-steroidal anti-inflammatory drugs (NSAIDs) had cardiovascular risk and bleeding adverse events. Many dialysis patients complaint various causes of pain, and need of NSAIDs is considerable. However, there was no known study about the effect of NSAIDs on patients with end-stage renal disease (ESRD) receiving dialysis. Therefore, a nationwide epidemiologic study to evaluate the effect of NSAIDs on dialysis patients

should be considered. We investigated the risk of mortality, major cardiovascular adverse events (MACE), major bleeding events associated with NSAIDs.

Methods: A retrospective case-cross over designed nationwide epidemiologic study was conducted by analyzing Korean National Health Insurance (NIH) database. Inclusion criteria was patients older than 20 years with maintenance dialysis between January, 2008 and April, 2015. We excluded the patients who could not maintain dialysis at least 90 days from the date of dialysis initiation. For each included dialysis patients, we defined a case period as 1 to 30 days before the index date and control period as 60 to 90 days and 91 days to 120 days before the index date.

Results: A total of 9,417 patients with mortality, 3,313 patients with MACE and 4,923 patients with major bleeding events were included. For mortality, increased risk more obvious in non-selective NSAIDs such as diclofenac and aceclofenac than selective NSAIDs. Non-selective NSAIDs showed increased risk of MACE, and selective NSAIDs did not increase MACE. In regarding to major bleeding events, both selective (OR: 1.684. CI: 1.310-2.165) and non-selective NSAIDs (OR: 1.945, CI: 1.813-2.087) showed increased risk in dialysis patients.

Conclusions: Use of NSAIDs increased mortality, MACE and major bleeding events in dialysis patients. Increased risk of non-selective NSAIDs was more evident in MACE than selective NSAIDs and both non-selective and selective NSAIDs increased risk of major bleeding events.

The Association of Comorbidity and Nephrology Care with Mortality in Incident Dialysis Patients: A Population-Based Study Yiwen Chiu,[1,2] Ming-Yen Lin,[1,2] Feng-Xuan Jian,[1,2] Ping-hsun Wu,[1,2] Shang-Jyh Hwang.[1,2] *[1]Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; [2]Kaohsiung Medical University, Kaohsiung, Taiwan.*

Background: Nephrology care in late CKD can improve the survival after dialysis, how the morbidity affects this effectiveness remains unclear.

Methods: We conducted a retrospective cohort study to include incident patient with dialysis ≥ 3 months by using Taiwan National Health Insurance Research Databases from 2004 through 2012. Incident patients were included from 2007 through 2011 and their comorbidities were identified within three years before dialysis start. Nephrology care was evaluated by cumulative care (total nephrology visits in 3 years before dialysis), critical period care (at least one nephrology visit in 6 months before dialysis), and consistent critical period care (nephrology visits more than 3 in the 6 months before dialysis). One-year mortality risks after dialysis start were evaluated in all study subjects as well as cohorts stratified by comorbidity number by various nephrology cares in late CKD.

Results: We included total 44,698 (mean age 63.3±14.2, male 51.9%) and identified 9,600 (21.5%, mean age 67.8±11.4, male 47.6%) patients with multi-morbidity(≥ 3 diseases). 5428 patients(12.1%, mean age 61.2±16.2, male 56.1%) had no any nephrology visit, and only one half had nephrology visits more than ten times in 3 years before dialysis. After adjusted age, sex, socioeconomic status, living area, urbanization and comorbidity number, higher cumulative care (> 10 times), having critical period care, and consistent critical period care were associated with a lower mortality risk. Regular care in other specialties didn't have such association. In addition, the increase of comorbidities didn't change the pattern of significant association. (Table1)

Conclusions: Regular nephrology care should be highlighted in late CKD no matter how the burden of comorbidities is.

Funding: Government Support - Non-U.S.

Health Literacy Improves Medication Adherence and Clinical Outcomes Sreejith M. Velliyattikuzhi, Dipesh Maan, Swathi Lavudi, Richard J. Marcus, Barbara A. Clark. *Allegheny General Hospital, Pittsburgh, PA.*

Background: Poor medication adherence (MA) remains an important issue in end stage renal disease (ESRD) making blood pressure (BP) and phosphorous (P) control a challenge. We speculated the root cause for poor MA as lack of health literacy (HL) and designed a study to measure the extent of MA in ESRD and to determine if HL education improves MA in turn improving clinical outcomes.

Methods: 35 dialysis patients at a single center underwent a baseline interview which included open ended questions to assess MA (good MA defined as self-reported missed medication ≤ twice per week) and HL (knowledge of implications of BP and P control and awareness of anti-hypertensives and P binders). Medications were reconciled with the patient's pharmacy and an updated medication list along with verbal and written education materials were provided. In six weeks, a follow up interview was performed to re-assess MA and HL. Average systolic and diastolic BP and P levels were measured before and after the study.

Results: MA at baseline was 54%. Only 66% and 29% understood implications of BP and P control respectively. 56% were not aware of their P binders. Post intervention showed significant improvement in MA (86%, p=0.002), awareness of antihypertensive medications (p=0.01) and P binders (p<0.001). Systolic BP after intervention showed significant improvement (p<0.001). There was a trend towards improvement in diastolic BP, but did not reach statistical significance. No significant difference was observed with P levels and with number of missed hemodialysis sessions after intervention. Refer to table.

Conclusions: MA and HL in ESRD is poor. Open ended questioning identifies gaps in HL and directed education improves MA, HL and clinical outcomes.

Variable		Pre	Post	p-value

Application of Extended Home Hemodialysis with the NxStage System One Eric D. Weinhandl,[2,3] J. Ken Leypoldt,[1] Allan J. Collins.[2,3] *[1]San Clemente, CA; [2]NxStage Medical, Inc., Victoria, MN; [3]University of Minnesota, Minneapolis, MN.*

Background: Extended hemodialysis, which is characterized by session duration beyond the usual interval of 3 to 5 hours, facilitates the removal of large fluid volumes at slow rates, likely resulting in fewer intradialytic hypotensive episodes and lower interdialytic blood pressure. There are few data about applications of extended hemodialysis with a low volume of dialysate per session. We used a telehealth platform to collect data about home hemodialysis (HHD) patients using the NxStage System One for extended hemodialysis.

Methods: We collected treatment factors and intermediate outcomes in HHD patients using the NxStage System One in tandem with the Nx2me Connected Health platform. We analyzed digital flowsheets collected from US patients between Nx2me product launch and March 31, 2016, and retained those patient-weeks with prescription of at least 3 sessions and receipt of at least 3 flowsheets with session duration ≥6 hours. We used descriptive analysis to summarize collected data.

Results: We identified 1932 patient-weeks of extended hemodialysis among 56 patients. Percentages of patient-weeks with 3.5, 4, and 5 prescribed sessions per week were 5%, 30%, and 65%, respectively. The mean number of delivered sessions per week was 4.22 (adherence, 90%). Mean session duration was 421 minutes, with 5th and 95th percentiles of 353 and 481 minutes, respectively; the mean number of cumulative treatment hours per week was 29.3. Sixty liters of dialysate were prescribed for 67% of sessions and the median blood flow rate was 300 mL/minute. Mean ultrafiltration volume was 2.1 L, with 5th and 95th percentiles of 0.6 and 3.9 L. In patient-weeks of extended hemodialysis, we identified 7429 digital flowsheets with complete data. Mean (standard deviation [SD]) ultrafiltration rate (UFR) was 2.97 (1.37) mL/hour/kg; 99.9% of sessions had UFR < 10 mL/hour/kg. Before treatment, mean (SD) systolic blood pressure (SBP) was 127 (24) mmHg and mean (SD) diastolic blood pressure (DBP) was 72 (12) mmHg. After treatment, mean (SD) SBP was 122 (23) mmHg and mean (SD) DBP was 72 (12) mmHg. The percentages of sessions with predialysis and postdialysis blood pressure in KDOQI target ranges were 67% and 56%, respectively.

Conclusions: Extended HHD on the NxStage System One delivered almost 30 hours of treatment each week, partially due to excellent adherence. UFR was very low and BP control was generally very good.

SA-PO839

Lymphopenia CD19+, a New Cardiovascular Risk Factor in Hemodialysis Patients Maria Molina, Enrique Morales, Claudia Yuste, Manuel Praga. *Nephrology Department, Hospital Universitario 12 de Octubre, Madrid, Spain.*

Background: Cardiovascular disease (CVD) is one of the most important causes of mortality in hemodialysis patients (HD). Traditional factors for CVD aren't good predictors of events. On the other hand, uraemia in HD induce have a proinflamatory environment that facilitate atheromatous lesions. Recently, the role of CD19+ lymphocytes in atheromatosis process has been described in non-uremic patients. The role of CD19+ lymphocytes in CVD in HD patients is unknown. **Aim:** To evaluate the role of lymphocytes CD19+ in cardiovascular deaths in HD patients.

Methods: A single centre prospective cohort study was started in 2011. We measured the lymphocytes CD19+ in 104 patients on HD and we followed them for 5 years, until a change in renal replacement therapy (kidney transplantation or peritoneal dialysis).

We studied the influence of lymphocytes CD19+ in CDV mortality; other causes of death were censored.

Results: The mean age was 64.8±15 y, 51% were male. Cardiovascular risk factors as arterial hypertension, diabetes mellitus and dyslipidaemia were found in 76%, 29.8% and 51.9%, respectively. 62 (60%) patients had previous CVD: 28% (29) ischemic heart disease, 14.5% (15) stroke and 25% (26) peripheral vascular disease. The follow up were 18 (7-47) months and 55 patients died. 22 patients (40% of all deaths) died for CVD. Multivariable analysis showed the variables associated with CDV mortality: age (HR: 1.04 (95% IC 1.006-1.1), p=0.02), Charlson index (HR: 1.16 (95% IC 1.02-1.3), p=0.02), previous ischemic heart disease (HR: 3.5 (95% IC 1.4-9), p=0.008), lymphocyte CD19+ < 100 cells/μL (HR: 4.1 (95% IC 1.18-14.6), p=0.02) and previous immunosuppression therapy (HR: 0.17 (95% IC 0.06-0.5), p=0.001).

Conclusions: Low CD19+ lymphocyte could be a new cardiovascular risk factor as important as ischemic heart disease in HD patients. To improve the immunological knowledge could decrease the CVD deaths of the HD patients. It is mandatory to performed more studies about the role of CD19+ lymphocyte in CVD in uremic patients.

SA-PO840

Aggravated Aging-Related Immune Changes Are Associated with Inflammation and Cardiovascular Diseases in ESRD Patients: Baseline Findings from the iESRD Study Kai-Hsiang Shu,[3,4] Yu-sen Peng,[2] Yen-Ling Chiu.[1] *[1]Far Eastern Memorial Hospital, Banciao, New Taipei City, Taiwan; [2]Far Eastern memorial hospital, Taipei, Taiwan; [3]Division of Nephrology, Far Eastern Memorial Hospital, New Taipei City, Taiwan; [4]Graduate Institute of Immunology, National Taiwan University, Taipei, Taiwan.*

Background: Patients with end-stage renal disease (ESRD) exhibit accelerated aging of the immune system and increased risk for cardiovascular diseases, but the overall contribution of "immune system aging", or "immunosenescence" to cardiovascular disease is not clear.

Methods: We performed a comprehensive lymphocyte and monocyte immunophenotyping in 412 ESRD patients on maintenance hemodialysis and age-matched 57 healthy individuals. Peripheral bloods were sampled before hemodialysis session and processed immediately for mononuclear cell isolation and staining. Using multicolor flow cytometry, lymphocytes were separated into subpopulations including naive T cells (CCR7+CD45RA+, T_{Naive}), central memory (CCR7+CD45RA-, T_{CM}), effector memory (CCR7-CD45RA-, T_{EM}), terminally differentiated (CCR7-CD45RA+, T_{EMRA}) and memory stem cells (naive cells with high CD28 andCD95, T_{SCM}). Monocytes were separated into classical (CD14++CD16-), intermediate (CD14++CD16+) and non-classical monocytes (CD14+CD16+).

Results: Compared to healthy individuals, ESRD patients showed decreased levels of naive CD4+ and CD8+ T cells, increased levels of terminally differentiated T_{EMRA} cells and intermediate monocytes (CD14++CD16+), and these changes not only significantly correlated with age but also enhanced by increasing dialysis vintage. Lymphocyte and monocyte aging also correlated with other established cardiovascular risk factors, including hemoglobin and high-sensitivity C-reactive protein. In multivariate-adjusted logistic regression models, a high terminally differentiated CD8+ T_{EMRA} cell level in combination with a high intermediate monocyte level was independently associated with the existence of coronary artery disease (OR=2.29, 95% CI=1.2~4.5, p=0.016) as well as cardiovascular diseases including stroke and peripheral arterial occlusive disease (OR=2.32, 95% CI=1.2~4.4, p=0.008).

Conclusions: Aging-related changes in the immune system are significantly aggravated in ESRD. Cardiovascular disease burden in the ESRD population might be enhanced by the presence of accelerated aging-related immune changes.

SA-PO841

The Modification Effects of Age, Inflammation, and Acyl-Ghrelin on the Relationship between Obestatin Levels and Clinical Outcomes in Maintenance Hemodialysis Patients Ilia Beberashvili,[5] Anna Katkov,[3] Inna Sinuani,[6] Ada Azar,[7] Gregory Shapiro,[4] Leonid Feldman,[1] Shai Efrati.[2] *[1]Nephrology division, Assaf Harofeh Medical Center, Zerifin, Israel; [2]None, Zerifin, Israel; [3]Nephrology division, Assaf Harofeh Medical Center, Zerifin, Israel; [4]Nephrology Division Assaf Harofeh Medical Center, Zerifin, Israel; [5]Nephrology division, Assaf Harofeh Medical Center, Zerifin, Israel; [6]Pathology department, Assaf Harofeh Medical Center, Zerifin, Israel; [7]Nutrition department, Assaf Harofeh Medical Center, Zerifin, Israel.*

Background: Obestatin, an anorexigen, was proposed as a physiological opponent of acyl-ghrelin (AG). While obestatin failed to reproduce the anorexigenic property in further studies, experimental evidence has accumulated suggesting protective cardiovascular effects of obestatin.

Methods: To examine the hypothesis that obestatin interactions with age, AG and inflammatory markers predict outcomes of maintenance hemodialysis (MHD) population, we investigated the associations between the obestatin, acyl-ghrelin, IL-6, TNF-α, and mortality in a prospective cohort of 261 MHD patients with 6 years of follow-up. During this period 160 patients died in total, with 74 because of cardiovascular causes.

Results: For each ng/ml increase in baseline obestatin level, in fully adjusted models (including malnutrition-inflammation score, IL-6 and AG) the hazard for death from all causes was 0.90 (95% CI, 0.81 to 0.99) and for cardiovascular death 0.85 (95% CI, 0.73 to 0.99). However, these associations were more robust in subgroup of patients aged above 71 years. An interactions between high IL-6 (above median) and low obestatin (below median) levels for increased risk of all-cause mortality (synergy index 5.14, p=0.001) and cardiovascular mortality (synergy index 4.81, p=0.02) emerged in multivariable adjusted models. Interactions were observed also between obestatin, TNF-α and AG, which were associated with mortality risk. High AG and high obestatin interaction was negative (synergy index 0.76, p=0.03) in predicting lower risk for all-cause mortality and cardiovascular mortality (synergy index 0.80, p=0.008).

Conclusions: The prognostic ability of obestatin is modified by age being very prominent in patients older than 71 years. In addition, we report on novel interactions between obestatin, inflammatory mediators and AG associated with mortality risk in the study population.

SA-PO842

Inflammatory and Angiogenic Factors Associated with Microvascular Changes over a 6-Month Period in a Cohort of Hemodialysis Patients Nicos Mitsides,[2] Tom Cornelis,[1] Natascha Broers,[3] Nanda Diederen,[3] Paul E. Brenchley,[2] Frank van der Sande,[3] Casper Schalkwijk,[3] Jeroen Kooman,[3] Sandip Mitra.[2] *[1]Jessa General Hospital, Hasselt, Belgium; [2]Central Manchester University Hospitals NHS Foundation Trust, Manchester, United Kingdom; [3]Maastricht University Medical Centre, Maastricht, Netherlands.*

Background: Cardiovascular (CV) disease is a major contributor to poor outcomes in haemodialysis (HD). Comorbidity & oxidative stress are confounding factors to this phenomenon. High Dose HD (HDHD) regimes have been linked with a CV benefit compared to Conventional HD (CHD). We investigate the relationship between HD intensity, pro-inflammatory & endothelial mediators and micro- & macrocirculatory parameters over a 6-month period.

Methods: We report the findings of the 6-month analysis of participants to the study of Uremic Toxins, Cardiovascular Effects & Physical Activity in Intensive Haemodialysis (INTHEMO); a 2yr multicentre study investigating the effects of HDHD on CV parameters. Macrocirculation was assessed with pulse wave velocity & 24hr ambulatory blood pressure measurements. Microcirculation was assessed using sublingual dark field capillaroscopy. A panel of pro-inflammatory & endothelial biomarkers added to the assessment of vascular health. Hydration state was assessed by means of multifrequency bio-impedance.

Results: Of the 47 followed up at over a 6-month period, 21 were performing HDHD (>12hr of haemodialysis per week) & 26 CHD. CHD participant were older (63.5±14.2 v 53.7±12.6yr; p=0.02), with a smaller dialysis vintage (median vintage 23, max-min 6-106 v 61, max-min 10-432 months; p<0.01) & better-preserved residual renal function (61.5% v 9.5%;p<0.01). HD intensity did not correlate to any changes to CV measurements over a 6-month period. Higher serum levels of IL 8 (median 14.3pg/ml, min-max 3.5-185.7) measured at baseline independently predicted increase in the Perfused Boundary Region (5-25μm) of the endothelial glycocalyx (β=0.408, p<0.01) while higher levels of soluble Flt-1 (median 253pg/ml, min-max 139-1434) had a significant inverse effect (β=0.408, p<0.01) in an adjusted multivariate linear regression model.

Conclusions: HD intensity did not predict any changes in either macro- or microvascular parameters in HD patients. Micro-inflammation mediated through the TNF-alpha & IL-8 pathway was a predictor of microvascular injury while Flt-1, a potential marker of angiogenesis & endothelial repair might have a significant protective role. Further exploration into the pathophysiological effects of these pathways is required.

Monocyte/Lymphocyte Ratio Is a Better Predictor Than Neutrophil/ Lymphocyte Ratio for Cardiovascular Events in Incident Dialysis Patients Sawako Kato,[1] Bengt Lindholm,[2] Yukio Yuzawa,[3] Yoshinari Tsuruta,[4] Shoichi Maruyama.[1] *[1]Nagoya University Graduate School of Medicine, Nagoya, Aichi, Japan; [2]Baxter Novum & Renal Medicine Karolinska Institute, Stockholm, Sweden; [3]Fujita Health University School of Medicine, Toyoake, Japan; [4]Meiyo Clinic, Toyohashi, Japan.*

Background: A higher neutrophil/ lymphocyte ratio (NLR) may indicate increased risk of cardiovascular disease (CVD) in incident dialysis patients (pts). However, recent studies suggest that monocyte/lymphocyte ratio (MLR) might a more sensitive predictor of CVD events than NLR, because the monocyte, a multifunctional immune professional cell and an ancestor of lipid-laden macrophages, may directly contribute to the progression of atherosclerosis. Here we explored the mortality predictive capacity of MLR among incident dialysis pts.

Methods: In an ongoing prospective cohort study, 132 incident Japanese dialysis pts (91 males, age 59 ±12 years) were enrolled and followed for a median of 48.7 months (range 1-113 months). Laboratory biomarkers including white blood cell count (WBC) - and its differential count - were determined at baseline.

Results: Median MLR was 0.35 (range 0.46-0.27). The duration from start of dialysis therapy to the first CVD event was shorter in pts with higher MLR (Log rank 5.60, P=0.018). The number of CVD events per year was higher in pts with high MLR (18.6 events per 100 person-years) than in pts with low MLR (11.1 events per 100 person-years). In Cox hazard model, after adjustments for age, gender, smoking habits, and presence of diabetes, the pts with high MLR and high monocyte count – treated as continuous variables - had a significantly increased relative risk of CVD (5.64, 95% CI; 1.1-24.8, P = 0.028; and 7.17, 95% CI; 1.1-43.5, P = 0.037, respectively). However, the relations of CVD events to NLR or to neutrophil and lymphocyte counts were not significant.

Conclusions: In Japanese incident dialysis pts, a higher MLR and higher monocyte count associated with increased long-term risk of CVD events. These results may suggest

that an increased circulating number of monocytes might play a role in the development of atherosclerosis in chronic kidney disease pts, possibly through differentiation of monocytes into macrophages in plaques, or by other mechanisms.

SA-PO844

Significant Association between Serum Magnesium and the Elevation of Troponin T in Maintenance Hemodialysis Patients Eiji Ishimura,[1] Shinya Nakatani,[2] Akihiro Tsuda,[2] Nobuyuki Kuwamura,[1] Ryusuke Kakiya,[1] Jiro Miyawaki,[3] Senji Okuno,[3] Tomoyuki Yamakawa,[3] Shigeichi Shoji,[3] Masaaki Inaba.[2] *[1]Meijibashi Hospital, Osaka, Japan; [2]Osaka City University Graduate School of Medicine, Osaka, Japan; [3]Shirasagi Hospital, Osaka, Japan.*

Background: Serum magnesium (Mg) levels is well known to be closely associated with cardiovascular disease in the general population. Troponin T has been reported to be a cardiac contractility modulating protein, and is measured as a biomarker for diagnosing myocardial injury. In hemodialysis patients, serum troponin T is elevated, and elevated serum troponin T has been reported to be a risk of death from all-cause mortality and cardiovascular disease. We hypothesized that serum Mg would be associated with the elevation of troponin T in hemodialysis patients.

Methods: A total of 432 stable maintenacne hemodialysis patients were examined (age: 64.0±11.3 years, hemodialysis duration: 8.0±6.9 years, 63.7% men, and 37.5% diabetics). Troponin T was measured twice in one year interval. Patients were divided into two groups; the group with elevation of serum troponin T in a year (98 patients) and the group with its non-elevation (334 patients).

Results: The group of elevation of serum troponin T showed significant older age, compared to the group of no-elevation of serum troponin T (67± 10 vs. 63 ± 12 vs. years, p = 0.0006). Cardia thoracic ratio (CTR) was significantly larger in the former than in the latter (50.5 ± 4.7 vs. 49.3 ± 4.4 %, p = 0.0260). Body mass index or duration of hemodialysis did not significantly differ between the two groups. Serum magnesium concentrations were significantly lower in the group of elevation of serum troponin T in a year, compared to the group of no elevation of serum troponin T in a year (2.6 ± 0.3 vs. 2.8 ± 0.4 mg/dL, p = 0.0015), although there were no significant differences in serum calcium, phosphate or intact PTH between the two groups. In a multivariate logistic analysis, serum Mg levels (OR = 0.394; 95% CI, 0.177 to 0.877; p = 0.0224) were significantly and independently associated with the elevation of troponin T, in addition to other significant factors of age, hemodialysis duration, and smoking (R^2=0.097, p < 0.0001), after adjustment of several clinical factors.

Conclusions: These results demonstrated that lower serum Mg concentration was significantly associated with the elevation of troponin T in hemodialysis patients, possibly suggesting that significant association of lower serum Mg and higher cardiac injury.

SA-PO845

Level of Anti-Cytomegalovirus Antibody Positively Correlates with Coronary Artery Disease and Cardiovascular Diseases in ESRD Patients Feng-Jung Yang,[1,3] Kai-Hsiang Shu,[2,4] Yen-Ling Chiu.[2,1] *[1]Graduate Institute of Medicine, College of Medicine, National Taiwan University, Taipei, Taiwan; [2]Far Eastern Memorial Hospital, Banciao, New Taipei City, Taiwan; [3]Internal Medicine Department, National Taiwan University Hospital Yunlin Branch, Douliu, Taiwan; [4]Internal Medicine Department, National Taiwan University Hospital, Taipei, Taiwan.*

Background: Accumulating evidence indicates cytomegalovirus (CMV) infection is associated with several health-related adverse outcomes including atherosclerosis and premature mortality in individuals with normal renal function. Patients with end-stage renal disease (ESRD) exhibit impaired immune function and may face higher risk of CMV-related adverse outcomes. Whether level of anti-CMV immune response may associate with the prognosis of hemodialysis patients is unknown.

Methods: The immunity in ESRD study (iESRD) recruited 412 hemodialysis patients from both northern and southern Taiwan. By history taking and detailed chart reviews, baseline co-morbidities were recorded. Peripheral blood was sampled before hemodialysis session and processed immediately. Plasma levels of CMV-IgG and high-sensitivity C reactive protein were determined by ELISA. Peripheral blood monocyte and T cell differentiation subsets were determined by multicolor flow cytometry.

Results: Among these patients, 99% were CMV-seropositive. In the univariate analysis, log level of anti-CMV IgG was independently associated with the existence of coronary artery disease (OR=1.944, 95% CI=1.2~3.0, p=0.004) as well as cardiovascular diseases including stroke and peripheral arterial occlusive disease (OR=1.53, 95% CI=1.03~2.276, p=0.034). In a multivariate-adjusted logistic regression model, log level of anti-CMV IgG was independently associated with the existence of coronary artery disease (OR=1.944, 95% CI=1.2~10.4, p=0.019) as well as cardiovascular diseases including stroke and peripheral arterial occlusive disease (OR=3.98, 95% CI=1.5~10.8, p=0.007) after adjusting for age, gender, dialysis vintage, hemoglobin, DM, and hs-CRP. Level of anti-CMV IgG positively correlated with both percentage and absolute number of terminally differentiated CD8+CD45RA+CCR7- TEMRA cells, indicating the accumulation of these cells participate in the progression of atherosclerosis.

Conclusions: Anti-CMV humoral immune response positively correlates with the existence of coronary artery disease and cardiovascular diseases in ESRD patients. Role of CMV and the associated immune response should be further investigated in the pathogenesis of atherosclerosis in this patient population.

Funding: Government Support - Non-U.S.

SA-PO846

Serum Sclerostin Level Is an Independent Predictor of Short-Term Mortality in Maintenance Hemodialysis Patients Kosaku Nitta, Ken Tsuchiya. *Tokyo Women's Medical University, Shinjuku-ku, Japan.*

Background: Sclerostin has recently been recognized as a novel marker of bone remodeling and vascular calcification. However, whether a high circulating sclerostin level is also a risk factor for death has not been clearly established. The aim of this study was to determine whether there is an association between the serum sclerostin levels and their mortality of maintenance hemodialysis (MHD) patients.

Methods: We measured the serum sclerostin levels in a Japanese MHD cohort, and followed over a 4-year period, and classified the patients into tertiles according to their serum sclerostin levels. We then assessed their short-term mortality (16 months) and long-term mortality (42 months) according to their serum sclerostin levels. Cox regression analyses were performed to test for associations between their serum sclerostin levels and both all-causemortality and cardiovascular disease (CVD)-related mortality. Kaplan-Meier curves were used to perform the survival analyses.

Results: The cohort consisted of 389 MHD patients aged 42.3 ± 18.8 years (55% males, 15% diabetics). There were 75 deaths during the follow-up period of 38.2 ± 9.3 months, 75 patients died. The main cause of death was CVD (n = 31), and was followed by infection (n = 30). The results of the multivariate logistic regression adjusted for confounders showed that history of CVD (HR 3.34, 95% CI 1.219 – 8.255, P = 0.0209) was the only significant predictor of all-cause mortality, but the serum tryglyceride level (HR 0.002, 95% CI 0.002 – 0.594, P = 0.0305) and being in the 1st tertile of sclerostin levels (HR 8.791, 95% CI 1.574 – 164.808, P = 0.0098) were significant predictors of CVD-related mortality during the 16 month-follow-up period. Kaplan-Meier analyses showed no significant differences in CVD-related mortality between tertiles during 16 month-follow-up period, but higher mortality in the 1st tertile (P = 0.0274). There were no significant differences in all-cause or CVD-related mortality tertiles during the 42 month-follow-up period.

Conclusions: The serum sclerostin level is an independent predictor of short-term mortality in MHD patients, but whether clinical interventions to modulate their serum sclerostin levels would improve their survival remains to be determined.

SA-PO847

Residual Urine Volume in Hemodialysis Patients: International Trends, Predictors, and Outcomes in the DOPPS Manfred Hecking,[3] Keith McCullough,[1] Friedrich K. Port,[1] Hiroyasu Yamamoto,[2] Michel Y. Jadoul,[5] Loreto Gesualdo,[4] Michelle M. Wong,[1] Bruce M. Robinson.[1] *[1]Arbor Research Collaborative for Health, Ann Arbor, AL; [2]Division of Nephrology and Hypertension, Department of Internal Medicine, Jikei University School of Medicine, Tokyo, Japan; [3]Medical University of Vienna, Nephrology & Dialysis, Vienna, Austria; [4]University of Bari, Altamura, Italy; [5]University of Louvain Medical School, Brussels, Belgium.*

Background: Residual urine volume (RUV) decline after hemodialysis initiation has received limited attention in hemodialysis, and preventive actions are matter of debate. We determined international trends in RUV and analyzed the effect of potentially modifiable predictors on the association between RUV and mortality.

Methods: Among n=21,199 patients from 12 countries in DOPPS phases 2-5 (2002-2015), RUV was self-reported as ≥200mL versus <200mL and was measured or estimated in categories (in DOPPS phase 5, 2012-2015). Statistical methods included Cox regression models with adjustment for demographics, vintage, country and comorbidities.

Results: In prevalent patients with median vintage of 3.5 years, 31% reported RUV ≥200mL, at a wide geographical range (19% in Japan to 58% Germany), without a substantial time trend identified over DOPPS phases. RUV ≥200 was reported for 59% of patients on dialysis less than 1 year, decreasing to 45%, 36% and 17% of patients on dialysis 1-1.9 years, 2-2.9 years, and 3+ years, respectively. Prevalent patients who reported RUV <200mL had higher adjusted mortality than patients with RUV ≥200mL. In line, higher RUV was predictive of better survival in a dose-dependent fashion (Figure). The mortality risk associated with RUV did not differ among patients who were prescribed (versus not prescribed) diuretics (p-value for interaction =0.32).

Conclusions: Maintenance of RUV differs by region and vintage, but has remained relatively stable in the DOPPS since 2002. The fact that >17% of patients on dialysis at 2 and 3 years have RUV may previously have been underrecognized. Our survival model among prevalent patients confirms the dose-dependent importance of RUV as a predictor of survival. Although diuretics did not modify RUV-associated mortality risk, high-dose diuretics and other means to potentially preserve RUV deserve more focused investigation.

Differences between Home and In-Center BP Readings in Dialysis Patients Dana Miskulin,[1] Ambreen Gul,[2] R. Schrader,[2] Jennifer J. Gassman,[4] Antonia Harford,[3] Philip Zager.[2] *[1]Tufts Medical Center, Sommerville, MA; [2]DCI, Albuquerque, NM; [3]UNM, Albuquerque, NM; [4]Cleveland Clinic, Cleveland, OH. Group/Team: For BID Study Investigators.*

Background: Critics argue that 'in-center' pre-dialysis BP readings in hemodialysis patients are not reflective of 'true BP' because patients are at the extremes of fluid balance, are more anxious than usual and staff do not follow AHA guidelines for measurement. Few studies have compared home with in-center readings, and those that have, have been limited to 1-2 weeks of home readings. The BID was a pilot RCT in which 126 thrice weekly hemodialysis patients were randomized to 12 months of treatment to a pre-dialysis standardized dialysis unit (SDU) systolic blood pressure (BP) 110-140 or 155-165 mm Hg. Patients measured BP at home on the day following the mid-week treatment for one year.

Methods: The difference between the mid-week pre-dialysis SDU and home systolic BP the next morning was modeled using linear mixed regression with cubic splines.

Results: Systolic BP at home was a mean (SD) 6.1 (0.7) mm Hg lower than the pre-dialysis SDU (Figure 1) though, the range of the difference was wide and for 25% of the population, home was less than SDU by more than 15 mm Hg. The 'within patient' variability in systolic BP was slightly higher for home (16.9 mm Hg) as compared with. pre-dialysis SDU (14.3) readings. Results were not different when SDU was compared with the average of the morning and evening home BPs.

Conclusions: The average difference between systolic BP taken pre-dialysis using a standardized protocol vs. at home of ~6 mm Hg is surprisingly consistent with the difference between office and home BP in the general population. However, for some patients, it is much larger, and the differences are likely to be even greater with routine (as opposed to standardized) in-center BP measurement. Obtaining home BP readings in dialysis patients may reduce 'overtreating' hypertension, which would be especially important in elderly patients and those prone to falls.

Effect of Spironolactone on Left Ventricular Mass in Hemodialysis Patients: The MiREnDa Study – A Randomized Controlled Trial Christoph Wanner,[5,12] Uwe Malzahn,[7] Julian Donhauser,[6] Christoph Betz,[13] Clemens Grupp,[2] Thomas Döltz,[4] Nils Pollak,[3] Sören Grebe,[10] Esther Murillo,[1] Severin Bausch,[6] Tobias G. Hauser,[11] Monika Mehling,[6] Kirsten Hofmann,[6] Christian O. Ritter,[9] Vera Krane,[10] Fabian Hammer.[8,12] *[1]University Hosptial Würzburg, Würzburg, Germany; [2]Department of Nephrology, Bamberg, Germany; [3]Hospital of the university of Würzburg, Würzburg, Germany; [4]KfH, Germany, Bamberg, Germany; [5]University Hospital, Wuerzburg, Germany; [6]University Hospital Wuerzburg, Wuerzburg, Germany; [7]University Hospital Würzburg, Würzburg, Germany; [8]University Medicine Greifswald, Greifswald, Germany; [9]University Medicine of Goettingen, Goettingen, Germany; [10]University of Wuerzburg, Wuerzburg, Germany; [11]University of Würzburg, Würzburg, Germany; [12]Comprehensive Heart Failure Centre, University Würzburg, Würzburg, Germany; [13]Medicine, University Hospital Frankfurt, Frankfurt, Germany.*

Background: Hemodialysis (HD) patients are characterized by an extraordinary high cardiovascular (CV) morbidity and mortality but effective medical treatment is lacking. Left ventricular mass (LVM) constitutes an independent predictor of all-cause and CV mortality risk. We here evaluated the effect of spironolactone on LVM in HD patients.

Methods: We enrolled 118 HD patients of which 97 patients (female: 22.9%; mean age: 60.3±13.3 years; mean body mass index: 27.6±5.0 kg/m2; median duration of dialysis: 42.0 (16.6-76.0) months) were randomized 1:1 to spironolactone 50mg once daily (N=50) or placebo (N=47). The primary efficacy end point was the change in the LVM index as determined by cardiac magnet resonance imaging before and at the end of the 40 week treatment period. Secondary outcomes included the effect on 24h ambulatory blood pressure and the development of severe hyperkalemia (potassium≥6.5mmol/l).

Results: Treatment with spironolactone compared to placebo did not result in a significant change of the LVM index (spironolactone vs. placebo: -2.86±11.87 vs. 0.41±10.84 g/m2, p=0.337, ANCOVA). Likewise treatment with spironolactone did not change mean 24h systolic (0.0±11.6 vs. 2.1±15.4 mmHg, p=0.433) or diastolic (-1.3±7.9 vs. 0.1±9.0 mmHg, p=0.505) ambulatory blood pressure. The incidence of severe hyperkalemia was not different between the two groups.

Conclusions: Treatment of HD patients with 50mg spironolactone had no effect on LVM or blood pressure and did not increase the risk of severe hyperkalemia.

SA-PO850

ECW/TBW Determined by Three Bioimpedance Devices: A Comparative Study in Hemodialysis Patients and Healthy Subjects Priscila Preciado, Fansan Zhu, Ohnmar Thwin, Xia Tao, Laura Rosales, Jochen G. Raimann, Stephan Thijssen, Peter Kotanko. *Renal Research Institute, New York, NY.*

Background: The ratio of extracellular (ECW) to total body water (TBW) is a widely accepted indicator of fluid status. However, ECW/TBW may differ between bioimpedance devices. We compared three commercially available bioimpedance devices in hemodialysis (HD) patients and health subjects (HS)

Methods: Ten patients (8 males, age 58.1±12 years) and 12 healthy subjects (7 females, age 33.3±5.6 years) were studied using two eight-point bioimpedance devices, InBody 770 (InBody USA, Cerritos, CA), Seca mBCA 514 (Seca North America, Chino, CA) and Hydra 4200 (Xitron Technologies, San Diego, CA). Measurements were performed pre and post HD in patients and once in HS.ECW, intracellular water (ICW), TBW, and ECW/TBW reported by the devices were compared between pre and post HD, and between patients and HS

Results: ECW and ICW were significantly lower in InBody compared to Seca and Hydra (**Table 1**). Peridialytic changes of ECW (ΔECW), ICW (ΔICW), and TBW (ΔTBW) did not differ. Peridialytic weight loss (ΔWt; 2.58±0.51 kg) did not differ from ΔTBW reported by InBody and Hydra. ΔECW reported by InBody and Hydra was significantly lower than ΔWt. Seca measurements of ΔTBW was higher than ΔWt. In HD patients and HS InBody measurements of ECW/TBW were lower compared to Seca and Hydra, respectively(**Fig.1**). Pre and post HD ECW/TBW measured with InBody and Hydra did not differ(**Fig.2**)

Conclusions: This pilot study indicates that ECW/TBW measurements differ between bioimpedance devices. InBody reports significantly lower ECW/TBW values compared to Seca and Hydra

Device	Pre HD ECW (L)	Pre HD ICW(L)	Pre HD TBW (L)	ΔECW (L)	ΔICW (L)	ΔTBW (L)	Post HD ECW/TBW

Magnesium Prevents Vascular Calcification by Inhibition of Hydroxyapatite Crystal Formation Jeroen H. De Baaij, Anique D. Ter braake, René J. Bindels, Joost Hoenderop. *Radboud University Medical Center, Nijmegen, Netherlands.*

Background: Mg^{2+} has been shown to effectively prevent vascular calcification in multiple experimental calcification models. Vascular calcification is common in chronic kidney disease and contributes to increased mortality. Mg^{2+} has been hypothesized to prevent the upregulation of osteoblastic gene expression that drive calcification. However, extracellular effects of Mg^{2+} on Ca^{2+}-Pi crystal formation have been largely neglected. This study aimed to investigate the effects of Mg^{2+} on both intracellular changes associated with vascular calcification as well as effects on crystal formation in the extracellular space.

Methods: Bovine vascular smooth muscle cells (bVSMC) were calcified using β-glycerophosphate (BGP). Transdifferentiation was assessed by transcriptional analysis, cellular alkaline phosphatase (ALP) activity and development of apoptosis. X-ray powder diffraction, scanning electron microscopy and energy dispersive spectroscopy on crystals isolated from cell culture supernatants were used to map extracellular effects of Mg^{2+} on crystal formation and crystal composition.

Results: Mg^{2+} effectively prevented BGP-induced calcification in bVSMC. BGP did not cause changes in mRNA expression of the osteogenic genes BMP2, RUNX2 or ALP. Moreover, alkaline phosphatase activity was stable and apoptosis was only detected after calcification independent of Mg^{2+}. In addition, blocking of the Mg^{2+} channel TRPM7 using 2-ABP did not abrogate the protective effects of Mg^{2+}, indicating that intracellular Mg^{2+} is not involved in BGP-induced calcification of bVSMCs. Extracellular Mg^{2+} prevented the formation of hydroxyapatite crystals, which formed extensively after BGP treatment. Further analysis of the composition of the hydroxyapatite crystals showed that Mg^{2+} supplementation resulted in reduced Ca^{2+} and Pi fractions of 68% and 41%, respectively, without increasing the fraction of Mg^{2+}.

Conclusions: This study demonstrates that Mg^{2+} inhibits bVSMC mineralization through inhibition of Ca^{2+}-apatite formation in the extracellular space, independent of VSMC transdifferentiation. These results emphasize the need for randomized-controlled clinical trials assessing the effects of Mg^{2+} supplementation on vascular calcification.

Bone Turnover in Patients with Calcific Uremic Arteriolopathy Sagar U. Nigwekar,[2] Jeffrey L. Hymes,[1] Diane M. Rondeau,[1] Franklin W. Maddux,[1] Ravi I. Thadhani.[2] *[1]Fresenius Medical Care, Waltham, MA; [2]Massachusetts General Hospital, Boston, MA.*

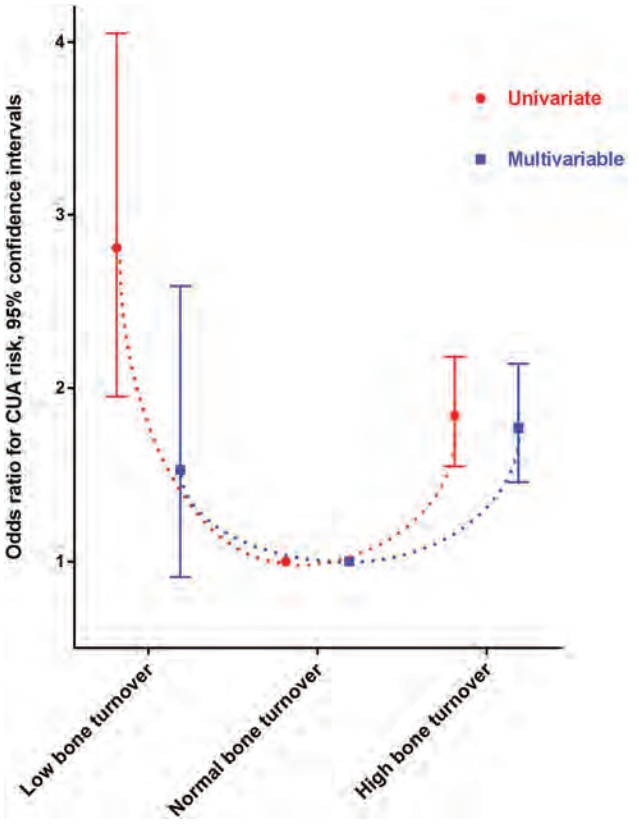
Background: Calcific uremic arteriolopathy (CUA) is an arteriolar calcification disorder with no effective treatment. Investigation of links between bone and vascular health in ESRD has largely focused on arterial calcifications; however the relationship between bone turnover and CUA is not well studied.

Methods: We examined the prevalence of bone turnover categories at hemodialysis (HD) initiation in patients who subsequently developed CUA. Bone turnover categories were defined by intact parathyroid hormone (iPTH) and alkaline phosphatase (ALK): high turnover if iPTH is >323 pg/mL and ALK>80 U/L; low turnover if iPTH is <103 pg/mL and ALK <25 U/L. We compared the prevalence of bone turnover categories between CUA patients and age, sex, and race matched controls. Univariate and multivariable logistic regression analyses were performed.

Results: We analyzed data from 1,030 CUA cases and 2,060 controls. High bone turnover at HD initiation was present in 8% of patients and low turnover in 9% of patients who subsequently developed CUA. Among controls, the prevalence of high bone turnover was 3% and of low turnover was 4%, both lower than in CUA patients (p<0.001). Both high and low bone turnover at HD initiation were associated with increased odds of subsequent CUA development in univariate and multivariable analyses adjusted for diabetes mellitus, obesity, and warfarin [figure].

Conclusions: The association between bone turnover at HD initiation and subsequent CUA development is U-shaped. Confirmation in future studies that apply bone biopsies will pave the way for targeted therapeutics to prevent/treat CUA (e.g. bisphosphonates, RANKL inhibitors for high turnover and teriparatide for low turnover).

Funding: Private Foundation Support



Risk of subsequent CUA development is increased in patients with low and high bone turnover at dialysis initiation

SA-PO853

The Specificity of Histologic Findings in Calciphylaxis W. Charles O'Neill. *Emory University, Atlanta, GA.*

Background: The diagnosis of calciphylaxis, also known as calcific uremic arteriolopathy (CUA), usually depends on a skin biopsy but data on the specificity of histopathologic criteria are limited. To assess this, histolology was compared in skin biopsies performed for a suspicion of CUA and in skin obtained from healthy margins of amputations in ESRD patients without CUA.

Methods: Skin biopsies in 38 patients with a clinical suspicion of CUA and 43 amputations from ESRD patients without CUA were identified retrospectively. Patients with skin biopsies were assigned a low (16), moderate (6), or high (16) suspicion for CUA based on review of the medical record by a nephrologist unaware of the biopsy results. This determination was based largely on the impression of the consulting dermatologist. Hematoxylin and eosin and von Kossa stains were examined for medial calcification, intimal hyperplasia, or thrombosis of small arteries or arterioles, and for extravascular soft tissue calcification by a pathologist unaware of the clinical information.

Results: Lesions in small arteries or arterioles were present in 35% of amputation specimens and 55% of skin biopsies, but in 87% of skin biopsies from patients with a high suspicion of CUA. Comparison of amputations and high-suspicion skin biopsies is shown in the table. The combination of vessel calcification and thrombosis showed the greatest difference, being 6-fold more prevalent in high-suspicion skin biopsies. The combination of vessel calcification and intimal hyperplasia was not seen in any specimen. There were no significant differences between the findings in amputations and those in the skin biopsies from patients without a high clinical suspicion for CUA.

Conclusions: Histopathologic findings historically associated with calciphylaxis also occur in viable tissue from unaffected ESRD patients. This calls into question the specificity of individual histologic findings for calciphylaxis. However, the combination of vessel calcification and thrombosis may provide more specificity.

Protein Carbamylation Exacerbates Vascular Calcification Daisuke Mori,[1] Isao Matsui,[1] Nobuhiro Hashimoto,[1] Ayumi Matsumoto,[1] Karin Shimada,[1] Satoshi Yamaguchi,[1] Tatsufumi Oka,[1] Keiichi Kubota,[1] Sayoko Yonemoto,[1] Yusuke Sakaguchi,[2] Takayuki Hamano,[2] Yoshitaka Isaka.[1] *[1]Osaka University Graduate School of Medicine, Suita, Japan; [2]Department of Comprehensive Kidney Disease Research, Osaka University Graduate School of Medicine, Osaka, Japan.*

Background: Protein carbamylation is an irreversible posttranslational modification that can occur non-enzymatically in the presence of urea. Although carbamylation is recognized as a prognostic biomarker, the effects of protein carbamylation on organ dysfunction remain uncertain.

Methods: Using *in vitro, ex vivo, in vivo* models, we investigated the effects of carbamylation on vascular calcification (VC), a life-threatening pathological condition that is common under carbamylation-prone situations.

Results: Protein carbamylation exacerbated the calcification of human vascular smooth muscle cells (hVSMCs) by suppressing the expression of ectonucleotide pyrophosphate/phosphodiesterase 1 (ENPP1), a key enzyme in the generation of pyrophosphate. By using immunoprecipitation in combination with mass spectrometry, we determined that several mitochondrial proteins, including ATP synthase subunits α and β, were carbamylated, although ENPP1 itself was not identified as a carbamylated protein. Rather, protein carbamylation reduced mitochondrial membrane potential and exaggerated mitochondria-derived oxidative stress, which downregulated ENPP1. The effects of carbamylation on ectopic calcification were abolished in mitochondrial-DNA-depleted hVSMCs and in hVSMCs treated with Mito-TEMPO, which indicated that mitochondria played essential roles in carbamylation-mediated effects. We also evaluated the carbamylation effects by using *ex vivo* and *in vivo* models: Protein carbamylation suppressed enzymatic histochemical staining for cytochrome c oxidase and succinate dehydrogenase in rat aortae, exacerbated calcifying-medium-induced VC in aortic ring cultures, and exacerbated warfarin/vitamin-D-induced VC in rats.

Conclusions: Protein carbamylation exacerbates VC by exaggerating mitochondria-derived oxidative stress and the resultant suppression of ENPP1.

SA-PO855

Direct Inhibition of Phosphate-Induced Vascular Smooth Muscle Cell Calcification via Suppression of PiT2 Expression by 25-Hydroxyvitamin D Masanori Tokumoto,[2] Shunsuke Yamada,[1] Kazuhiko Tsuruya,[3] Takanari Kitazono,[1] Hiroaki Ooboshi.[2] *[1]Department of Medicine and Clinical Science, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan; [2]Department of Medicine, Fukuoka Dental College, Fukuoka, Japan; [3]Department of Integrated Therapy for Chronic Kidney Disease, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan.*

Background: Inverse association between 25-hydroxyvitamin D (25(OH)D) level and cardiovascular (CV) risk has been reported. Recently, the low serum 25(OH)D levels, which are frequently recognized in chronic kidney disease, has been also connected with vascular calcification, but the mechanism remains fully unknown. In the present study, we examined whether 25(OH)D directly reduce phosphate (P)-induced vascular smooth muscle cell (VSMC) calcification and its mechanism.

Methods: Human VSMCs were cultured in high P media with the additional P load of 2.0mM to induce calcification and treated with 25(OH)D of 10^{-10} ~ 10^{-6} M for a week. The degree of calcification and the expression of intrinsic calcification inhibitors and osteogenic differentiation markers were examined at Day 1 and 7. The degree of calcification was expressed as the calcium (Ca) content precipitated on the human VSMCs, and the content of calciprotein particle (CPP) was expressed as the Ca content in the precipitation of media, centrifuged by 16,000g for 2 hours at room temperature.

Results: Megalin and 1-hydroxylase were expressed in human VSMCs, and P-induced calcification was decreased with 25(OH)D of 10^{-10} ~ 10^{-7} M ($p<0.01$) at Day 7. The PiT1 expression was not altered by administration of 25(OH)D, but the PiT2 expression was decreased with 25(OH)D of 10^{-10} ~ 10^{-6} M at Day 1 and 7 ($p<0.01$). The Ca contents at Day 7 were correlated with the PiT2 expression at Day 1 and 7 ($p<0.01$, $r=0.66$ and 0.57, respectively). Furthermore, the CPP content and the SOX9 expression were correlated with the PiT2 expression at Day 1 ($p<0.01$, $r=0.55$, and $p<0.05$, $r=0.49$, respectively). Our results indicate that 25(OH)D ameliorates P-induced calcification via the inhibition of PiT2 expression in human VSMCs.

Conclusions: Our results indicate that 25(OH)D ameliorates P-induced calcification via the inhibition of PiT2 expression in human VSMCs.

Source of Matrix Vesicles (MV) Differentially Affect Cell Signaling and Calcification in Co-Cultures with Recipient Vascular Smooth Muscle Cells (VSMC) Neal X. Chen,[1] Kalisha O'Neill,[1] Sharon M. Moe.[1,2] *[1]Indiana University School of Medicine, Indianapolis, IN; [2]Roduebush Veterans Affairs Medical Center, Indianapolis, IN.*

Background: In patients with CKD the major risk factor for progression of arterial calcification is the presence of existing (baseline) calcification. VSMC from CKD rats produce MV; vesicles isolated from cell lysate (cellular) induce calcification in co-cultures with recipient normal rat VMSC whereas those from media do not. We hypothesized that

the induction of different signaling pathways by recipient normal VSMC explains the differential effect on calcification.

Methods: Cellular and Media derived MV from VSMC were examined for structure and content by transmission electron microscopy (TEM) and Western blots. Both types of MV were co-cultured with recipient VSMC and alteration of oxidative stress (ROS production), intracellular calcium ($[Ca]_i$), gene expression and calcification were determined by biochemical assay or real time PCR.

Results: TEM showed both types of MV are around 100 mm diameter membrane–bound vesicles of similar structure. By Western blot, both media and cellular MVs contain the exosomal tetraspanins CD63 and CD81. Media MV contain significantly greater fetuin-A and lower annexins than cellular MV. The addition of media MV to recipient normal VSMC increased ROS production but had no effect on intracellular Ca ($[Ca^{2+}]_i$). In contrast, the addition of cellular MV to normal VSMC had no effect on ROS but significantly increased $[Ca^{2+}]_i$ despite evidence that both are similarly endocytosed. Both media and cellular MV increased gene expression of NOX1 but cellular MV also increased the expression of anti-oxidant superoxide dismutase-2 (SOD2) by 94% whereas media MV had no effect. Blockade of NOX1 activity with GKT137831 reduced media MV-induced ROS production by 25% in recipient VSMC and blocked cellular MV-induced calcification in recipient VSMC.

Conclusions: Cellular and media derived MV from CKD rats have different components and induce distinct cell signaling, gene expression and calcification in recipient normal VMSC. Cellular derived MV, as compared to media MV, do not induce ROS presumably due to a favorable oxidant/anti-oxidant ratio suggesting the ultimate cellular fate of the two MV types may be different.

CKD Patients with Calciphylaxis and Sodium Thiosulfate Treatment: A Systematic Review and Meta-Analysis Suwasin Udomkarnjananun, Paweena Susantitaphong, Somchai Eiam-Ong, Kearkiat Praditpornsilpa. *Chulalongkorn University, Bangkok, Thailand.*

Background: Chronic kidney disease (CKD) patients with calcific uremic arteriolopathy (CUA, calciphylaxis) are at high cardiovascular and mortality risks. Sodium thiosulfate (STS) is currently the most common treatment for CUA but the outcome is still unclear. Our objective is to systematically explore the outcome of CUA treatment with STS in CKD patients.

Methods: We searched MEDLINE, Scopus, and Cochrane Central Register of Controlled Trials from 1960 to April 2017 to identify case-control, cohort, and randomized controlled trials reporting the mortality rate of CKD patients with CUA and the outcomes after treated with STS. Only human studies published in English language were included.

Results: From 1,071 articles searched, 24 cohort and case-control studies reporting mortality rate of CKD patients with CUA were included into a systematic review. Ten of them were specified on STS treatment outcomes and had enough details for data analysis. No randomized controlled trial were found. There were total 284 patients receiving STS,27.1(22.2-32.7)% were male and 53.1(47.2-58.9)% had diabetes mellitus. The CUA lesions were mainly in the lower extremities (87.3%,63.2-96.5%). Mean accumulated STS dosages were 796±276 grams and mean duration of treatment were 10±2 weeks. After treatment with STS the wound completely resolved in 34.8 (22.6-49.55)% and partially resolved in 35.5 (24.6-48.2)%. The overall mortality rate of CUA patients receiving STS was 57.8 (45.7-68.9)%, as high as the pooled mortality rate from general 1,707 CUA patients (57.2%,49.3-64.8%). The odds ratio for mortality showed no statistical significance between the patients who had received STS and who had not (odds ratio 0.62,95%CI 0.27-1.42).

Conclusions: This is the first systematic review and meta-analysis of STS treatment in CKD patients with CUA. Although about 70% of CUA patients had wound improvement, the mortality was not lowered with STS treatment compared to the general CUA patients. Lacking of controlled trials may limit the evidence of the true efficacy of STS.

Combined Therapy of Menaquinone-7 and Omega-3 Fatty Acid Prevents Progression of Aortic Calcification in Adenine and Low Protein Diet Induced Rat Model Su mi Lee,[1] Hyuck jae Choi,[1] Kitae Kim,[2] Sung Hyun Son,[2] Young ki Son,[1] Seong Eun Kim,[1] Won Suk An.[1] *[1]Department of Internal Medicine, Dong-A University, Busan, Not Applicable, Republic of Korea; [2]BHS Han Seo Hospital, Busan, Republic of Korea.*

Background: Vascular calcification is common and progressing in chronic kidney disease and dialysis patients. Diet with high-dose menaquinone-7 (MK-7) (100 ug/g diet) inhibited the development of cardiovascular calcification in 5/6 nephrectomy rat combined with high phosphate diet. Eicosapentaenoic acid (1g/kg/day), one of omega-3 fatty acid (FA), attenuates arterial medial calcification induced by warfarin. We evaluated whether the effect of omega-3 FA and MK-7 on aortic calcification in adenine and low protein diet induced vascular calcification rat model.

Methods: Male Sprague Dawley rats were fed the diets containing 0.75% adenine and 2.5% protein for 3 weeks. After 3 weeks, 4 rats were sacrificed for calcification evaluation of thoracic aorta. Thirty two rats were randomly divided into four groups, which were treated and fed the diets containing 2.5% protein for 4 weeks: adenine control (0.9% saline), adenine control treated with omega-3 FA (300 mg/kg/day by gastric gavage), adenine control treated with MK-7 (50 ug/kg/day by gastric gavage), adenine control treated with omega-3 FA and MK-7. Normal control rats were fed the diets containing 2.5% protein for 7 weeks. For quantitative assessment of aortic calcification, von Kossa stain of aorta was done and calcium contents were measured with calcium colorimetric kit.

Results: Serum creatinine of adenine control group treated with omega-3 FA and MK-7 was lower than adenine control group without treatment. Serum calcium and BUN levels were not significantly different between adenine control group with treatment and without treatment. Two rats among 4 rats showed aortic calcification at 3 weeks. After 4 weeks, aortic calcification was progressed in adenine control group without treatment on von Kossa stain and calcium contents analysis of aorta. Aortic calcification on von Kossa stain and calcium contents was the least progressed in adenine control group treated with combination of omega-3 FA and MK-7 compared to omega-3 FA or MK-7 single therapy.

Conclusions: Combined treatment with omega-3 FA and MK-7 definitely prevents progression of aortic calcification compared to rat without treatment in adenine and low protein diet induced vascular calcification rat model.

SA-PO859

Nrf-2 Attenuates Vascular Calcification in CKD-MBD by Suppression of Oxidative Stress Yi Li,[3] Daqing Hong,[2] Guisen Li,[1] Li Wang.[2] *[1]Renal Division and Institute of Nephrology, Sichuan Academy of Medical Sciences and Sichuan Provincial People?s Hospital, Chengdu, China; [2]Sichuan Provincial People's Hospital, CHENGDU, China; [3]University of Electronic Science and Technology, Chengdu, China.*

Background: Under pathological conditions in vascular calcication, uncontrolled production of ROS induced increased oxidase activities and impaired cellular antioxidant systems. NF-E2 p45-related factor-2 (Nrf-2) is a powerful factor to regulate oxidative stress. In our study, we aimed to validate the effect and mechanism of Nrf-2 on vascular calcification of ESRD involving oxidative stress.

Methods: We selected 36 patients admitted at the Department of Nephrology in Sichuan Provincial's Hospital between 2011 and 2012. 14 cases of age and sex matched biopsy-proven non-calcification were selected as negative control and 7 healthy volunteers as normal control. To mimick vascular calcification in ESRD, we used β-glyceophosphate to stimulate the rat vascular smooth muscle cells (RASMCs). 24 rats were randomly assigned to 4 groups: normal control group, vascular calcification group, vascular calcification with DMF treatment group and DMF treated alone group. The rattus CKD-MBD vascular calcification was induced by injection of Vitamin D3 and gavage nicotine.

Results: The blood phosphorus and iPTH in ESRD patients with vascular calcification was significantly increased. Nrf-2 expression was negaitvely correlated with vascular calcification in ESRD patients indicating by Alizarin-red S staining and immunohistological staining. To further elucidate the role of Nrf-2 in vascular calcification of CKD-MBD, we had knockdown or pharmacological blockaded Nrf-2 in rat aortic smooth cells (RASMCs) followed by hyperphosphate treatment. Then we observed that knockdown or pharmacological blockade Nrf-2 could induce vascular calcification in CKD-MBD. Nrf-2 agonist treatment showed that activation Nrf-2 could ameliorate vascular calcification in RASMCs. Then ROS inhibitor NAC pretreatment increased the level of Nrf-2 and ameliorated vascular calcification in RASMCs. Activation of Nrf-2 inhibited oxidative stress and attenuated mitochondria injury in RASMCs upon vascular calcification. Pathological examination reaveled that Nrf-2 agonist could suppress vascular calcification in rat CKD aortas. Immunohistological staining about Nrf-2 indicated that calcified rat aortas decreased the expression of Nrf-2. However, DMF increased the expression of Nrf-2 in vascular calcification rat aortas.

Conclusions: These resluts might indicate Nrf-2 attenuates vascular calcification in CKD-MBD by suppression of oxidative stress.

SA-PO860

BMP7 Ameliorates Procalcific Gene Expression Patterns in the Calcified Uremic Aorta Eva Gravesen,[3] Maria L. Mace,[1] Anders Nordholm,[1] Jacob Hofman-Bang,[3] Keith A. Hruska,[2] Klaus Olgaard,[3] Ewa Lewin.[1] *[1]Herlev Hospital, Copenhagen, Denmark; [2]Washington University St. Louis, St. Louis, MO; [3]Rigshospitalet, University of Copenhagen, Copenhagen, Denmark.*

Background: Hyperphosphatemia and vascular calcification(VC) are frequent complications of chronic renal failure(CRF). BMP7 has been shown to protect against development of VC in uremia. Thus the potential reversibility of established VC was examined in two experimental models; 1. by studying if BMP7 treatment could reduce the degree of VC in uremia and 2. by isogenic transplantation(ATx) of the calcified aorta from uremic rats to healthy littermates.

Methods: CRF and VC was induced in adult DA-rats by 5/6 nephrectomy, high phosphate(P) diet and alfacalcidol treatment. After 14 wks, severe VC was present. In model 1, CRF rats were allocated either to 250µg/kg of BMP7 ip once weekly or vehicle for 8 wks. In model 2, the abdominal aorta was transplanted orthotopically from CRF rats to healthy littermates. Ctrl group had normal to normal ATx. Rats were sacrificed 4 wks after ATx.

Results: BMP7 treatment resulted in a significant reduction of plasma P from 2.06±0.14 to 1.56±0.07mmol/L, p<0.01, despite persistent uremia. Uremia induced increase in aortic expression of fibronectin 1.15±0.11, periostin 1.31±0.14 and activin-A 1.34±0.06, and BMP7 treatment resulted in a significant decrease; Fn1 0.82±0.09, Postn 0.91±0.09, Inhiba 0.97±0.11, p<0.05. In the BMP7 study Ca content was significantly increased in the uremic vehicle treated rats both in the distal abdominal aorta 1.9±0.2µg/mg and in the proximal thoracic aorta 71±11µg/mg, and similar levels were seen in the BMP7 treated rats; 2.2±0.2µg/mg in the distal abdominal aorta and 54±7µg/mg in the proximal thoracic aorta. In the ATx study Ca content of the aorta from uremic rats was significantly elevated to 17.0±0.2µg/mg in the proximal abdominal aorta and similarly increased in the transplanted uremic aorta 15.9±0.6µg/mg, confirming that established uremic VC is not reversible despite removal of the uremic milieu.

Conclusions: BMP7 treatment resulted in a significant decrease in the expression of procalcific genes and a siginificant decrease in plasma P. Despite these favorable changes no effect on aortic Ca content was seen. These results were confirmed in the ATx study, where complete reversal of the uremic mileu neither reversed established uremic VC.

Maintenance of Vascular Microrna-145 Levels Effectively Attenuates Uremia- and High Phosphate-Induced Aortic Calcification Sara Panizo,[1] Natalia Carrillo-Lopez,[1] M. Vittoria Arcidiacono,[2,3] Sandra De la fuente,[3] Anabel Castro,[3] Manuel Naves,[1] Isabel Rodriguez,[1] Jorge B. Cannata-Andia,[1,4] Adriana S. Dusso.[1] *[1]Bone and Mineral Research Unit, Hospital Universitario Central de Asturias, Instituto Reina Sofía de Investigación, REDinREN del ISCIII, Oviedo, Spain; [2]Department of Morphology, Surgery and Experimental Medicine and LTTA Centre, University of Ferrara, Ferrara, Italy; [3]Division of Experimental Nephrology, IRB Lleida, Lleida, Spain; [4]Department of Medicine, Faculty of Medicine, University of Oviedo, Oviedo, Spain.*

Background: In CKD, the control of vascular calcification (VC) is essential to reduce the risk of cardiovascular mortality. Herein, maintenance of mature microRNA-145 (miR-145) was examined as an anti-calcifying strategy because: a) miR-145 is the prevalent miR in vascular smooth muscle cells (VSMC) and essential to maintain their contractile phenotype; b) miR-145 targets osteogenic Osterix in osteoblasts; c) high phosphate (P) reduces normal VSMC miR-145 levels supporting a link between high P, miR-145 reductions, increased Osterix and VC.

Methods: Aortic calcium (Ca), pri-miR-145, miR-145 content and mRNA levels of vascular/osteogenic markers (a-actin and Osterix) were measured in: a) A7r5 cells (rat aorta VSMC), with or without miR-145 over-expression or silencing, and exposed to calcifying (2mM Ca; 3mM P) or non calcifying (1mM Ca; 1mM P) conditions for 4 days; b) Aortas from either 5/6 nephrectomized (NX) rats fed high dietary P for a month or from 3/4NX mice fed normal dietary P for 3½ months.

Results: In A7r5 cells, the exposure to calcifying media (CM) significantly reduced miR-145 levels in part through a 30% downregulation of pri-miR-145 (p<0.04) which supports the inhibition of miR-145 gene expression. Also, while miR-145 silencing further exacerbated the osteogenic differentiation (reduced α-actin and increased Osterix mRNAs) and Ca deposition induced by the CM, miR-145 overexpression markedly attenuated both. Importantly, miR-145 silencing also reduced α-actin and increased Osterix under non-CM. Accordingly, in 5/6NX rats fed high P, an inflexion point value was found for aortic miR-145 that accurately discriminated aortas with higher than normal Ca content (miR-145 levels below the threshold) from those with normal Ca content (aortic miR-145 above the threshold) (p<0.005, n=24). Also, in the mouse model mimicking slow human CKD progression with no hyperphosphatemia, an 85% reduction of aortic miR-145 concurred with an 80% reduction in aortic α-actin but no significant increases in Osterix or Ca content.

Conclusions: Maintaining vascular miR-145 levels should attenuate the vascular phenotype switch prompting osteogenic differentiation and calcification from early CKD stages and regardless of serum P.

Change in EXTL2, a Novel Factor Related to Vascular Calcification, in Hemodialysis Patients Shunsuke Goto,[1] Hideki Fujii,[1] Satomi Nadanaka,[2] Kentaro Watanabe,[1] Shuhei Watanabe,[1] Keiji Kono,[1] Shohei Nakanishi,[3] Jong-Il Kim,[3] Hiroshi Kitagawa,[2] Shinichi Nishi.[1] *[1]Kobe University Graduate School of Medicine, Kobe, Japan; [2]Kobe Pharmaceutical University, Kobe, Japan; [3]Chibune General Hospital, Osaka, Japan.*

Background: Vascular calcification is an important risk factor in hemodialysis patients. Although various factors are associated with vascular calcification, the mechanisms are not fully understood. Recent experimental study has reported that knockout of glycosaminoglycan-related enzyme exostosin-like 2 (EXTL2) was associated with vascular calcification in 5/6 nephrectomized mice. However, there are only a few clinical papers on it and EXTL2 has not been investigated in hemodialysis patients yet. The aim of our study was to investigate EXTL2 in hemodialysis patients.

Methods: We included 15 stable hemodialysis patients and 12 healthy control subjects in this study. We measured mRNA expressions of EXTL2, other glycosaminoglycan-related enzyme chondroitin 4-O-sulfotransferase 1 (C4ST1), xylosyltransferase 2 (XYLT2), and family with sequence similarity 20 member B (Fam20B) in blood. These mRNAs expressions were compared between hemodialysis patients and controls.

Results: mRNA expression levels of EXTL2 were 0.15 (0.10-0.24) in hemodialysis patients, and those were significantly lower compared to the control subjects (0.45 (0.27-0.55), p < 0.05), while, mRNA expression levels of C4ST1, XYTL2, and Fam20B were comparable between the two groups.

Conclusions: Our data suggested that EXTL2 levels decreased in hemodialysis patient compared to general population. Further study is needed to elucidate whether the decrease in EXTL2 is associated with the progression of vascular calcification in hemodialysis patients.

SA-PO863

Relationship between Abdominal Aortic Calcifications by a Plain Lateral Lumbar X-Ray and Coronary Artery Calcifications by a CT-Based X-ray in CKD Patients Kittisak Thanwirunroj, Pongsathorn Gojaseni, Anutra Chittinandana. *Department of Medicine, Bhumibol Adulyadej Hospital, Royal Thai Air Force, Bangkok, Thailand.*

Background: The presence and severity of cardiovascular calcifications strongly predict cardiovascular mortality in patients with chronic kidney disease (CKD). Most studies examining calcifications in CKD patients use computed tomographic (CT)-based techniques which are relatively expensive to detect coronary artery calcifications (CAC). This study focuses on testing whether lateral abdominal radiographs, which are widely available and less costly, could be used instead of CT imaging.

Methods: A cross-sectional study was done in patients diagnosed as pre-dialysis CKD stage 3-5. All participants were detected CAC scores by a CT-based technique and abdominal aortic calcification (AAC) by a lateral plain film of the lumbosacral (LS) region within 3 months after enrollment. Medical data were collected from patients and medical records.

Results: A total of 70 patients (44 males, 26 females), aged 70.59 ± 10.16 years were enrolled in this study. There was a significant association between CT-based Agatston CAC scores and plain film-based AAC scores. The correlation coefficient (r) between CAC scores and 4-scale AAC, 8-scale AAC and 24-scale AAC were 0.399 (p = 0.001), 0.364 (p = 0.002) and 0.385 (p = 0.001), respectively. From ROC analysis, it was shown that AAC scores had strong correlation with CAC scores ≥ 400, which is considered to be a good predictor of cardiovascular mortality [figure 1].

Conclusions: Abdominal aortic calcification detected by lateral abdominal radiographs could be used instead of CT-based coronary calcification scores. Prognostic value of the abdominal aortic calcification in this population should be determined in large scale, prospective cohort studies.

Funding: Government Support - Non-U.S.

SA-PO864

Do Hemodialysis and Peritoneal Dialysis Differ Regarding Their Effect on Coronary Calcification? Thijs T. Jansz,[2] Franka E. Van reekum,[2] Akin Ozyilmaz,[1,5] Marianne C. Verhaar,[2] Brigit C. van Jaarsveld.[3,4] *[1]University Medical Center Groningen, Groningen, Netherlands; [2]University Medical Center Utrecht, Amsterdam, Netherlands; [3]VU medical center, Amsterdam, Netherlands; [4]Diapriva Dialysis Center, Amsterdam, Netherlands; [5]Dialysis Center Groningen, Groningen, Netherlands. Group/Team: NOCTx investigators*.

Background: Identifying modifiable risk factors of vascular calcification in end-stage renal disease is crucial in light of the associated high cardiovascular morbidity and mortality. In this cross-sectional study, we compared coronary artery calcification and levels of biomarkers associated with vascular calcification in pts treated with hemodialysis (HD) and peritoneal dialysis (PD), respectively.

Methods: We assessed coronary artery calcification using multi-slice computed tomography in 121 pts treated with HD (≤ 16 hrs/wk) and 46 pts treated with PD, who were included in the NOCTx study (NCT00950573). Biomarker measurements were performed in a subset of 55 HD and 33 PD pts using enzyme-linking immuno-assays and multiplex assays. We adjusted for age, sex, dialysis vintage, diabetes mellitus, use of vitamin K antagonists, smoking and residual diuresis in multivariate analyses.

Results: Pts treated with HD were somewhat older (53.1 ± 12.2 versus 49.8 ± 15.1 years) and had been on dialysis longer (26, IQR 12 – 57 versus 14, IQR 7 – 33 months). In univariate and multivariate analyses, coronary artery calcification in HD pts (median score 208, IQR 1 – 809) was not significantly different from PD pts (median score 84, IQR 0 – 1066). In HD pts, phosphate levels tended to be higher compared with PD pts (1.68 ± 0.39 versus 1.59 ± 0.35 mmol/L). Osteoprotegerin was evidently lower in HD pts (2.95 ± 1.33 versus 3.43 ± 1.81 µg/L, $p < 0.01$), while inactive matrix Gla protein (dp-ucMGP) levels did not differ significantly between HD and PD pts. Only dp-ucMGP was independently associated with extent of coronary artery calcification. Inflammatory markers C-reactive protein, interleukin-1β and interleukin-6 did not differ significantly between HD and PD pts. Probably due to intermittent fluid overload in HD, NT-proBNP was significantly higher in HD pts (2217 ± 1817 versus 1045 ± 1372 pmol/l, $p = 0.01$).

Conclusions: Uremia per se is detrimental for the coronary vasculature, seemingly irrespective of treatment with HD or PD. Whether coronary artery calcification and its progression are affected by other renal replacement therapies needs further evaluation.

Iron Stimulation Enhanced Calcification Along with TNF-Alpha in Human Vascular Smooth Muscle Cells Yasuyuki Nagasawa,[1,5] Sayuri Kawada,[1,5] Mutsuki Kawabe,[1] Aritoshi Kida,[1,5] Masayoshi Nanami,[5] Takahiro Kuragano,[4] Yukiko Hasuike,[1,5] Keiji Nakasho,[3] Hiromitsu Kishimoto,[1,5] Takeshi Nakanishi.[2,5] *[1]Hyogo College of Medicine, Nishinomiya, Japan; [2]Hyogo College of Mediicne, Nishinomiya, Japan; [3]Hyogo college of medicine, Nishinomiya, Japan; [4]Internal Medicine Division of Kidney and Dialysis, Nishinomiya, Japan; [5]Internal Medicine, Division of Kidney and Dialysis, Nishinomiya, Japan.*

Background: In CKD patients, atherosclerosis is one of important key factors which determine their prognosis. It was reported the calcification induced by TNF-alpha was related with iron in HUVEC cells by our group. The feature of the atherosclerosis in CKD patients was called as Moenckeberg's arteriosclerosis which was seen in vascular media, but the relationship between iron and calcification in vascular smooth muscle cell remained unclear. To reveal the relationship between calcification in vascular media and iron stimulation using cultured vascular smooth muscle cells.

Methods: The aorta smooth muscle cells were cultured for three weeks. At day 0, we changed the usual culture medium to calcification medium, and TNF-alpha and iron were added to the calcification medium. Calcification in each condition was confirmed by Alizarin staining. And to reveal early mechanism to enhance the calcification by iron and TNF-alpha stimulation, we compared the gene expression profile between each condition in day 1 and day 3 using microarray analyses. We confirmed gene expression of cytokine which had increased in microarray analysis in time course.

Results: We confirmed both iron and TNF-alpha stimulation enhanced calcification by Alizarin Staining. Moreover, both iron and TNF-alpha stimulation at the same time enhanced calcification more strongly than single stimulation. We picked up a cytokine which had increased with both iron and TNF-alpha stimulation in the microarray analysis as similar as the Alizarin Staining result had shown. Also, we confirmed gene expression of this cytokine by real-time PCR. Gene expression was increased at day1 by stimulation of iron(5.8±3.0 fold change vs control), TNF-alpha (7.8±1.9 fold change vs control), and both stimulation(53.1±27.1fold change vs control), synergistically(shown below). At day 3, gene expression showed as same increase as at day 1. The time course of this cytokine was confirmed in mRNA level and in protein levell.

Conclusions: Iron stimulation enhanced calcification in vascular smooth muscle cells along with TNF-alpha stimulation. The possibility was suggested that iron stimulation along with inflammatory induced cytokine expression changes in early stage, which continued during calcification process.

SA-PO866

Relationship between Bone Sialoprotein and Vascular Calcification in Maintenance Hemodialysis Patients Hongwei Wu, Fanna Liu. *The First Affiliated Hospital of Jinan Universtiy, Guangzhou, China*.

Background: Recent studies shown that vascular calcification was a osteoblast-like process involving multiple factors. Bone sialoprotein, a recently discovered protein, participated in the metabolism of bone-vascular axis and expressed in the medial layer of calcified vessel in uremia patients. The mechanism of vascular calcification that influenced by bone sialoprotein was not clear. This study was to evaluate the potential association of bone sialoprotein with the development of abdominal aortic calcification (AAC)in maintenance hemodialysis (MHD) patients.

Methods: Seventy-five patients who were on MHD between May 2016 and Feb 2017 in the dialysis center were enrolled. Serum bone sialoprotein was tested. AAC was measured by abdomen lateral plain. Kauppila score was used to assess the degree of CAC. Referring to CORD segmentation method, patients was divided into three groups: no or mild calcification group, moderate calcification group and severe group. Logistic regression analysis was used to determine the risk factor of AAC in MHD patients. The diagnostic value of serum bone sialoprotein for AAC was assessed using receiver operator characteristic curve (ROC).

Results: AAC(AACs>4) was present in 49.3% (37/75) patients, the median AAC score was 4(0,24). The median of serum bone sialoprotein was 20.12(18.63,24.21)ng/mL. The serum bone sialoprotein levels were significantly elevated in moderate calcification group and severe group compared to no or mild calcification group [22.43(19.58,26.84) ng/L and 21.99(19.87,26.18)vs 19.16(17.3,23.3)g/L, $P<0.05$]. Multivariate logistic regression analysis showed that serum bone sialoprotein level was independent risk factor for AAC (OR=1.175,95%CI 1.004~1.375, $P<0.05$). The area under the ROC curve of serum sclerostin for AAC was 0.718 (95%CI 0.604~0.833,P=0.001), sensitivity was 0.711, and specificity was 0.595 for a cutoff value of 21.51 ng/L.

Conclusions: Serum bone sialoprotein level is associated with AAC. Serum bone sialoprotein level may have a diagnostic value for AAC in MHD patients.

Endothelial Hyperpermeability Induced by Mineral Stress Is Involved in the Development of Medial Layer Vascular Calcification Yasuto Shikida,[1] Masahide Mizobuchi,[1] Hiroaki Ogata,[2] Fumihiko Koiwa,[3] Takanori Shibata.[1] *[1]Division of Nephrology, Department of Medicine, Showa University School of Medicine, Tokyo, Japan; [2]Department of Internal Medicine, Showa University Northern Yokohama Hospital, Yokohama, Japan; [3]Division of Nephrology, Department of Medicine, Showa University Fujigaoka Hospital, Yokohama, Japan.*

Background: Mineral stress such as high calcium and/or phosphate induces vascular calcification (VC) in chronic kidney disease. Although investigations regarding VC are growing, the precise mechanisms underlying the development of VC by the mineral stress remain to be studied. We investigated the role of vascular endothelial cell (EC) function in medial layer VC.

Methods: Human Umbilical Endothelial Cells (HUVEC) and aortic rings from normal and 5/6 nephrectomized uremic rats were used. Mineral stress was induced by a high calcium (3.6 mM) and phosphate (2.2 mM) media to HUVEC and aortic rings. Thereafter permeability and EC markers (CD31, VE-cadherin, and ZO-1) of HUVEC, and calcium contents and EC markers of aortic rings were studied. Alizarin red staining was also performed to evaluate the localization of mineral deposition in the rings. Regular media was utilized as control groups in each experiment.

Results: The mineral stress significantly increased permeability of HUVEC (2.5-fold to control, $p<0.05$) in conjunction with a significant decrease in mRNA levels of EC markers (CD31:0.5-fold to control, $p<0.01$, VE-cadherin: 0.7-fold to control, $p<0.05$, and ZO-1: 0.7-fold to control, $p<0.05$). The mineral stress also significantly increased calcium content in the aortic rings of normal ($p<0.05$ vs control) and uremic rats ($p<0.05$ vs control), respectively. A similar tendency was observed for EC markers in the rings of normal and uremic rats, respectively. Alizarin red staining showed medial layer mineral deposition of the aortic rings. (Figure: the ring of a uremic rat with the mineral stress).

Conclusions: Hyperpermeability of vascular ECs was induced by mineral stress indicating that loss of barrier function of ECs might have a crucial role in the development of medial layer VC.

Vitamin K and Vascular Health: A Systematic Review and Meta-Analysis Jennifer S. Lees,[2,1] Fiona A. Chapman,[1] Patrick B. Mark.[2,1] *[1]NHS Greater Glasgow and Clyde, Glasgow, United Kingdom; [2]University of Glasgow, Glasgow, United Kingdom.*

Background: Vitamin K deficiency is prevalent among patients with chronic kidney disease. Matrix Gla protein, an important regulator of vascular calcification, is dependent on adequate vitamin K intake. We conducted a systematic review and meta-analysis of effect of vitamin K supplementation on vascular health, and assessed evidence that level of desphospho-uncarboxylated Matrix Gla protein (dpucMGP) is associated with incident cardiovascular disease (CVD) or mortality.

Methods: Two authors searched Medline, Embase, Cochrane and Google for: i) adult human studies of vitamin K supplementation versus control which measured effect on vascular calcification, vascular stiffness or dpucMGP, and ii) prospective observational studies assessing effect of baseline dpucMGP on incident CVD or mortality. Random effects meta-analysis was conducted using *meta* and *metafor* packages for R statistical software package. Egger regression and Trim and Fill were used to assess for publication bias.

Results: Electronic searching identified i) 5095 and ii) 1850 references of which i) 8 and ii) 12 met our pre-specified inclusion criteria. In groups treated with vitamin K, there was a meaningful change in vascular calcification (see Figure, p=0.038) and dpucMGP (n=6, -235.5 (-292.1; -178.8) pmol/l, p<0.001), and a trend towards improvement in vascular stiffness (n=3, -3.70 (-7.77; 0.37) %, p=0.075). Over a median follow up period of 7.8 years (IQR 4.9-11.3), stepwise increase in dpucMGP was not associated with fatal or non-fatal CVD (log HR 0.06 (-0.1; 0.23), p=0.48) or mortality (log HR 0.02 (-0.11; 0.16), p=0.74). Egger regression and Trim and Fill analyes suggest a degree of publication bias in favour of positive results.

Conclusions: Vitamin K supplementation significantly reduces dpucMGP level, though dpucMGP is not associated with incident CVD or mortality. Supplementation appears to reduce progression of vascular calcification, with a trend towards improvement in vascular stiffness, though there are limited data available. Further clinical trials of the effect of vitamin K supplementation on vascular health are warranted.

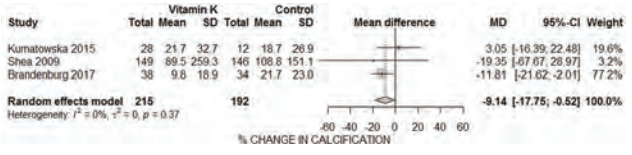

Figure: Forest plot of random effcts meta-analysis: % change in calcification with vitamin K supplementation versus control

SA-PO869

Mortality Prediction of Abdominal Aortic and Pelvic Calcification on Plain X-Ray in CKD, Hemodialysis, and Kidney Transplant Patients Sinee Disthabanchong. *Division of Nephrology, Faculty of Medicine, Ramathibodi Hospital, Mahidol University, Bangkok, Thailand.*

Background: Vascular calcification (VC) is highly prevalent in CKD and predicts poor outcomes. Both cardiovascular and CKD related risk factors participate in the development of VC. The gold standard for evaluation of VC is computed tomography but plain x-rays offer a less costly and less radiation exposure alternative. Lateral abdominal and pelvic x-rays have been utilized to evaluate the calcification of abdominal aorta, iliac and femoral arteries which was found to be highly correlated with abdominal aortic calcification (AAC) and CAC obtained by CT. The data regarding the predictability of AAC and pelvic arterial calcification (PAC) on patient outcomes are limited.

Methods: Four hundred and nineteen CKD stages 2-5 (CKD 2-5), maintenance HD (HD) and long-term KT (KT) patients were included. Only KT recipients who had been transplanted for at least 1 year were enrolled in order to allow the time for stabilization of mineral metabolism. AAC score as described by Kauppila et al and PAC score as described by Adragao et al were applied to determine the severity of AAC and PAC on lateral abdominal and pelvic x-rays respectively. The median follow-up time was 62.7 months for CKD 2-5, 52 months for HD and 62.5 months for KT.

Results: AAC and PAC scores correlated well with the correlation coefficients (*r*) >0.4 in all 3 populations (p<0.001). Patients with AAC score >6 or PAC score >1 were older, had higher prevalence of DM, serum PO_4 and PTH but lower serum albumin and eGFR. Increased KT duration was associated with a more severe degree of AAC, whereas prolonged dialysis vintage was associated with a more severe degree of PAC. Kaplan-meier survival curves revealed AAC score >6 as a significant predictor for all-cause mortality in CKD 2-5 but not in HD or KT, whereas PAC score >1 was a significant predictor of mortality in all 3 populations. After an adjustment for age, the predictability of AAC in CKD 2-5 was lost, whereas PAC >1 remained an independent predictor of mortality in all 3 populations. Further adjustments for age, sex, BMI, serum albumin, calcium and PO_4 revealed the predictability of PAC for mortality in CKD 2-5 patients and KT recipients but not in HD patients.

Conclusions: PAC was a better predictor of mortality than AAC in all 3 populations of CKD and should be considered in the evaluation of VC in CKD and KT patients.

SA-PO870

The Mechanism of Sodium-Dependent Phosphate Cotransporter Pit-1 in Phosphate-Induced Vascular Calcification in HASMCs Minwen Ding, Xinxin Jiang, Mengjing Wang, Minmin Zhang, Jing Chen. *Huashan Hosopital, Fudan Univeristy, Shanghai, China.*

Background: Vascular calcification (VC) is an important risk factor for cardiovascular disease in maintenance hemodialysis (MHD) patients. Hyperphosphatemia and micro-inflammatory state are known to be the prevalent conditions in MHD patients, which contribute greatly to the development of VC. The aims of this study were to explore the effects of hyperphosphate on peripheral blood mononuclear cells (PBMCs) and then the direct effects of hyperphosphate and TNF-αon human aortic smooth muscle cells (HASMCs).

Methods: Low concentration TNF-α(10pg/ml) and supernatants of monocytes (isolated from healthy donors' PBMCs) were used to evaluate the effects of micro-inflammatory on HASMCs. Cells were divided into five groups: NP, HP, TNF-α, supernatants and PFA group. The antagonist of Pit-1 (PFA) was used to explore the possible effects of Pit-1 on monocytes and the further effects on HASMCs. We used Alizarin red staining to determine the vascular calcification extent. The gene expressions of TNF-α, Pit-1 and osteochondrogenic factors (OCF) were tested by Realtime PCR. The excretion of TNF-α in monocytes was evaluated by ELISA. The protein expression of Pit-1 was tested by Western Blot.

Results: 1. After exposure of human monocytes to HP (4M), the concentration and mRNA expression of TNF-α was increased (p<0.05 vs. NP). HP also increased the protein and mRNA expression of Pit-1 (p<0.05 vs. NP). Incubation in the presence of PFA (2M) partially prevented the effects of HP (p<0.05 *vs.* HP). 2. The presence of low concentration TNF-α(10pg/ml) alone or supernatants of monocytes alone had no effect of OCF gene expression or mineralization (p>0.05 vs.NP) on HASMCs. HP increased the mRNA and protein expression of OPN and Runx2 (p<0.05 *vs.* NP) and caused mineralization in HASMCs. 3. After exposure to both HP(4M) and TNF-α(10pg/ml) or supernatants, the mineralization and OCF gene expression were markedly increased in HASMCs (p<0.05 vs.HP). Incubation in the presence of PFA (2M) also partially prevented the aforementioned effects (p<0.05 vs.HP) in HASMCs.

Conclusions: We conclude that via Pit-1, hyperphosphate could increase the synthesis and secretion of TNF-α in human monocytes, furthermore accelerating the vascular calcification in HASMCs, which may be the therapeutic target in preventing vascular calcification in MHD patients.

SA-PO871

Fibroblast Growth Factor-23 and Vascular Calcification in Human Atherosclerosis Juan F. Navarro-Gonzalez, Javier Donate, Ernesto Martín-Núñez, Carla M. Ferri, Angel López-Castillo, Alejandro Delgado-Molinos, Nayra Pérez-Delgado, Carolina Hernández-Carballo, Victoria Castro López-Tarruella, Carmen Mora. *Hospital Universitario Nuestra Señora de Candelaria, Santa Cruz de Tenerife, Spain.*

Background: Fibroblast growth factor 23 (FGF23) is a phosphaturic hormone implicated in disorders of serum phosphorus concentration and vitamin D, as well as in cardiovascular disease. Vascular calcification (VC) is a significant component of vascular disease and atherosclerosis in chronic kidney disease, with important clinical and outcome implications. However, the role of FGF23 in VC remains controversial. In this study we investigate the relationship between FGF23 and VC in patients with clinical atherosclerotic disease.

Methods: Eighty-six patients (mean age, 69.7±10.3 years; 76% males) undergoing an elective open vascular surgery procedure affecting different vascular territories (carotid, aorta, femoral) were included in this study. Serum intact and C-terminal FGF-23 were measured by ELISA. A rabbit polyclonal anti-FGF-23 antibody (1:250 dilution) was used for immunohistochemistry. Transcripts encoding for FGF-23, RunX-2 and GAPDH (housekeeping gene) were measured by TaqMan real-time quantitative PCR.

Results: VC was present in 35 patients (41%). Serum concentrations of FGF-23, both the intact form and the C-terminal, were significantly higher in patients with VC: 24.2

(12-44) vs. 16.8 (10-26) pg/mL; and 36 (27-93) vs. 31.7 (19-52) RU/mL, respectively (P<0.01). We also determined the expression levels of FGF-23 and RunX-2 genes in vascular samples. Expression levels of both genes were significantly higher in samples with VC (P<0.05). Correlation analysis showed a significant association between vascular expression levels of FGF-23 and RunX-2 (r = 0.74, P<0.01). Finally, FGF-23 immunoreactivity was present in 90% of artery samples obtained from subjects with VC, but only in 56% of samples recovered from patients without VC (P<0.05). In all the samples with positive immunoreactivity for FGF-23, the signal for this factor was detected both intra- and extra-cellularly.

Conclusions: In conclusion, FGF-23 is related to VC in patients with clinical atherosclerosis. These findings suggest that transformation of vascular smooth muscle cells (the main cell type involved in VC process in the renal patient) towards an osteogenic phenotype is associated with the capability of these cells to produce FGF-23.

SA-PO872

Premature Vascular Smooth Muscle Cell Ageing Drives Inflammation and Calcification in Children on Dialysis Catherine M. Shanahan,[1] Pilar Sanchis,[1] Yiwen Liu,[1] Chin Yee Ho,[1] Leilani Beltran,[1] David A. Long,[3] Rukshana Shroff.[2] *[1]Cardiovascular Division, King's College London, London, United Kingdom; [2]Nephrology Unit, Great Ormond Street Hospital, London, United Kingdom; [3]University College London, London, United Kingdom.*

Background: Children on dialysis have a cardiovascular mortality risk equivalent to the very elderly in the general population. Medial vascular calcification, an age-associated pathology, is prevalent in these children therefore we investigated whether premature vascular smooth muscle cell (VSMC) ageing might play a role in driving calcification.

Methods: Vessels from children with CKD and controls were harvested at time of surgery and subjected to histological analysis for parameters of ageing. VSMCs grown from these vessels were also phenotyped for calcification propensity and ageing markers including growth capacity, DNA damage, senescence and inflammation. Children with CKD were subjected to vascular phenotyping including pulse wave velocity and spiral CT and these measures were correlated with serum markers of inflammation.

Results: Vessels from children on dialysis showed oxidative DNA damage as well as increased expression of the senescence markers p16 and p21. *In vitro* VSMCs from dialysis patients showed elevated levels of DNA damage, grew poorly and senesced early compared with control VSMCs. DNA damage correlated with increased expression of the osteogenic markers Runx2 and BMP2, and increased calcification in response to elevated levels of calcium (Ca) and phosphate (P). Ca and P treatment induced oxidative DNA damage in CKD vessel rings *ex vivo*, and accelerated VSMC senescence *in vitro*. Cytokine array analysis showed that VSMCs from CKD patients displayed a proinflammatory, senescence associated secretory phenotype (SASP) *in vitro*, and blockade of ATM-mediated DNA damage signalling reduced inflammation. Clinically, children on dialysis showed elevated circulating levels of SASP factors including BMP2, OPG and IL6 and these correlated with increased vascular stiffening and calcification *in vivo*.

Conclusions: Taken together, these data suggest that dysregulated mineral metabolism accelerates VSMC ageing by inducing oxidative DNA damage and premature senescence. In turn, the paracrine SASP promotes osteogenic differentiation, vascular calcification and systemic inflammation suggesting drugs that target DNA damage signalling or senolytics may be therapeutic agents for vascular calcification.

SA-PO873

Activation of the mTORC1 Pathway by Inflammation Contributes to Vascular Calcification in Patients with ESRD Liu Jing. *Institute of Nephrology, Affiliated Drum Tower Hospital, Medical School of Nanjing University, Nanjing, China.*

Background: Chronic inflammation plays an important role in the progression of vascular calcification (VC). This study was designed to explore the effects and underlying mechanisms of inflammation on VC in the radial arteries of patients with end-stage renal disease (ESRD) with arteriovenostomy.

Methods: Forty-eight ESRD patients were divided into control (n=25) and inflamed groups (n=23) according to plasma C-reactive protein (CRP) level. Surgically removed tissues from the radial arteries of patients receiving arteriovenostomy were used in this study. Alizarin Red S staining was used to examine calcium deposition. The expression of inflammation markers, bone structure-associated proteins and mammalian target of rapamycin complex1 (mTORC1) pathway-related proteins were assessed by immunohistochemical staining.

Results: The expression of tumor necrosis factor-α (TNF-α) and monocyte chemotactic protein-1 (MCP-1) was increased in the radial arteries of the inflammation group. Additionally, Alizarin Red S staining revealed an obvious increase in calcium deposition in the inflammation group compared to that in the control group. Further analysis by immunohistochemical staining demonstrated that the deposition was correlated with the increased expression of bone-associated proteins such as bone morphogenetic proteins-2 (BMP-2) and osteocalcin and collagen I, which suggested that inflammation induces osteogenic differentiation in vascular tissues and that osteogenic cells are the main cellular components involved in VC. Interestingly, there was a parallel increase in the expression of phosphorylated mTOR (p-mTOR) and p-ribosomal protein S6 kinase 1 (p-S6K1) in the inflammation group. Furthermore, mTORC1 pathway-related proteins were significantly associated with the enhanced expression of bone formation biomarkers.

Conclusions: Inflammation contributed to VC in the radial arteries of ESRD patients via the induction of osteogenic differentiation in vessel walls, which could be regulated by the activation of the mTORC1 pathway.

SA-PO874

Loss of Secreted Frizzled-Related Protein 5 Contributes to Vascular Calcification in CKD by Activating Non-Canonical WNT Pathway Ji Yong Jung, Ae jin Kim, Han Ro, Jae Hyun Chang, Hyun Hee Lee, Wookyung Chung. *Gachon University Gil Medical Center, Incheon, Republic of Korea.*

Background: Vascular calcification (VC) is frequently accompanied with bone loss in patients with chronic kidney disease (CKD). WNT regulates osteoblast activation through canonical (β-catenin dependent) and non-canonical (-independent) signaling pathways, but a common pathophysiology between the pathways during VC and bone loss still remained a conundrum. Therefore, we hypothesized that VC results from phenotypic conversion of vascular smooth muscle cell (VSMC) into an osteoblast-like cell involves induction of an osteoblast transcriptional program via a non-canonical WNT pathway, while bone loss is mainly regulated by canonical WNT pathway.

Methods: Adenine-induced CKD animal model with VC was induced in male Sprague Dawley rats fed 0.75% adenine (2.5% protein, 0.92% phosphate) and intraperitoneal calcitriol (0.08 μl/kg/day) injection for 4 weeks. In an angiotensin II (3μM)-induced VC in high phosphate milieu (3mM) through its effect on VSMC, the effect of WNT signaling on VC was determined by expression of osteoblastic transcriptional factor (RUNX2), Von Kossa stain and WNT downstream signaling factors.

Results: In mRNA profiler PCR assay of WNT signaling pathway from animal model, secreted frizzled-related protein 4 (sFRP4) were increased, while sFRP5 was decreased than those of control group fed with normal rat chow (0.62% phosphate). From the in vitro study, the protective effect of sFRP5 on VSMC differentiation was mediated through the inhibition of Rho/ROCK and JNK pathways. Moreover, the effect of Rho/ROCK and JNK pathways on sFRP5 repression through VSMC differentiation were aggravated by anisomycin (JNK activator), whereas recovered with SP600125 (JNK inhibitor). Those expressions of RUNX2 and WNT signaling factors in adenine-induced CKD animal model with VC showed in the similar patterns.

Conclusions: Our study suggests that loss of sFRP5 was associated with VC in CKD environment by activating non-canonical WNT pathway, which indicate that sFRP5 may be a new therapeutic target in VC in CKD environment.

SA-PO875

Association between Circulating Osteogenic Precursors and Vascular Calcification in CKD Patients Janaina d. Ramalho,[2] Brygida Bisikirska,[1] Michael T. Yin,[1] Stavroula Kousteni,[1] Rosa M. Moyses,[2] Thomas Nickolas.[1] *[1]Columbia University Medical Center, New York, NY; [2]University of São Paulo, São Paulo, Brazil.*

Background: Vascular calcification (VC) is highly prevalent in CKD patients and is an independent predictor of cardiovascular morbidity and mortality. It has been recognized as an active process mediated by trans-differentiated vascular smooth muscle cells. Previously we found and association between higher frequency of circulating osteogenic precursors (COPS) among peripheral blood mononuclear cells (PBMCs), defined as lineage (LIN)-CD34-osteocalcin(OCN)+RUNX2+ cells, and higher bone strength (stiffness) measured by high-resolution peripheral quantitative computed tomography (HR-pQCT). We aimed to investigate the relationship of COP cells with prevalence and severity of VC in CKD.

Methods: In 53 CKD patients from Columbia University, USA, we compared the distribution of COP cells between those with or without lower leg arterial calcification (LLAC) and wrist arterial calcification (WAC) as assessed by HR-pQCT. LLAC and WAC presence were defined as measurements ≥ 1 mgHA. We evaluated Spearman correlations between COPs (LIN-CD34-OCN+RUNX2+, LIN-CD34-OCN+RUNX2-) and CD34- and endothelial precursor cells (LIN-CD34+KDR+CD133+) and severity of VC.

Results: Mean age was 48 ± 13 years, 71% male. Of 53 with LLAC measurement, 36% had LLAC, and of 49 with WAC measurement, 24,5% had WAC. Percentage of LIN-CD34-OCN+RUNX2- cells among LIN- parental cells was significantly higher in those with than without LLAC (p = 0.04) and WAC (p=0.02). Percentage of LIN-CD34-OCN+RUNX2+ was negatively correlated with WAC (rho = -0.55, p = 0.04). We did not find significant association between endothelial precursor cells and vascular calcification.

Conclusions: Osteocalcin+ COP cells are associated with the presence and severity of vascular calcification assessed by HR-pQCT in CKD patients. The role of COP cells and its association with bone versus vascular disease should be focus of future studies.

SA-PO876

RIPK-Independent Necroptosis Plays Significant Roles in the Progression of Vascular Calcification In Vitro Yu-Chun Chang,[1] Yan Ding,[3] Langjing Zhu,[4] Qinghua Liu,[1] Li-Li Hsiao.[2] *[1]Brigham and Women's Hospital, Boston, MA; [2]Brigham and Women's Hospital, Harvard Medical School, Boston, MA; [3]None, Newton, MA; [4]The Eighth Affiliated Hospital, Sun Yat-sen University, Roxbury Xing, MA.*

Background: Vascular calcification (VC) is a major complication in individuals with chronic kidney disease. A constant inflammatory state remains a key characteristic in the

development of VC. Necroptosis is a programmed form of cell death that results in an inflammatory phenotype. Early descriptions of necroptosis involve phosphorylation of Mlkl by RIPK1/3 signaling. Many studies have shown that necroptosis is a key contributor in various inflammatory diseases, but none in VC. In this study we aim to examine the roles of necroptosis in a model of VC *in vitro.*

Methods: We establish VC by utilizing Human Aortic Smooth Muscle Cells (HA-SMCs) treated with 5mM $CaCl_2$ and β-glycerolphosphate for 7, 14, 21 days. VC was confirmed by Arsenazo III and Alizarin Red Staining and by expression of Klotho and Runx2. Necroptosis is assessed through the expression of Mlkl, phospho-Mlkl, RIPK1, RIPK3 using Western Blot. Pan-caspase inhibitor Z-VAD.fmk (10mM), RIPK inhibitor necrostatin-1 (20mM, 40mM), and Mlkl inhibitor necrosulfonamide (0.5mM, 1mM), were used to assess the effects of necroptosis inhibition.

Results: The VC was confirmed by down regulation of Klotho and up regulation of Runx2. RIPK1 and RIPK3 expression were down regulated in a time-dependent manner in our VC model. The opposite was seen in Mlkl and phospho-Mlkl, indicating the presence of necroptosis in VC. Furthermore, treatment with Mlkl inhibitor, necrosulfonamide, alone displayed a dose-dependent reduction of calcification. Neither Z-VAD.fmk (Pan-caspase inhibitor) nor necrostatin-1 (RIPK inhibitor) resulted in significant changes in calcification.

Conclusions: Calcification of HA-SMCs highlight increased activity of Mlkl, but not RIPK1/3. Inhibition of Mlkl resulted in significant decrease of total degree of calcification, an effect not seen with treatment with necrostatin-1 or Z-VAD.fmk. Our results indicate that RIPK-independent activation of Mlkl may play a significant role in the development of VC. These findings suggest a novel pathway of necroptosis whose inhibition may be a target in the treatment of vascular calcification.

SA-PO877

OPA1 Disruption Is Involved in the Development of Arterial Calcification in CKD Fengying Guan,[1,2] Junnan Li,[1] Kenneth Lim,[3] Linjing Feng,[1] Yali Zhao,[1] Fei Teng,[1] Li-lun Ho,[2] Thomas F. Hiemstra,[4] Tzongshi Lu,[2] Li Chen.[1] *[1]College of Basic Medical Sciences, Jilin University, , Changchun, China; [2]Brigham and Women's Hospital, Harvard Medical School, Boston, MA; [3]Massachusetts General Hospital, Boston, MA; [4]University of Cambridge, Cambridge, United Kingdom.*

Background: Arterial calcification is a significant contributor to cardiovascular disease in patients with Chronic Kidney Disease (CKD). OPA1 is a GTPase of the dynamin family that functions in the mitochondrial inner membrane. It is involved in 1) maintenance of the respiratory chain and membrane potential; 2) cristae organization and control of apoptosis; and 3) stabilization of mitochondrial DNA. OPA1 protect cells from mitochondrial dysfunction by blocking intramitochondrial cytochrome c redistribution, which proceeds remodeling of the cristae in the presence of mitofusin 1 (MFN1). Our preliminary data has shown that OPA1 mediated disruption of mitochondrial dynamics may be involved in β-cell damage in type 2 diabetes. In this study, we investigated the role of OPA1 in human arteries from healthy and CKD patients.

Methods: Human arteries were collected from healthy (n=15) and CKD (n=15) patients. Arterial calcification was analyzed qualitatively by Alizarin Red. Total RNA from human arteries was extracted using the Nucleospin RNA isolation kit. cDNA was synthesized and fragmented using SMART-seq2 and Nextera XT (Illumina), respectively to generate libraries for sequencing on Hi-seq 2000 (Illumina). Five million single-ended raw reads from each sample were mapped to the human reference genome consortium GRCh38 by Burrows-Wheeler Aligner (BWA). Gene analysis were performed by the combinations of fold-changes on log 2 ratio, and p value < 0.05.

Results: Human arteries from CKD patients had extensive medial calcification while arteries from healthy controls did not develop significant calcification. RNA sequencing analysis revealed that OPA1 was significantly downregulated (Fold changes, FC, 2.33) in CKD arteries compared to arteries from healthy patients. CKD arteries had also reduced MFN1 (FC=1.83) and the downstream anti-apoptotic Bcl2 gene (FC=4.52). Both caspase 3 (FC=2.6) and cytochrome c (FC=2.29) expression were significantly increased in CKD arteries compared to control.

Conclusions: Mitochondrial OPA1 and MFN1 dysfunction may be involved in the pathogenesis of accelerated arterial calcification in CKD. Further investigation into the molecular mechanisms are needed.

Immune Cell Subsets Related to Vascular Calcification in Hemodialysis Patients Javier Rodriguez-Carrio,[1,2] Mariana Seijo,[1] Catalina Ulloa,[3] Natalia Carrillo-Lopez,[1] Minerva Rodriguez,[3] Ana Suarez,[2] Jorge B. Cannata-Andia,[1,4] Adriana S. Dusso.[1] *[1]Bone and Mineral Research Unit, Hospital Universitario Central de Asturias, Instituto Reina Sofía de Investigación, REDinREN del ISCIII, Oviedo, Spain; [2]Area of Immunology, Department of Functional Biology, Faculty of Medicine, University of Oviedo, Oviedo, Spain; [3]Division of Nephrology, Hospital Universitario Central de Asturias, Oviedo, Spain; [4]Department of Medicine, Faculty of Medicine, University of Oviedo, Oviedo, Spain.*

Background: In CKD patients, inflammation contributes to the disproportionally high incidence of vascular calcification (VC) through immune mechanisms that remain incompletely understood. This study aims to characterize different immune cell subsets related to VC in the context of CKD.

Methods: A group of individuals with normal renal function (n=5) and non-diabetic hemodialysis (HD) patients (n=17), matched by CKD etiology, age and gender but with either none, moderate or severe arterial calcification (Kauppila and Lumbar Spine indexes) were studied for inflammatory and aging markers (flow cytometry) and biochemical parameters of bone and mineral homeostasis.

Results: HD patients exhibited an increased frequency of the senescent $CD4^+CD28^{null}$T-cell subset (p=0.030), which were associated with the degree of VC and negatively correlated with 25-hydroxyvitamin D levels (r=-0.594, p=0.025). Angiogenic T cells ($CD3^+CD31^+CD184^+$), related to vascular homeostasis, were decreased in HD patients (p=0.024), regardless of their degree of VC. The frequency of regulatory T cells (Treg, $CD4^+CD25^{high}CD127^{low/neg}FOXP3^+$) did not differ between HD patients and healthy controls, although they were slightly reduced in patients without VC (p=0.022) compared to those with VC (moderate and severe groups). However, the analysis of cytokine expression may point to a non-regulatory phenotype of Treg in the latter. Additionally, ACE expression was higher in monocytes from HD patients (p=0.020) compared to healthy counterparts. This increase was restricted to intermediate monocytes ($CD14^+CD16^+$), strongly increased in patients (p<0.001), and was found even in patients without VC. ACE expression on intermediate monocytes was negatively associated with vitamin D (r=-0.499, p=0.060) and positively with PTH (r=0.578, p=0.030). Finally, a higher percentage of low-density granulocytes ($CD14^{low}CD15^+$) was observed in CKD (p<0.001).

Conclusions: Several immune cell subsets related to inflammation, immunosenescence and vascular homeostasis are altered in CKD, even in the early stages of VC. Impaired vitamin D levels may be associated with this abnormal immune profile. This study paves the ground for the identification of early biomarkers to identify patients at higher risk of developing VC.

SA-PO879

Bone Phenotype in ADPKD Patients with ESRD Pieter Evenepoel,[5] Kathleen Claes,[4] Bert Bammens,[5] Etienne Cavalier,[6] Bjorn Meijers,[5] Peter Stenvinkel,[1] Magdalena Jankowska,[2] Patrick C. D'Haese.[3] *[1]Karolinska University Hospital Huddinge, Stockholm, Sweden; [2]Medical University of Gdansk, Gdansk, Poland; [3]University Antwerp, Edegem, Belgium; [4]University Hospitals Leuven, Leuven, Belgium; [5]University Hospitals Leuven, Leuven, Belgium; [6]University of Liege, CHU Sart-Tilman, Liege, Belgium.*

Background: Autosomal dominant polycystic kidney disease (ADPKD) is among the most common hereditary nephropathies and arises as the consequence of mutations in one of two genes, pkd1 or pkd2. PKD1 and PKD2 proteins form a complex on the primary cilium and are thought to play a role in mechanosensation in various cells including osteocytes. Preliminary data showed increased sclerostin levels suggesting impaired mechanosensation in ADPKD patients with end stage renal disease (ESRD). A bone phenotype of reduced bone mass and turnover has been reported in mice with targeted disruption of pkd1 and normal kidney function. The aim of the present post-hoc analysis was to compare the bone phenotype between ADPKD patients with ESRD to non-ADPKD controls.

Methods: Laboratory parameters of mineral metabolism including FGF23 (Kainos) and sclerostin (Tecomedical), bone turnover markers (all IDS iSYS) and bone mineral density (BMD, by dual energy x-ray absorptiometry, DXA) were assessed in 518 renal transplant candidates (ADPKD, n=99), with also bone biopsy data available in a subset of patients (n=71).

Results: Circulating sclerostin levels were significantly higher in ADPKD patients (2.20 vs 1.84 ng/L, p=0.001). Circulating levels of bone alkaline phosphatase (17.4 vs 22.6 ng/mL, p<0.0001) and tartrate-resistant acid phosphatase 5b (4.65 vs 5.46 U/L, p=0.006) were significantly lower in ADPKD, as were histomorphometric parameters of bone formation (e.g. Ob.Pm/T.Pm p=0.04). Associations remained after adjustment for classical determinants (e.g. PTH, age, gender …) in regression analysis. Histomorphometric parameters of bone mineralization were numerically higher in ADPKD (e.g. O.Pm/B. Pm, p=0.06). DXA showed better preserved BMD in skeletal sites rich in cortical bone (Z-score radius 1/3 -0.04 vs -0.14, p<0.0001; femoral neck -0.72 vs -1.02, p=0.01).

Conclusions: Our data confirm a distinct bone phenotype in ADPKD patients with ESRD, characterized by high sclerostin levels, depressed bone turnover and preserved areal bone mineral density in skeletal sites rich in cortical bone.

SA-PO880

Bone Disease Characterization in a Portuguese Predialysis Cohort Ricardo Neto,[2,1] Luciano Pereira,[2,1] João Frazão.[2,1] *[1]Nephrology and Infectious Diseases Research and Development Group, INEB-(I3S), Porto, Portugal; [2]Centro Hospitalar São João, Porto, Portugal, Porto, Portugal.*

Background: Renal osteodystrophy (ROD) is an early and common complication of chronic kidney disease (CKD). Histomorphometry is the gold-standard diagnostic tool for ROD, but there is little data on bone histological changes in pre-dialysis patients. Most studies are old and results are inconsistent. We report the results of bone biopsies performed on a cohort of Portuguese pre-dialysis patients.

Methods: Transiliac bone biopsy after double tetracycline labelling was performed on 35 consecutive patients enrolled in our pre-dialysis clinic. Inclusion criteria were age between 18 and 80 years old and glomerular filtration rate between 15 and 60 mL/min/1.73 m^2. Patients were excluded if they were on calcium salts, any form of vitamin D, steroids or bisphosphonates. KDIGO TMV classification was used to characterize biopsy results. Clinical and biochemical data were recorded at the time of biopsy.

Results: Four patients (11.4%) were excluded due to inadequate bone sample. Thirty-one biopsies were therefore analyzed. Twenty-two patients (70.9%) were male. Mean age was 67.3 ± 8.1 years. Mean serum creatinine and glomerular filtration rate were 2.2 ± 0.4 mg/dL and 27.6 ± 7.0 mL/min/1.73 m2, respectively. Mean serum calcium, phosphorus, intact parathyroid hormone (iPTH) and native vitamin D (VD) levels were 9.0 ± 0.5 mg/dL, 3.5 ± 0.6 mg/dL, 140.6 ± 130.2 pg/mL and 17.8 ± 11.9 ng/mL, respectively. Twenty-four patients (77.4%) had normal bone histology, 3 (9.7%) had adynamic disease, 3 (9.7%) had mild hyperparathyroid disease and one (3.2%) had mixed uremic osteodystrophy. No cases of osteomalacia were found. Except for mineralization lag time and bone volume, histomorphometric parameters did not significantly differ between histological classes. Despite a trend for higher iPTH with rising bone formation rate, levels did not significantly differ between groups.

Conclusions: In a contemporary Portuguese pre-dialysis cohort, roughly 3/4 of the patients had normal bone histology, one tenth had adynamic bone disease and another tenth had mild hyperparathyroid disease. There was one case of mixed disease and none of osteomalacia. Our results also suggest that biochemical testing are not predictive of histological findings, thus highlighting the importance of bone biopsy as the gold-standard tool to evaluate ROD. Further histomorphometric studies are needed to enlighten the spectrum of ROD in pre-dialysis CKD.

SA-PO881

HIV/AIDS Is Associated with Bone Histomorphometric Abnormalities before Antiretroviral Therapy Janaina d. Ramalho,[2] Carolina S. Martins,[3] Juliana C. Galvão,[4] Rosa M. Pereira,[2] Thomas Nickolas,[1] Michael T. Yin,[1] Luciene dos Reis,[2] Vanda Jorgetti,[3] Rosa M. Moyses.[2,4] *[1]Columbia University Medical Center, New York, NY; [2]Faculdade de Medicina da Universidade de Sao Paulo, Sao Paulo, Brazil; [3]Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil; [4]Universidade Nove de Julho, São Paulo, Brazil.*

Background: The reduction in bone mineral density (BMD) is a known metabolic complication of antiretroviral therapy (ART), especially tenofovir, which may cause tubular dysfunction, excess phosphaturia and osteomalacia. Low BMD and increased fracture risk, however, has been recognized in patients with HIV/AIDS even before treatment initiation. We aimed to identify and describe abnormalities in bone histomorphometry in ART-naïve HIV patients.

Methods: In 20 male patients with HIV infection, ART-naïve, we evaluated bone structure, turnover and mineralization by iliac crest bone biopsy with histomorphometry. Main exclusion criteria were eGFR < 60ml/min/1,73m², metabolic bone disease, cirrhosis, diabetes, and medications affecting bone metabolism. HIV viral load and CD4+ T cell count (CD4) were determined. Serum 25 vitamin D (25vitD), PTH and RANKL levels were measured. BMD was assessed by DXA.

Results: Mean age was 29.6 ± 5.5 years, mean BMI was 24.7 ± 2.4, median time since diagnosis of HIV infection was 87 (71 – 231) days, with median viral load of 29,945 (IQR 5,485 – 53,118) copies/mL and mean CD4 of 375 ± 200 cells. Mean 25vitD was 22.3 ± 7.9 ng/ml and PTH was within reference range in all patients. RANKL levels correlated positively with HIV viral load (r = 0.48, p = 0.04) and negatively with CD4 (r -0.65, p =0.003). Three patients (15%) had low BMD (Z score ≤ -2) at any site. By histomorphometry, 20% had low bone trabecular volume and 25% had decreased cortical thickness, whereas cortical porosity was normal in all of them. Decreased bone formation rate was seen in 80% and abnormal mineralization was detected in 60%. Increased osteoclastic and eroded surface were seen in 40 and 30%, respectively.

Conclusions: Abnormalities in bone volume, turnover and mineralization are common among HIV-infected persons, especially decreased formation and mineralization, even before ART exposure. Immune dysregulation, mediated by abnormalities in RANKL levels, may contribute. Further study is necessary to determine which factors (immunologic, hormonal or others) predict greater bone loss with ART initiation.

SA-PO882

The Trabecular Bone Score as a Tool to Assess Bone Microarchitecture in CKD Janaina d. Ramalho,[3] Igor Marques,[6] Vanda Jorgetti,[5] Rosa M. Moyses,[4] Didier Hans,[2] Thomas Nickolas.[1] *[1]Columbia University Medical Center, New York, NY; [2]Lausanne University Hospital - CHUV, Lausanne, Switzerland; [3]None, Sao Paulo, Brazil; [4]Universidade Nove de Julho, São Paulo, Brazil; [5]Universidade de Sao Paulo, Sao Paulo, Brazil; [6]University of Sao Paulo School of Medicine, Sao Paulo, Brazil.*

Background: Recent studies have demonstrated that low bone mineral density (BMD) by dual energy X-ray absorptiometry (DXA) predicts fractures in CKD patients. However, as bone strength reflects the integration of both BMD and bone quality, BMD only partially describes fracture risk. The Trabecular Bone Score (TBS) is a novel clinical tool that uses grayscale variograms of the lumbar spine image from DXA to assess bone quality and fracture risk. Its ability to assess trabecular (Tb) bone quality has been validated against bone biopsy in the general population but not in CKD. We hypothesized that TBS would reflect Tb bone quality at the iliac crest in CKD patients.

Methods: In 52 CKD patients from Columbia University, USA and University of Sao Paulo, Brazil, we determined Spearman correlations controlling for age between TBS and bone microarchitecture assessed by both high-resolution peripheral quantitative computed tomography (HR-pQCT) at the radius and tibia and iliac crest bone histomorphometry.

Results: Mean age was 50.4 ± 15.5 years, 35 (67%) were on dialysis; 25%, 18% and 13% had T-Scores ≤ -2.5 at spine, femoral neck and total hip respectively. Mean TBS was 1.29±0.13 (normal TBS ≥1.35). Correlations between TBS and microarchitectural parameters are shown in Table.

Conclusions: TBS reflects Tb microarchitecture from bone biopsy and Ct and Tb microarchitecture from HR-pQCT. TBS may be a useful tool in the clinic to assess bone quality and fracture risk in CKD patients.

Clinical Characteristics of Susceptible Factors and Nutritional Status in 576 Secondary Hyperparathyroidism Patients Undergoing Parathyroidectomy Ningning Wang,[1] Yao Jiang,[3] Guang Yang,[1] Chang Ying Xing,[2] Xiaoming Zha.[4] *[1]Department of Nephrology, The First Affiliated Hospital with Nanjing Medical University, Nanjing, China; [2]First Affiliated Hospital of Nanjing Medical University, Nanjing, China; [3]Nanjing Medical University, Nanjing, China; [4]First Af?liated Hospital with Nanjing Medical University, Nanjing, China.*

Background: Secondary hyperparathyroidism(SHPT) is a common complication of chronic kidney disease-mineral and bone disorder(CKD-MBD). Parathyroidectomy(PTX) is the prior therapy for severe SHPT, however, few large samples studies on predisposing factors and nutritional status of severe SHPT were explored. We aim to analyze the characteristics of high risk group and summarize the nutritional status of CKD patients with PTX.

Methods: Clinical data of 576 PTX patients were collected and grouped according to the age and dialysis vintage.

Results: There were 55.9% males and the mean age of all PTX patients were (46.4±11.3) years. The major cause of CKD was chronic glomerulonephritis (91.5%). Severe SHPT was more common in middle aged patients with long hemodialysis vintage (Fig 1). Levels of serum intact parathyroid hormone(iPTH) were gradually reduced from young age group to old age group(Fig2). The levels of BMI were (21.9±3.5) kg/m², which was negative correlated with serum iPTH levels. Serum albumin in each age group was lower than the reference range, and in age groups of ≤18 and >70 years old were lower than the other groups.

Conclusions: Susceptible factors of severe SHPT include middle age, chronic glomerulonephritis and long hemodialysis vintage. Focused surveillance and timely treatment for mild or moderate SHPT patients with risk factors are suggested. The elderly and juveniles severe SHPT patients may have more serious malnutrition and higher operation risk. We recommend personalized diagnosis and treatment strategy for CKD-MBD patients.

Funding: Government Support - Non-U.S.

SA-PO884

Parathyroidectomy (PTX), KDOQI Targets, PTH Lowering Therapies, and Mortality in a Cohort of Italian Dialysis (D) Patients: A Multicenter Observational Study Sandro Mazzaferro. *Sapienza University of Rome, Rome, Italy. Group/Team: On behalf of Italian Study Group of Mineral Metabolism*.

Background: PTX might improve survival by improving biochemical control.

Methods: We prospectively collected data of 528 prevalent PTX cases (age: 57.63 ±12.52 y.o; D time: 14.63±8.37 y; M/F: 44/56%) from 149 D units in Italy, out of 12515 patients on D (=4,2%) and evaluated KDOQI targets, therapies and survival. Control cases (n=418, nested case-control selection) were balanced for sex (45/55%) but not age (60.30±14.36 y.o, p<.01) or D duration (11.2±7.3 y; p<.001).

Results: PTX cases were at lower KDOQI targets for Ca (50 vs 57 %; p<.05) and PTH (19 vs 37%; p<.001) and received more calcitriol and Ca-based phosphate binders and less calcimimetic than controls. Also PTX cases included in the follow-up were less frequently at target for PTH and were confirmed to receive more calcitriol and Ca-based phosphate binders and less calcimimetic than controls (table 1). Univariate analysis adjusted for D age, showed lower HR of mortality for PTX (0.556, CI:0.387-0.800, p=.002), albumin (0.327; CI:0.249-0.555, p=.000) and hemoglobin (0.672, CI:0.558-0.810, p=.000). Multivariate analysis confirmed PTX (HR 0.679, CI:0.465-0.970, p<.05), age (HR 1.043, CI 1.014-1.055, p<.001) and D duration (HR 1.034, CI 1028-1059, p<.001) as independent predictors of mortality. Albumin inclusion in the model excluded PTX (p=0.065). Indeed, PTX cases had higher albumin levels than controls (3.8±0.4 vs 3.6±0.4; p<.01).

Conclusions: PTX associates with lower risk of mortality regardless of PTH control and despite "more risky" therapy. As a toxin, PTH could negatively affects serum albumin.

Effects of Vitamin D Supplementation on Markers of Bone and Mineral Metabolism in Pediatric Patients with Early and Late CKD Dieter Haffner,[2] Christian Lerch,[2] Franz S. Schaefer,[3] Rukshana Shroff.[1] *[1]Renal Unit, Great Ormond Street Hospital for Children, London, United Kingdom; [2]Department of Pediatric Kidney, Liver and Metabolic Diseases, Hannover Medical School Children's Hospital, Hannover, Germany; [3]Division of Pediatric Nephrology, University Children's Hospital Heidelberg, Heidelberg, Germany. Group/Team: ESPN CKD-MBD working group and 4C Study consortium*.

Background: Recent research findings suggest that vitamin D may have PTH independent effects on the regulation of bone and mineral metabolism. We investigated the effects of vitamin D supplementation on circulating fibroblast growth factor 23 (FGF23), Klotho, and sclerostin levels in two pediatric cohorts with early and late CKD.

Methods: Eighty vitamin D deficient children were selected: 40 with early CKD from the ERGO Study, a randomized placebo-controlled trial of ergocalciferol supplementation in children (mean eGFR 55 ml/min/1.73m^2), and 40 with advanced CKD from the observational 4C Study (eGFR 24 ml/min/1.73m^2, p<0.01). In each study 20 children received vitamin D supplementation, and 20 age and eGFR-matched children not on vitamin D served as controls. Z-scores (SDS) were calculated for serum levels of Klotho, FGF23, and sclerostin, at baseline and after a median period of 8 months.

Results: Untreated patients in the ERGO study had normal FGF23 (0.31 SDS) but decreased levels of klotho (-0.77 SDS) and sclerostin (-1.04 SDS), whereas untreated children in the 4C cohort had increased FGF23 (3.87 SDS) and sclerostin (0.76 SDS), but normal klotho (-0.27 SDS) levels. Vitamin D supplementation further increased FGF23 levels in 4C but not in ERGO patients. Serum klotho and sclerostin normalized during vitamin D supplementation in ERGO but remained unaffected in 4C patients. In the whole cohort significant differences between vitamin D treated patients and controls were noted for Klotho at eGFR 40-70 ml/min/1.73 m^2 and for sclerostin at eGFR 60-70 ml/min/1.73 m^2. 25-hydroxyvitamin D levels >75nMol/L was independently associated with the changes in Klotho and sclerostin levels.

Conclusions: Vitamin D supplementation normalizes Klotho and sclerostin levels in vitamin D deficient children with early CKD, but further increases FGF23 levels in vitamin D deficient children with advanced CKD.

SA-PO886

Bone Disease Post Kidney Transplantation – Beyond Bone Mineral Density Ashish K. Sharma,[1,3] Nigel D. Toussaint,[1,3] Stephen G. Holt,[1,3] Grahame J. Elder,[1,1] Paul A. Baldock,[1] Kiara Honma,[2] Chamith S. Rajapakse,[2] Rosemary Masterson.[1,3] *[1]The Royal Melbourne Hospital, Parkville, VIC, Australia; [2]University of Pennsylvania, Philadelphia, PA; [3]Department of Medicine (RMH), University of Melbourne, Parkville, VIC, Australia*.

Background: Post-transplant bone disease in kidney transplant recipients (KTRs) is traditionally characterised by severe loss of bone mineral density (BMD) and increased fracture risk. Recent studies have shown less dramatic decrease in BMD at various skeletal sites. Bone microarchitecture changes post-transplant are not well defined and cannot be accurately evaluated with bone biomarkers and dual energy x-ray absorptiometry (DXA). Bone biopsy is invasive and infrequently performed. We longitudinally evaluated changes in BMD, microarchitecture and biomarkers post kidney transplantation, using high-resolution magnetic resonance imaging (MRI, distal tibia), peripheral quantitative computed tomography (pQCT, radius), DXA and biomarkers of mineral metabolism.

Methods: Twelve adult live donor KTRs (mean age 49+/-10.96, 66% M) underwent MRI, pQCT and DXA (hip, spine) at baseline and 12 months post transplantation. Laboratory testing was performed at baseline, 6 and 12 months.

Results: Compared with baseline, 12-month MRI (tibia) showed deterioration in indices of trabecular network integrity - surface to curve ratio (S/C, -15%, p=0.042) and erosion index (EI, +19%, p=0.005). Changes were also seen in cortical thickness (+4.6%, p=0.0269) and cortical area (+11.5%, p=0.03). Numerical changes in areal BMD and volumetric BMD were not statistically significant. Interval changes in S/C and EI correlated with total hip T-score (DS/C; r= 0.70, p=0.01 & EI; r=-71, p=0.009) and trabecular vBMD at radius (DS/C; r= -0.68, p=0.015 & DEI; r=71, p=0.009). There was no significant difference in serum calcium, but PTH and phosphate levels decreased after 12 months (-80.5%, p=0.03 & -49.3%, p<0.001 respectively). Changes in PTH were inversely predictive of BMD at the lumbar spine (r=-0.58, p=0.04) and femoral neck (r=-0.69, p=0.014) but were unrelated to cortical parameters.

Conclusions: Post-transplantation, there was deterioration in trabecular bone quality and network without significant changes in trabecular volume, structural parameters and BMD at central or peripheral sites. The preservation of cortical structure in our cohort is differs from recent studies and highlights the heterogeneous nature of histologic changes and multifactorial pathology of post-transplant bone disease.

Deterioration of Cortical Bone Microarchitecture in Renal Osteodystrophy – Under-Represented in the "Turnover Mineralisation Volume" (TMV) Classification? Ashish K. Sharma,[1,3] Nigel D. Toussaint,[1,3] Stephen G. Holt,[1,3] Alyssa J. Johncola,[2] Chamith S. Rajapakse,[2] Rosemary Masterson,[1,3] Grahame J. Elder,[1,5] Paul A. Baldock.[5] *[1]The Royal Melbourne Hospital, Parkville, VIC, Australia; [2]University of Pennsylvania, Philadelphia, PA; [3]Department of Meidicne (RMH), University of Melbourne, Parkville, VIC, Australia; [5]Garvan Institute of Medical Research, Darlinghurst, NSW, Australia*.

Background: Cortical bone contributes significantly to mechanical strength of bone and its deterioration is associated with non-vertebral fractures. Recent imaging and histomorphometric studies demonstrate prevalence of thin cortices and increased cortical porosity in CKD which may have diagnostic and therapeutic implications. Changes in bone microarchitecture as measured by TMV classification do not completely reflect deterioration in cortical parameters. We evaluated trabecular and cortical bone microarchitecture in patients with chronic kidney disease (CKD) by classical histomorphometry and microcomputed tomography (mCT) of iliac crest biopsies

Methods: Iliac crest bone biopsies were performed in 14 patients undergoing kidney transplantation (n=12) and parathyroidectomy (n=2). Trabecular structural parameters

were analyzed by histomorphometry and 3D mCT and included trabecular bone volume, thickness, number and separation. Cortical thickness (CtTh) and porosity (CtPo) were measured by 3D mCT. Bone mineral density (BMD) was measured by peripheral quantitative CT (radius) and dual energy x-ray absorptiometry. Associations were determined by analysis with Spearman's rank correlation coefficients.

Results: Trabecular parameters from bone biopsy were within normally accepted ranges in most patients. In contrast, all patients showed decreased CtTh (mean thickness; 30 +/- 40 μm) and significantly increased CtPo (60.31 +/- 22.53%) at the iliac crest. CtPo was unrelated to turnover status but demonstrated positive relationship with PTH levels (r=0.62; p=0.021) and was inversely related to trabecular thickness (r=-0.60; p=0.024) at the iliac crest and cortical area (r=-0.59; p=0.045) at the radius. CtTh was also associated with lumbar spine (r=-0.72; p=0.013) and femoral neck BMD (r=-0.55; p=0.07)

Conclusions: Marked deterioration of cortical microarchitecture in the setting of relatively normal trabecular parameters in our cohort reinforces the importance of comprehensive cortical bone evaluation in CKD.

SA-PO888

FRAX® Predicts Fracture Risk in Patients with CKD Reid Whitlock,[2] William Leslie,[1] James A. Shaw,[2] Claudio Rigatto,[2] Paul Komenda,[2] David T. Collister,[2] Navdeep Tangri.[2] *[1]St Boniface General Hospital, Winnipeg, MB, Canada; [2]University of Manitoba, Winnipeg, MB, Canada.*

Background: FRAX® was developed to predict fracture risk in the general population but its applicability to patients with chronic kidney disease (CKD) is unknown.

Methods: Using the Manitoba Bone Mineral Density (BMD) Database, we identified adults not receiving dialysis services with serum creatinine measurements and bone densitometry within 1 year between 2005-2010. Estimated glomerular filtration rate (eGFR) was calculated using the *Chronic Kidney Disease* Epidemiology Collaboration equation. Incident major osteoporotic fractures (MOF) and hip fractures were ascertained from population-based healthcare databases. The performance of FRAX, derived without and with BMD, was studied in relation to CKD stage.

Results: We studied N=10,099 subjects (mean age 64 ± 13 y), including N=2154 with GFR 30-60 mL/min/1.73 m^2 (CKD stage 3) and N=590 with GFR <30 mL/min/1.73 m^2 (CKD stages 4-5). During a 5 year observation period, there were 772 individuals with an incident MOF and 226 with incident hip fractures. In Cox proportional hazards models, FRAX predicted risk for MOF and hip fracture in all eGFR strata. For every standard deviation increase in FRAX score derived with BMD, the HR for hip fracture was 4.54 (95% CI 3.57-5.77) in those with eGFR ≥ 60 mL/min/1.73m2, 4.52 (95% CI 3.15-6.49) in individuals with eGFR 30-60 mL/min/1.73m2, and 3.10 (95% CI 1.80-5.33) in individuals with eGFR <30 mL/min/1.73m2. HRs for MOF were lower than the equivalent hip fracture HRs in all eGFR categories, but greater for MOF in those with moderate and severe reductions in eGFR (FRAX*eGFR interaction P≤0.001)

Conclusions: FRAX stratifies fracture risk in patients with moderate to severe CKD as well as in those with preserved eGFR. These findings support the use of the FRAX score to risk stratify patients with CKD for hip and major osteoporotic fractures.

SA-PO889

Relationships between Vitamin D and Bone Formation and Mineralization in Adults and Children with Pre-Dialysis CKD Thomas Nickolas,[1] Renata C. Pereira,[7] Maria Coco,[4] Joachim H. Ix,[6] Michel Chonchol,[8] James M. Pullman,[3] Stuart M. Sprague,[5] Isidro B. Salusky.[2] *[1]Columbia University Medical Center, New York, NY; [2]Mattel Children's Hospital, Los Angeles, CA; [3]Montefiore Medical Center, Bronx, NY; [4]Montefiore Medical Center, Bronx, NY; [5]NorthShore University HealthSystem University of Chicago Pritzker School of Medicine, Chicago, IL; [6]UCSD, San Diego, CA; [7]University of California, Los Angeles, CA; [8]University of Colorado, Aurora, CO. Group/Team: Kidney Disease Bone Biopsy Working Group.*

Background: The Institute of Medicine (IOM) recommends levels of 25-hydroxyvitamin D (25D) >20ng/mL to optimize bone quality for the general population. In contrast, optimal 25D levels in adults and children with pre-dialysis CKD have not been established. We used bone-tissue level data to investigate the 25D level that is associated with optimal turnover and mineralization in adult and pediatric patients with pre-dialysis CKD.

Methods: From Columbia University, Montefiore Medical Center, NorthShore University and UCLA, we pooled iliac crest bone biopsies with tetracycline double labeling and quantified relationships between 25D and 1,25-dihydroxyvitamin D (1,25D) and histomorphometry in 25 adults and 31 children with CKD. Spearmen correlations were adjusted for kidney function (CKD-EPI in adults; Schwartz Formula in children). To determine 25D levels that optimized bone formation and mineralization we used receiver operator curve (ROC) analysis and defined high turnover renal osteodystrophy (ROD) as bone formation or mineralization in the upper tertile of respective adult and pediatric populations.

Results: In adults, mean±SD age and GFR were 63±14yrs and 27±18mL/min, respectively, and levels of 25D and 1,25D were 28±17ng/mL and 34±20pg/mL, respectively. 25D was inversely correlated with bone formation rate (BFR; r -0.47, p0.02) and mineralizing surface (r -0.48, p0.02), and 1,25D was inversely correlated with osteoid surface (r -0.54, p0.006). In ROC analysis, 25D levels ≥35ng/mL provided 100% specificity of both non-high turnover and normal mineralization rates and no patient had high turnover ROD. In contrast, >60% of patients with 25D <35ng/mL had high turnover ROD. In children, age and GFR were 14±4yrs and 50±21mL/min respectively and levels of 25D and 1,25D were 27±7ng/mL and 33±14pg/mL, respectively. 25D did not correlate with histomorphometry, but 1,25D was positively correlated with BFR (r 0.41, p0.02) and mineral apposition rate (r 0.46, p0.01).

Conclusions: Relationships between 25D and 1,25D and bone differ in adult and pediatric CKD patients. In adults, 25D levels that are greater than the IOM recommendations may be needed to optimize bone quality. In children, 1,25D may have more of an effect on bone quality than 25D. Larger studies will further explore these findings.

Risk Factors of Fractures in Patients with Stage 3 CKD: Analysis of CARTaGENE Louis-Charles Desbiens,[1] Remi Goupil,[2] Francois Madore,[2] Aboubacar Sidibé,[1] Fabrice Mac-Way.[1] *[1]CHU de Québec Research Center, Faculty of Medicine, Laval University, Quebec City, QC, Canada; [2]Hopital du Sacre-Coeur de Montreal, Montreal, QC, Canada.*

Background: The association between end-stage renal disease and increased fracture risk is well described. However, whether mild chronic kidney disease (CKD) is also associated with higher fracture risk is poorly known. We aimed to determine if mild CKD increases fracture risk vs general population. Secondary objectives were to evaluate whether bone mineral density (BMD) is associated with fracture and to compare the risk factors of fractures in mild CKD vs general population.

Methods: Cross-sectional, retrospective study of the CARTaGENE cohort, a large health population-based survey of 40 to 69 years old individuals from province of Quebec (Canada). Patients with CKD stage 3 (eGFR between 30 and 60 ml/min/1,73m^2) were compared to controls (eGFR > 60 ml/min/1,73m^2). Self-reported fractures were classified as osteoporotic (femur, hip, rib, vertebra, wrist, pelvis, sacrum) or total fractures. Fracture risk was adjusted for baseline demographic, clinical, pharmacological and biochemistry parameters using multivariate logistic regression. Stepwise multivariate regressions stratified for CKD were performed to evaluate risk factors of fractures.

Results: 17,614 patients without anti-resorptive therapy had available data on fractures and BMD (656 CKD and 16,958 controls). CKD patients (mean eGFR 53±6 ml/min/1,73m^2) were older, had more diabetes, cardiovascular disease, hypertension, smokers and a lower BMD t-score. Total but not osteoporotic fracture risk was higher in CKD patients, but remained similar when stratified by age group and after adjustments for covariables. In multivariate stepwise models, BMD t-score and use of benzodiazepines were associated with total fracture in both groups. Total cholesterol levels and mean blood pressure were associated with fracture in CKD while age, smoking and body mass index were associated with fracture in control group.

Conclusions: Stage 3 CKD patients have a similar fracture risk but different risk factors for fracture vs general population. Our results suggest that bone pathology in CKD is different from the general population even at early stages of CKD.

Funding: Government Support - Non-U.S.

SA-PO891

Relation of Dietary Acid Load to Bone Mineral Density (BMD) and Osteoporosis in Early CKD Tanushree Banerjee,[5] Chi-yuan Hsu,[4] Austin G. Stack,[2] Nilka Rios Burrows,[1] Rajiv Saran,[6] Neil R. Powe.[3] *[1]Centers for Disease Control and Prevention, Atlanta, GA; [2]Graduate Entry Medical School, University of Limerick, Limerick, Ireland; [3]Priscilla Chan and Mark Zuckerberg San Francisco General Hospital & University of California SF, San Francisco, CA; [4]University of California San Francisco, San Francisco, CA; [5]University of California, San Francisco, San Francisco, CA; [6]University of Michigan, Ann Arbor, MI.*

Background: Acidosis is buffered by bone leading to the release of calcium and bone resorption. High dietary acid load (DAL) may contribute to low BMD with studies in the general population showing inconsistent results. Inconsistencies may be due to lack of consideration of protein intake in the etiology of bone loss. Further, it has not been explored whether high DAL is associated with a decrease in bone turnover in chronic kidney disease (CKD). We investigated the association between DAL and BMD/osteoporosis by gender in early CKD and explored whether higher protein intake modifies these associations.

Methods: We studied 1,580 participants aged>=20 years with early CKD (stages 1 and 2) from 1999-2006 National Health and Nutrition Examination Survey. Nutrient intake from 24-hour recall was used to calculate net endogenous acid production (NEAP) and potential renal acid load (PRAL) (mEq/d). BMD measurements were made at the lumbar spine or pelvis and osteoporosis was defined as a T-score≤−2.5 standard deviation. Linear and logistic regression analyses explored associations between energy-adjusted NEAP or PRAL and BMD (including osteoporosis) after adjustment for demographics, weight, height, physical activity, smoking, alcohol, estrogen use, total calories, dietary magnesium and calcium, eGFR, and protein intake.

Results: Mean age in men and women was 52.5±0.7 and 49.7±0.8 yrs. Among men, a statistically significant inverse association was observed between PRAL with either pelvis or lumbar BMD (β[95% CI]:-0.03[-0.05,-0.01],-0.12[-0.14,-0.09], respectively) as well as with NEAP (-0.03[-0.06,-0.003],-0.13[-0.15,-0.10], respectively). When adjusted for protein intake, the association was positively modified between PRAL or NEAP with BMD (all p>0.05). In women, PRAL was positively associated with pelvis BMD (0.03[0.01-0.06]) but not with lumbar BMD. NEAP was positively associated with both pelvis and lumbar BMD and was inversely modified by protein intake. Neither PRAL

nor NEAP associated with osteoporosis and further adjustment for protein intake did not modify these null associations.

Conclusions: DAL was associated with reduced BMD in men and was positively associated with BMD in women. Protein intake modified the association in both genders. Additional studies could help explain the reasons underpinning these gender differences.

Advanced Glycation End-Products (AGEs) Is Associated with Vascular Calcification and Osteoporosis in CKD Patients

Kelcia R. Quadros,[1] André B. Esteves,[1] Renata A. Franca,[1] Cynthia M. Borges,[1] Cinthia E. Carbonara,[1] Marcela T. Watanabe,[3] Maryanne Z. Silva,[3] Fabiana S. Antonialli,[1] Noemi A. Roza,[1] Jacqueline T. Caramori,[3] Vanda Jorgetti,[2] Rodrigo B. de Oliveira.[1] *[1]School of Medical Sciences, Department of Internal Medicine, University of Campinas, Campinas, Brazil; [2]Medical School, Department of Nephrology, University of São Paulo, São Paulo, Brazil; [3]Medical School, University of São Paulo State, Botucatu, Brazil.*

Background: Chronic kidney disease (CKD) is associated with mineral and bone disorder (MBD) and cardiovascular disease (CVD). Advanced glycation end-products (AGEs) contribute to these complications and their tissue accumulation can be indirectly measured through skin autofluorescence (sAF) by AGE-Reader™.

Methods: To investigate the relations between AGEs intake, tissue and serum AGEs levels with CVD and MBD parameters in CKD patients stages 3-4 and in peritoneal dialysis (PD), clinical and observational study with healthy subjects (N=37) and patients distributed in 2 groups: CKD stages 3-4 (N=20) and PD (N=28). Clinical and laboratorial parameters, ankle-brachial index (ABI), AGEs-sAF levels and AGEs intake were analyzed. In addition, CKD patients performed hip, hands and lateral abdomen radiographs for investigation of vascular calcification (VC), echocardiogram, bone densitometry and serum carboxymethyllysine (CML) levels assay.

Results: AGEs-sAF was increased in CKD 3-4 and PD patients compared to the healthy subjects (3.05±0.6 *vs.* 2.4±0.4; p<0.05), despite similar AGEs intake (10.118±4.760 *vs.* 11.942±5.581; p>0.05). There are no differences in AGEs-sAF levels between CKD3-4 and PD patients (3.04±0.6 *vs.* 3.06±0.7; p=0.9); AGEs-sAF levels were positively correlated with interventricular septum (R=0.36; p=0.02), age (R=0.56; p=0.0001) and negatively correlated with the T *score* from bone densitometry (R=-0.36; p=0.03). In addition, AGEs-sAF levels were higher in patients with VC [N=14 (31%)] (3.4±0.5 *vs.* 2.8±0.5; p=0.01) and among patients with osteoporosis (3.2±0.8 *vs.* 2.6±0.4; p=0.04).

Conclusions: CKD stages 3-4 and PD patients have increased AGEs-sAF levels, which can be measured non-invasively with the AGE-Reader™. AGEs tissue accumulation might play a role on development of VC and osteoporosis in CKD patients.

SA-PO893

Association of Pre-ESRD Mineral and Bone Disorder Parameters with Post-ESRD Hospitalization for Fractures

Keiichi Sumida,[2] Miklos Z. Molnar,[4] Praveen Kumar Potukuchi,[4] Abduzhappar Gaipov,[4] Fridtjof Thomas,[4] Elani Streja,[1] Kunihiro Yamagata,[5] Kamyar Kalantar-Zadeh,[3] Csaba P. Kovesdy.[4] *[1]Harold Simmons Center for Kidney Disease Research and Epidemiology, Orange, CA; [2]Nephrology Center, Toranomon Hospital Kajigaya, Kawasaki, Japan; [3]University of California Irvine, School of Medicine, Orange, CA; [4]University of Tennessee Health Science Center, Memphis, TN; [5]University of Tsukuba, Tsukuba, Japan.*

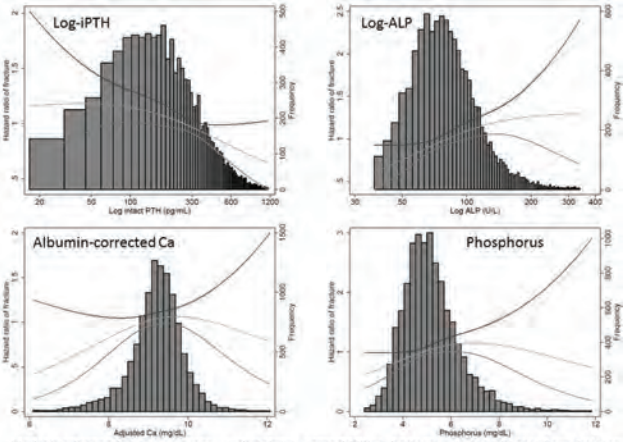
Background: Mineral and bone disorder (MBD) is associated with fractures both in CKD and ESRD. However, the association of MBD parameters in advanced CKD with fracture risk after dialysis is unknown.

Methods: We identified 10,942 US veterans starting dialysis between 10/2007-3/2014 with measurements of serum intact parathyroid hormone [iPTH], alkaline phosphatase [ALP], albumin-corrected calcium, and phosphorus within six months prior to dialysis start. MBD parameters were examined using splines and were also categorized into 3 groups with the reference group defined using guideline-based ranges, except for ALP which was categorized into tertiles. Associations of each MBD parameter with post-ESRD fracture-related hospitalization were examined in multivariable adjusted Cox regressions.

Results: 478 events occurred over a median follow-up of 1.8 years. Higher ALP was associated with higher fracture risk (adjusted hazard ratio [HR] [95% CI] for the highest [vs. lowest] tertile: 1.43 [1.11-1.85]). Both higher iPTH and lower calcium were associated with lower fracture risk (0.76 [0.59-0.98] and 0.64 [0.43-0.94], vs. referent). No association was seen between phosphorus and fracture risk (Figure).

Conclusions: Derangements of distinct pre-ESRD MBD parameters are associated with fracture risk after dialysis start. Further studies are needed to determine if correction of ALP, iPTH and calcium could prevent fractures.

Funding: NIDDK Support



SA-PO894

Comparison of the Prevalence of Mineral and Bone Disorders in Elderly and Non-Elderly Dialysis Population

Andre F. Costa,[1] Flavio Teles de Farias Filho.[2] *[1]Federal University of Alagoas, Brazil, Maceió, Brazil; [2]UNCISAL, Maceio, Brazil.*

Background: Disorders in mineral and bone metabolism are common in patients with chronic kidney disease (CKD). These disturbs is a set of clinical-laboratory changes that cause negative effects on the various outcomes of chronic renal failure patients. International consensuses, like KDOQI and KDIGO were intended to assist the practitioner caring for adults and children with CKD stages 3-5, on chronic dialysis therapy, or with a kidney transplant. But there are no specific recommendations for analysis and management of elderly patients.

Methods: The study included a population of hemodialysis patients from a in-hospital service in the city of Maceió, Brazil. We performed a cross - sectional study of patients on hemodialysis for at least 3 months. We observed the socio-demographic, clinical data and the annual average of the laboratory analyzes. The data were then compared between Group 1 patients > 60 years and Group 2 patientes < 55 years.

Results: 168 patients were evaluated, 41 of Group 1 and 147 of Group 2. Group 1: age 68.5 years (± 5.81); 68% men; diabetic nephropathy as the main underlying disease (51%); weakness as the most reported complaint (50%); PTH 183 ± 23.86 pg / ml; alkaline phosphatase 104 ± 9.07 U / L; serum calcium 9 ± 0.11 mg / dL; serum phosphorus 4.56 ± 0.13 mg / dl. Group 2: age 39.5 years (± 14.9); 54% men; hypertensive nephrosclerosis as the main underlying disease; PTH 368.20 ± 29.78pg/ml; alkaline phosphatase 148.60 UI ± 9.61; serum calcium: 8.93 ± 0.05 mg/dL; serum phosphorus: 5.51 ± 0.10 mg/dL. Group 1 exibited PTH and alkaline phosphatase values lower than Group 2, especially in females (p <0.0001). There were differences in serum phosphorus levels - being higher in Group 1 (p <0.001). The comparison between elderly women and men showed no siguinificative differences. It is inferred that sex is probably not a determining factor in the pattern of alterations in the parameters of mineral disorders but age was an independent factor in the profile of this population.

Conclusions: Differences in the pattern of prevalence of the main bone and mineral disorders among the elderly and non-elderly can be observed. Studies with a greater number of patients may corroborate the need to establish specific guidelines for the mineral and bone disorders of elderly patients with chronic kidney disease.

SA-PO895

Efficacy of Denosumab for Dialysis Patients with Osteoporosis

Junichi Hoshino,[1] Kyohei Kunizawa,[1,2] Masahiko Oguro,[1] Akinari Sekine,[1] Keiichi Sumida,[1] Masayuki Yamanouchi,[1] Yoshifumi Ubara.[1] *[1]Toranomon Hospital, Tokyo, Japan; [2]kyorin University, Mitaka Tokyo, Japan.*

Background: Osteoporosis is a major complication in patients on hemodialysis (HD) because therapeutic drugs for it are limited. Recently, the superior efficacy of denosumab—human monoclonal antibody to RANKL—in non-HD patients was reported, but evidence of its effect in HD patients remained very limited. Accordingly, we studied the safety and efficacy of denosumab in these patients.

Methods: We prospectively enrolled HD and non-HD patients who started denosumab between June 2013 to October 2015 in our hospitals, and followed them for a year. Changes in bone mineral density (BMD), serum calcium, and bone metabolic markers before and after the treatment were analyzed.

Results: In this study, 192 patients (65 HD patients, 127 non-HD patients) were enrolled. Increase of BMD in the lumbar spine among HD patients was similar to that of non-HD patients (7.1±10.7 vs 6.2±6.8 %, p=0.73), and also similar in the femoral neck (4.8±6.5 vs 3.3±7.8). On the other hand, prevalence of hypocalcemia (<8.5mg/dL) was significantly higher in HD patients than non-HD patients (32% vs 4%, p<0.001). The median duration of appearance of hypocalcemia after injection was 6 days, and change of serum calcium at day 7 was significantly lower in HD patients than in non-HD patients

(-0.7±1.0 vs -0.3±0.4, p=0.03). Changes of bone metabolic markers were similar in both groups.

Conclusions: Our study suggests that denosumab was effective in HD patients, much as it was in non-HD patients. However, careful monitoring of blood tests—at least for a week—is recommended for HD patients.

Cinacalcet Attenuates Bone Loss in CKD through Preventing the Endothelial to Adipocyte Transition Li-Hua Ni,[1] rining tang,[1] Kaiyun Song,[1] Bi-Cheng Liu.[2] *[1]Institute of Nephrology, Zhongda Hospital, Southeast University School of Medicine, Nanjing, China, Nanjing, China; [2]Zhong Da Hospital, Southeast University Medical School, Nanjing, China.*

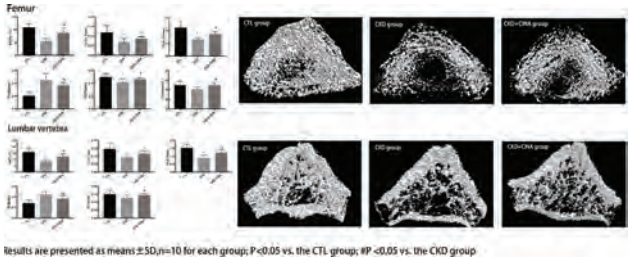
Background: Recently, cinacalcet (CINA) has been proved to be beneficial to bone lose in chronic kidney disease (CKD), while the exact mechanism is largely unknown. Emerging studies have shown that the conversion into mesenchymal stem cells (MSCs) via the endothelial-to-mesenchymal transition (EndMT) could be trigger into adipocytes. In this study, we hypothesized whether CINA could attenuate bone loss in CKD rats by inhibition the endothelium to adipocytes transformation.

Methods: Eight-week male Sprague Dawley rats were divided into three groups: a control group (CTL), vehicle-treated CKD group (CKD) and a cinacalcet-treated CKD group (CKD+CINA). CKD was induced by a 0.75% adenine diet. After adenine withdrawal, all rats were maintained on high phosphate diets. We performed blood analysis, emission computed tomography (ECT), bone mechanical properties tests, dual energy X-ray absorptiometry (DEXA) and micro-computed tomography (micro-CT), bone histomorphometry assessments in rats at the age of 42 weeks. The bone marrow expression of EndMT- and adipocyte-markers were also examined.

Results: In CKD rats, CINA treatment significantly decreased the serum PTH, phosphate (P), and Ca (Calcium) × P product ($P < 0.05$). The ECT images of the parathyroid glands indicated hyperparathyroidism in CKD rats but normal parathyroid function in CTL rats and CKD+CINA rats. Bone mineral density, trabecular BV/TV, trabecular number, cortical area, cortical thickness, force and stiffness were decreased in the CKD group, which were alleviated in the CKD+CINA group ($P < 0.05$). The expression of endothelial marker (CD31) was significantly down-regulated in CKD rats, whereas the expression of mesenchymal marker (FSP1), mesenchymal stem cell markers (STRO-1, CD44, CD10), adipocyte-markers (PPAR-γ and LPL) were markedly up-regulated. These changes were inhibited by CINA treatment ($P<0.05$).

Conclusions: This study firstly demonstrated that CINA exerted a beneficial effect on bone loss in CKD through a novel mechanism of preventing bone marrow endothelial-to-adipocyte transition.

Funding: Clinical Revenue Support, Government Support - Non-U.S.



Results are presented as means ±SD,n=10 for each group; P<0.05 vs. the CTL group; #P <0.05 vs. the CKD group

SA-PO897

Bisphosphonate Skeletal Accumulation Is Increased in Early and Mid-Stage CKD Mohammad W. Aref,[1] Elizabeth A. Swallow,[1] Neal X. Chen,[1] Sharon M. Moe,[1,2] Matthew R. Allen.[1,2] *[1]Indiana University School of Medicine, Indianapolis, IN; [2]Roudebush VA, Indianapolis, IN.*

Background: Bisphosphonates represent the gold standard pharmacological treatment for skeletal disease. Despite limited data, this class of drugs is contraindicated in patients with chronic kidney disease (CKD) due to concerns of compromised excretion and thus increased skeletal accumulation. The goal of this study was to use an animal model of progressive chronic kidney disease (Cy/+ rat) to study bisphosphonate distribution in the setting of reduced kidney function.

Methods: At 25 weeks of age, CKD and normal (NL) animals were administered a single bolus of fluorescently labelled zoledronic acid (Fam-ZOL). Animals were euthanized either 24 hours or 5 weeks later (30 weeks of age) and radius/ulna, distal femur, tibia, and 3rd lumbar vertebra (L3) were collected. Bulk levels of FAM-ZOL accumulation were estimated using whole bone fluorescence imaging (NightOwl LB981). Skeletal perfusion, to estimate blood flow and thus FAM-ZOL delivery, was measured prior to euthanasia via intra-cardiac injection of fluorescent microspheres.

Results: CKD animals had blood urea nitrogen (BUN) levels 2x higher than NL. At 24-hours post-dose, total bone fluorescence was higher in CKD radius (+134%, $p<0.05$), distal femur (+105%, NS), L3 body (+26%, NS) and tibia (+51%, $p<0.05$) compared to NL. Five-weeks post-dose, levels of drug in bone were significantly higher in all four bone sites of CKD animals relative to NL. Levels of drug in the bone at 5 weeks were indistinguishable from levels at 24-hrs post dose in both treatment groups. Skeletal perfusion was non-significantly higher in CKD relative to NL at 25 weeks of age. By 30 weeks (~20% NL GFR), perfusion was higher in CKD humeri (+155%, $p<0.05$), distal femur (+138%, NS) and L4 body (+142%, NS) compared to NL.

Conclusions: Based on these data we conclude that animals with reduced kidney function have altered dynamics of zoledronate accumulation in the skeleton, but such accumulation might be driven by factors other than compromised kidney excretion and may be due to altered blood flow.

SA-PO898

VS-605, a Mg+2-gum Arabic complex, Is a Non-Absorbed, Calcium- and Aluminum-Free, Highly Effective Phosphate Binder J. Ruth Wu-Wong, Yung-wu Chen, Jerry Wessale. *Vidasym, Chicago, IL.*

Background: Inadequate control of serum phosphate (Pi) in chronic kidney disease can lead to pathologies of clinical importance. Effectiveness of on-market phosphate binders is limited by safety concerns and low compliance due to large pill size/burden and gastrointestinal (GI) discomfort.

Methods: VS-605, a novel phosphate binder, is a polymer consisting of only Mg^{+2} and gum Arabic (a fiber component commonly used in food), with ~30% Mg^{+2} tightly complexed to gum Arabic (by X-ray photoelectron spectroscopy). VS-605 was evaluated for its efficacy and potential side effects in various pre-clinical studies including dosing 5/6 nephrectomized (NX) uremic SD rats with either VS-605 or sevelamer for 1 month.

Results: VS-605 has a high density at 1.89 g/cm^3 (vs. 1.27 g/cm^3 for sevelamer) as determined by helium pycnometer. When exposed to simulated gastric fluid, VS-605 exhibited a low swell volume at 0.3 cm^3/ml/0.1 g (vs. 4 cm^3/ml/0.1 g for sevelamer). After incubating with a phosphate buffer or in simulated gastric fluid for 24 hr at 37°C, VS-605 released <2% of Mg^{+2} into solution. In 5/6 NX uremic SD rats fed a high-phosphate diet, increasing dietary Pi led to an increase in serum Pi, which was prevented in rats treated with VS-605 or sevelamer (0.2 - 5% in food). Urinary Pi increased from 71 ± 19 at Week 0 to 785 ± 58 μmol/24 hr at Week 4 ($p<0.001$) in the vehicle-treated group; treatment with VS-605 or sevelamer (0.2 - 5% in food) reduced urinary phosphate in a dose-dependent manner (to 100 ± 28 and 102 ± 42 μmol/24 hr for 3% VS-605 and 5% sevelamer at Week 4, respectively). Concurrently, VS-605 or sevelamer increased fecal Pi in a dose-dependent manner. The high Pi diet also increased serum FGF-23 and parathyroid hormone in 5/6 NX rats, which was prevented by VS-605 or sevelamer. More aortic calcification was observed in the 5/6 NX rats treated with 5% sevelamer; neither VS-605 nor sevelamer exhibited any significant effects on intestine histology and intestinal sodium-dependent phosphate cotransporter gene expression.

Conclusions: These results support the conclusion that VS-605 effectively controls Pi imbalance in uremic rats by adsorbing dietary Pi in the GI tract. The minimal swell volume and high density of VS-605 may result in a potential advantage for a small pill size and reduced GI discomfort.

SA-PO899

Roles for Type III Sodium-Dependent Phosphate Transporter, PiT-2, in Bone Development and Growth in Mice with Normal and Impaired Kidney Function Shunsuke Yamada, Mary C. Wallingford, Timothy C. Cox, Cecilia M. Giachelli. *University of Washington, Seattle, WA.*

Background: Phosphate (Pi) is an essential component of bone and involved in normal bone development, growth, and homeostasis. The type III sodium-dependent phosphate transporters, PiT-1 and PiT-2, are expressed in bone but their exact functions remain unclear. In this study, the role of PiT-2 in bone homeostasis in normal and chronic kidney disease (CKD) mice was evaluated.

Methods: Global PiT-2 knockout (KO) and wild type (WT) male mice with intact kidneys were euthanized at 10 weeks of age and subjected to serum biochemical determination and micro CT analyses, which included measurement of bone length and bone mineral density (BMD) and calculation of static bone parameters. Furthermore, to determine the impact of PiT-2 deficiency on renal Pi handling, 10-week-old WT and PiT-2 heterozygous knockout (HET) female mice were subjected to 24-hour urine collection and serum measurement, followed by kidney collection. WT and PiT-2 HET mice also underwent two-step 5/6th nephrectomy and were subjected to micro CT analyses at 3 weeks after CKD induction.

Results: Bone length in PiT-2 KO mice was significantly shorter in femur, tibia, and vertebral column than the WT mice. BMD in systemic bones including mandibles and both trabecular and cortical bone of femurs were significantly lowered in the PiT-2 KO mice than the WT mice. When femurs were analyzed by micro CT, both cortical and trabecular bone thickness were decreased in the PiT-2 KO mice compared with the WT mice. No significant differences were observed in bone mineral density, serum calcium and Pi levels, kidney function, renal mRNA expression of SLC34A1 and SLC34A3, and fractional excretion of Pi between the WT and PiT-2 HET mice. However, in the setting of CKD and high Pi diet feeding, PiT-2 haploinsufficiency decreased trabecular bone volume and thickness but did not change cortical bone volume and had no effect on serum levels of creatinine, calcium, and Pi.

Conclusions: PiT-2 is required for bone development and growth under both normal kidney function and CKD, and enhancing its activity might provide benefits in CKD patients with bone disorders.

SA-PO900

Bone Expression of HIF-1 in Osteocytes Is Decreased in CKD Rats

Sarah-Kim Bisson,[1,2] Roth-Visal Ung,[1] Sylvain Picard,[1] Darren E. Richard,[2,1] Mohsen Agharazii,[1] Richard Lariviere,[1] Fabrice Mac-Way.[1,2] *[1]CHU de Québec, Université Laval, HDQ, Québec, QC, Canada; [2]Université Laval, Québec, QC, Canada.*

Background: Different studies, including our own, have shown that hypoxia-inducible factor-1 (HIF-1) enhances vascular calcification. However, HIF-1's role in chronic kidney disease (CKD)-related bone disease is currently unknown. The aim of this study is to determine bone HIF-1 expression in chronic kidney disease (CKD) rats with vascular calcification.

Methods: CKD was induced by 5/6 nephrectomy and vascular calcification by a supplement of calcium, phosphorus and 1,25-dihydroxyvitamin D3 (Ca/P/VitD). Three groups were studied: control (n=8), CKD (n=14) and CKD + Ca/P/VitD (n=12). At 2 months, tibia bone and thoracic aorta were harvested for micro-CT, histomorphometry and vascular calcification quantification. HIF-1α expression, the essential HIF-1 subunit, was assessed in the tibia by immunohistochemistry and quantified using ImageJ.

Results: Vascular calcification occurred only in CKD + Ca/P/VitD rats. Compared to controls, CKD and CKD + Ca/P/VitD rats presented with a lower bone volume and bone mineral content, while trabecular thickness and separation were significantly increased in the CKD+Ca/P/vitD group. Osteoid volume and surface were also increased in CKD + Ca/P/VitD rats, which is compatible with a mineralisation defect (low turnover and mineralisation parameters). HIF-1α was expressed in osteocytes. Interestingly, the proportion of positive osteocytes for HIF-1α was decreased in CKD and CKD+Ca/P/vitD rats as compared to the controls (respectively 63.01 ± 16.78% vs 60.91 ± 23.17% vs 89.31 ± 5.87% in controls, p<0.01)

Conclusions: Our study is the first to describe HIF-1 expression in bone from CKD rats with vascular calcification. Since HIF-1 was previously suggested to play a role in bone formation, these results suggest that lower osteocyte HIF-1 expression could be involved in the development of bone anomalies during CKD.

Leptin Signaling Blockade Ameliorates Muscle Wasting, Bone Disease, and Growth Failure in CKD

Wai W. Cheung,[2] Urszula T. Iwaniec,[1] Sheng Hao,[2] Zhen Wang,[2] Russell T. Turner,[1] Robert H. Mak.[2] *[1]Oregon State University, Corvalis, OR; [2]UCSD, La Jolla, CA.*

Background: We showed that aberrant leptin signaling is important in the pathophysiology of CKD-associated wasting (Cheung W et al JCI 115:1659-65, 2005 & JASN 25:119-28, 2014). As muscle and bone health are related, we investigated whether leptin signaling blockade affects bone disease and growth failure in CKD.

Methods: We performed 5/6 nephrectomy (CKD) or sham-operation (S) in 8 week old c57BL/6J wild-type (WT), leptin-deficient (ob/ob) and leptin receptor deficient (db/db) mice. Then, WT-CKD mice were treated with a pegylated leptin antagonist (PLA) (7 mg/kg/day) or vehicle (V) for 4 weeks. Secondary hyperparathyroidism was restricted with low phosphorus diets. WT-CKD mice were fed ad libitum while all other mice were pair-fed to that of WT-CKD. Body composition was determined by EchoMRI. Whole body and femoral mineral content (BMC) and bone mineral density (BMD) were assessed by dual-energy x-ray absorptiometry. Femoral bone strength and bone architecture were assessed by 3-point failure load test and X-ray microtomographic scanning (μCT), respectively.

Results: WT-CKD, ob/ob-CKD, db/db-CKD, WT-CKD+PLA and WT-CKD+V mice had significantly higher blood urea nitrogen and serum creatinine than WT-S, ob/ob-S, db/db-S, WT-S+PLA and WT-S+V mice. Bone disease in WT-CKD mice was characterized by decreased whole body BMC, BMD as well as decreased femoral length, BMC, BMD, cortical area, thickness and failure load. μCT confirmed that femoral bone volume, cortical area and thickness were significantly reduced in WT-CKD. Uremic bone phenotype was significantly improved in ob/ob-CKD and db/db-CKD compared to WTCKD mice. Weight gain, lean mass and muscle function were normalized in WTCKD+PLA relative to WT-S+V mice. Increased expressions of muscle inflammatory cytokines (IL-1α, IL-1β, IL-6 and TNF-α) were normalized in WT-CKD+PLA relative to WT-S+V mice. Uremic bone disease was prevented in WT-CKD+PLA mice. Whole body BMC, BMD as well as femoral length BMD, BMC, and failure load were normalized in WT-CKD+PLA relative to WT-S+V mice.

Conclusions: Aberrant leptin signaling may play an important role in the pathogenesis of muscle wasting, osteodystrophy and growth failure in CKD. Its blockade may represent a novel therapeutic strategy.

Increased Bone FGF23 expression Is Linked to Impaired Osteocyte Maturation in CKD

Katherine Wesseling-Perry,[1] Renata C. Pereira,[1] Isidro B. Salusky.[2] *[1]David Geffen School of Medicine at UCLA, Los Angeles, CA; [2]Mattel Children's Hospital, Los Angeles, CA.*

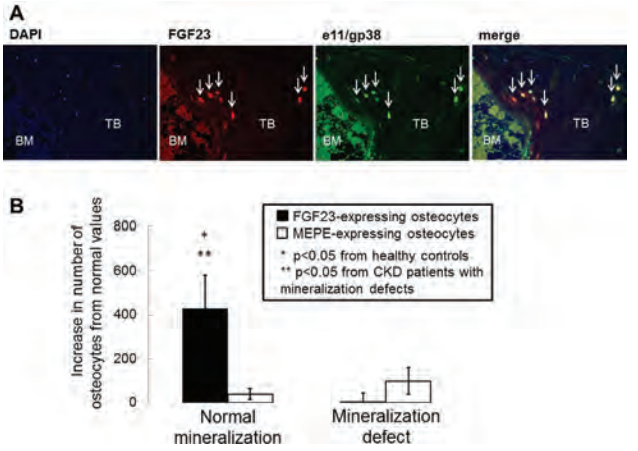
Background: Increased FGF23 expression and skeletal mineralization defects characterize bone in CKD. FGF23-expressing osteocytes are located in clusters at the trabecular periphery. Since young osteocytes are also at the trabecular periphery, we hypothesized that FGF23 is a marker of young osteocytes. We also hypothesized that increased numbers of young, FGF23-expressing, osteocytes reflect an adaptive response to impaired osteocyte maturation, the consequence of which is defective skeletal mineralization, in CKD.

Methods: We evaluated bone from 32 pediatric CKD patients (stages 2-4: n=12; stage 5: n=20). Patients were dichotomized based on the presence (n=13) or absence (n=19) of skeletal mineralization defects, defined by increased osteoid volume along with prolonged osteoid maturation time. Co-expression of FGF23 (FGF23(225-244); Quidel) with markers of osteocyte maturity (early osteocytes: e11/gp38 (ab25, Abcam); late osteocytes: MEPE(ab108073, Abcam)) was evaluated by immunofluorescence. Numbers of FGF23 and MEPE expressing osteocytes were evaluated by immunohistochemistry.

Results: FGF23 co-localized with e11/gp38 but did not co-localize with MEPE. Normal skeletal mineralization indices were associated with a 429 ± 153% increase in numbers of FGF23-expressing osteocytes (p<0.05 from control values; p<0.05 from patients with skeletal mineralization defects). Numbers of MEPE-expressing osteocytes did not differ between groups or between CKD patients and controls.

Conclusions: FGF23 is a marker of young osteocytes. Normal mineralization indices in CKD are associated with a robust increase in young osteocytes. Impaired osteocyte maturation may precede and contribute to the development of skeletal mineralization defects and secondary hyperparathyroidism in CKD.

Funding: NIDDK Support, Private Foundation Support



A) Colocalization of FGF23 and e11 in iliac crest. B) Increased numbers of FGF23-expressing osteocytes, but not MEPE-expressing osteocytes, in CKD patients with normal mineralization indices.

Relationship between Sarcopenia and Bone Mineral Density in Hemodialysis (HD) Patients

Senji Okuno,[1] Hisanori Okazaki,[1] Jiro Miyawaki,[1] Kyoko Norimine,[1] Shigeichi Shoji,[1] Tomoyuki Yamakawa,[1] Eiji Ishimura,[2] Masaaki Inaba.[2] *[1]Shirasagi Hospital, Osaka, Japan; [2]Osaka City University Graduate School of Medicine, Osaka, Japan.*

Background: Little is known about the relationship between sarcopenia and bone mass in HD patients. Moreover, definition of sarcopenia was made only in considering the muscle mass in most of the previous studies. The purpose of this study was to strictly assess sarcopenia by both muscle mass and muscle strength in HD patients, and was to compare bone mineral density (BMD) between HD patients with and without sarcopenia.

Methods: A total of 287 patients on maintenance HD were examined. BMD at the 1/3 distal radius and appendicular skeletal muscle mass were measured by dual energy X-ray absorptiometry (DXA). Low muscle mass was defined as skeletal muscle mass index (SMI) of < 6.87 kg/m² for males and < 5.46 kg/m² for females. Low muscle strength was defined as hand grip strength of < 26 kg for males and < 18 kg for females, according to the criteria of Asian Working Group for Sarcopenia. Sarcopenia was defined as decline in both hand SMI and grip strength.

Results: There were no significant differences in HD duration or in prevalence of diabetes between patients with and without sarcopenia in both genders. Age was significantly higher in patients with sarcopenia than those without sarcopenia in both genders (62.2 ± 12.7 *vs.* 53.3 ± 10.4 years, p < 0.0001 in males; and 65.3 ± 8.6 *vs.* 55.3 ± 11.2 years, p < 0.0001 in females). BMD of the 1/3 distal radius in patients with sarcopenia was significantly lower than that of patients without sarcopenia in both genders (0.62 ± 0.12 *vs.* 0.69 ± 0.09 g/cm², p < 0.0001 in males; and 0.44 ± 0.09 vs. 0.53 ± 0.09 g/cm², p < 0.0001 in females). In a multiple linear regression analysis, presence of sarcopenia (β = - 0.196, p = 0.0075 in males; β = - 0.188, p = 0.0340 in females) was significantly, independenly associated with BMD of the 1/3 distal radius after adjustment with age, HD duration, presence of diabetes, body mass index, and serum parathyroid hormone levels in both genders (R^2 = 0.320, p < 0.0001 in males; and R^2 = 0.448, p < 0.0001 in females).

Conclusions: These results clearly demonstrate that sarcopenia, which was strictly assessed by muscle mass and strength, is significantly associated with decrease in BMD in HD patients, suggesting that sarcopenia should be regarded as a significant risk factor for either osteoporosis or renal osteodystrophy in these patients.

SA-PO904

Bone Mineral Density by Quantitative Computed Tomography Can Predict Fractures in Kidney Transplantation Candidates

Hanne S. Joergensen,[2,1] Simon Winther,[4] Ellen-Margrethe M. Hauge,[6] Lars Rejnmark,[5,1] My Svensson,[3] Per R. Ivarsen.[2,1] *[1]Aarhus University, Aarhus N, Denmark; [2]Nephrology, Aarhus University Hospital, Aarhus, Denmark; [3]Nephrology, Akerhus University Hospital, Oslo, Norway; [4]Cardiology, Aarhus University Hospital, Aarhus, Denmark; [5]Endocrinology, Aarhus University Hospital, Aarhus, Denmark; [6]Rheumatology, Aarhus University Hospital, Aarhus, Denmark.*

Background: Fracture risk is increased in chronic kidney disease (CKD), but the role of bone mineral density (BMD) in assessing bone fragility is still controversial. This study investigates if BMD can predict incident fractures in late stage CKD.

Methods: Adult kidney transplantation candidates were included. Volumetric BMD of spine and hip was analyzed from computed tomography (CT) scans. Low trauma fractures were recorded from patient interviews and records.

Results: During a median follow-up of 3.7 years, 19 out of 157 patients (12%) sustained a clinical fragility fracture. Patients with fracture had reduced BMD at the hip, but not at the spine (Table 1). Type 1 diabetes ($p < 0.001$), bone specific alkaline phosphatase ($p = 0.03$), and hip *T*- and *Z*-scores ($p < 0.05$) were identified as predictors of fracture by univariate cox regression. Thus, patients with total hip or femoral neck *T*-scores≤-2.5 were at increased risk (Figure 1). A 1 unit decrease in total hip *Z*-score was associated with a 2-fold increase in the risk of fracture (HR 2.01, CI 1.24 to 3.24, p<0.01) after adjusting for dialysis therapy at baseline and kidney transplantation during follow-up.

Conclusions: Hip BMD by CT may predict fractures in adult kidney transplantation candidates with severe CKD.

Funding: Private Foundation Support

Table 1 Bone density in patients with and without fracture

		Fracture (n=19)	No fracture (n=136)	p
Lumbar spine	vBMD	123±40	122±39	0.86
	Z-score	-0.54±1.30	-0.43±1.38	0.75
	T-score	-1.83±1.53	-1.93±1.46	0.79
Total hip	vBMD	210±45	232±44	0.04
	Z-score	-1.82±1.12	-1.15±1.07	0.01
	T-score	-2.47±1.04	-1.89±1.07	0.03

Data are mean±SD with p values by Student's t-test

Risk of Fracture in Glomerular Disease: A Population-Based Cohort Study Using the Health Improvement Network

Michelle Denburg,[1] Laura H. Mariani,[2] Dorey A. Glenn,[3] Lawrence A. Copelovitch,[1] Mary B. Leonard,[4] Thomas Nickolas.[5] *[1]The Children's Hospital of Philadelphia, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; [2]University of Michigan, Ann Arbor, MI; [3]University of North Carolina, Chapel Hill, NC; [4]Stanford School of Medicine, Stanford, CA; [5]Columbia University Medical Center, New York, NY.*

Background: Current understanding of skeletal complications in glomerular disease (GD) is limited. To our knowledge, there have been no studies in children or adults addressing the risk of fracture associated with GD independent of kidney function.

Methods: We performed a population-based retrospective cohort study using The Health Improvement Network. The median calendar year at the start of observation was 2005 (1994-2015). We identified 16,111 patients with ≥1 of 155 diagnostic codes for primary GD and 161,045 randomly selected age, sex, and practice-matched individuals. Exclusion criteria included age ≥90 years, systemic lupus or vasculitis, multiple myeloma, amyloidosis, inflammatory bowel disease, celiac disease, HIV, hepatitis B or C, malignancy, and non-renal solid organ transplant. Cox regression was used to estimate the hazard ratio (HR) for first fracture.

Results: Median age was 42 years, and 57% were male. Over a median observation period of 5 years, 1328 incident fractures (132 per 10,000 person-years) occurred in participants with GD versus 11,423 in those without GD (110 per 10,000 person-years). In multivariable analysis adjusted for age, sex, and diabetes and chronic kidney disease (stage 3-5D and/or renal transplant) as time-varying covariates, GD was associated with an increased risk of fracture (HR 1.13; 95% CI: 1.06, 1.19, p<0.001). The adjusted HR for first incident vertebral fracture was 1.47 (95% CI: 1.10, 1.95, p=0.009). The adjusted HR for first incident hip/femur fracture was 1.46 (95%CI: 1.21, 1.75, p<0.001), and the increased risk associated with GD was more pronounced in younger individuals (HR 2.65 for those <40 years old vs. 1.42 for those ≥40 years, interaction p=0.03).

Conclusions: In this large-population based cohort study, GD was associated with an increased risk of incident fracture, particularly at the hip and spine, independent of impaired kidney function.

Effects of Parathyroidectomy on Blood Bone Markers and Heart Rate Variability in CKD Patients

Ningning Wang,[1] Huimin Chen,[3] Xiaoming Zha,[4] Chang Ying Xing.[2] *[1]Department of Nephrology, The First Affiliated Hospital with Nanjing Medical University, Nanjing, China; [2]First Affiliated Hospital of Nanjing Medical University, Nanjing, China; [3]The First Affiliated Hospital of Nanjing Medical University, Nanjing, China; [4]First Affliated Hospital with Nanjing Medical University, Nanjing, China.*

Background: Lower heart rate variability (HRV) in chronic kidney disease (CKD) patients is associated with increased risk of cardiovascular disease (CVD). We aimed to evaluate the relationships between blood bone markers and HRV in stage 5 CKD patients, longitudinal changes in severe secondary hyperparathyroidism (SHPT) subgroup with parathyroidectomy (PTX) were also explored.

Methods: This cross-sectional study included 134 CKD patients, 100 controls, and a prospective study in PTX group(n=45) with median follow-up time of 6.7 months. Bone parameters included (1) intact parathyroid hormone (iPTH), as classic bone remodeling regulators; (2) bone-specific alkaline phosphatase (BAP), representing bone formation; (3) tartrate-resistant acid phosphatase (TRACP-5b), indicating bone resorption; (4) bone-derived hormone, fibroblast growth factor 23 (FGF23). HRV were measured by 24h Holter.

Results: Circulating bone markers of the participants were shown in Table 1. Baseline iPTH, BAP and lnFGF23 levels were independently associated with decreased HRV in CKD patients. Elevated blood iPTH, BAP, TRACP-5b, FGF23 levels and attenuated HRV were ameliorated after PTX, furthermore, improved HRV were associated with reduced iPTH, TRACP-5b and FGF23 levels(Fig1).

Conclusions: In CKD patients, circulating iPTH and FGF23 levels may play important roles in imbalances of cardiovascular autonomic nervous system while the roles of bone resorption/formation need more research.

Funding: Government Support - Non-U.S.

Circulating Bone Markers of Different Participants

SA-PO907

Kidney Stones Associate with Increased Risk for Fracture in Patients with CKD Dong Ho Shin,[1] Jung-woo Noh,[2] Jeonghwan Lee.[3] *[1]College of Medicine, Hallym University, Seoul, Republic of Korea; [2]Hallym University, Seoul, Republic of Korea; [3]Hallym University Hangang Sacred Heart Hospital, Seoul, Republic of Korea.*

Background: Most of kidney stones may result from renal hypercalciuria, which is a systemic dysregulation of calcium homeostasis. Accordingly, fractures related with this dysregulation occur more frequently in patients with nephrolithiasis than in the general population. However, little is known about the potential influence of kidney stones on bone health status in patients with chronic kidney disease (CKD).

Methods: A total of 2284 patients with stage 3 – 4 CKD, who were treated at Kandong Scared Heart Hospital were included. Patients were divided into 2 groups according to the presence and absence of kidney stones, and clinical and laboratory data were compared between groups. The association of fractures with kidney stones analyzed using Cox proportional hazards analysis.

Results: Patients with kidney stones and without kidney stones were 502 and 1782, respectively. Among these patients, 172 (7.4 %) were diagnosed with fractures. Hip, pelvis, vertebra, proximal humerus or distal forearm fractures were 43, 31, 50, and 48, respectively. Compared to patients without kidney stone, patients with kidney stones had a significantly higher proportion of fractures (12.4 % vs 6.2 %, P = 0.02). In particular, Cox proportional hazard analysis revealed that kidney stones were a significant independent predictor of vertebral fracture even after adjusting for other factors in patient with CKD stage 3-4 (HR, 1.81, 95% CI 1.12 – 1.81, P = 0.04).

Conclusions: Kidney stones are at increased risk for fractures. Especially, kidney stones are independently associated with higher risk of vertebral fracture in patients with CKD.

SA-PO908

Effects of Primary Kidney Disease on Bone Histomorphometry in Pediatric Dialysis Patients Ornatcha Sirimongkolchaiyakul,[1] Katherine Wesseling-Perry,[1] Barbara Gales,[3] Georgina Chow,[4] Renata C. Pereira,[5] Isidro B. Salusky.[2] *[1]David Geffen School of Medicine at UCLA, Los Angeles, CA; [2]Mattel Children's Hospital, Los Angeles, CA; [3]None, Calabasas, CA; [4]UCLA, Murrieta, AL; [5]University of California, Los Angeles, CA.*

Background: Little is known as to the effect of primary kidney disease on renal osteodystrophy. The current study was thus designed to assess the association between CKD etiology, mineral metabolism and bone histromorphometry in pediatric ESKD.

Methods: Demographic, biochemical and bone histomorphometric data were analyzed from 207 patients (aged 12.7 ± 5.6 years) with ESKD who underwent double tetracycline labeled bone biopsy at UCLA. Patients were divided into 2 groups according to CKD etiology: inflammatory (n = 85) v. non-inflammatory (n=122) disease. Non-inflammatory disease was further divided into CAKUT (n = 87) v. non-CAKUT (n = 35). Serum Ca, P, ALP, PTH, 25D, and C-term FGF23 levels were measured at the time of biopsy.

Results: Serum Ca, P, PTH and 25D did not differ between groups. Serum ALP levels were higher, and cFGF23 levels were lower, in patients with CAKUT (Table). Bone turnover and volume did not differ between groups. Osteoid volume (OV/BV), osteoid surface (OS/BS), osteoid thickness (O.Th) and osteoid maturation time (OMT) were increased in patients with CAKUT. As previously reported, multiple regression analysis demonstrated that Ca, P, ALP and PTH were independent predictors of OV/BV and O.Th. ALP and PTH were an independent factors affecting BFR/BS. Disease etiology was not an independent predictor of any histomorphometric variable.

Conclusions: After controlling for biochemical variables, ESKD etiology did not affect bone histomorphometric parameters of turnover, mineralization, or volume.

Funding: NIDDK Support, Private Foundation Support

PPI Use Is Associated with Higher Prevalence of Bone Fractures and Mortality in Young Hemodialysis Patients Maria Fusaro,[5] Maurizio Gallieni,[6] Graziella D'arrigo,[3] Annalisa Pitino,[4] Andrea Aghi,[7] Bruce M. Robinson,[1] Brian Bieber,[1] Keith McCullough,[1] Francesca Tentori,[8] Giovanni Tripepi.[2] *[1]Arbor Research Collaborative for Health, Ann Arbor, MI; [2]CNR-IBIM, Reggio Calabria, Italy; [3]Clin. Epid. and Physiopath. of Renal Dis. and Hypertens., CNR-IBIM, Reggio Calabria, Italy; [4]Consiglio nazionale delle ricerche (CNR), Rome, Italy; [5]National Research Council (CNR) e Institute of Clinical Physiology (IFC), Pisa, Italy, Padua, Italy; [6]Ospedale San Carlo Borromeo - ASST Santi Paolo e Carlo - University of Milano, Milano, Italy; [7]Department of Medicine, University of Padua, Padua, Italy; [8]DaVita Clinical Research, Minneapolis, MN.*

Background: Proton pump inhibitors (PPIs) are extensively used in the general population and even more in dialysis patients. The aim of this observational study was to evaluate the association between use of PPIs and bone fractures (BFs) in hemodialysis (HD) patients enrolled in the Dialysis Outcomes and Practice Patterns Study (DOPPS) study.

Methods: Among 49564 (58% male) hemodialysis patients from the DOPPS dataset, 39,9% of patients received PPI treatment, aged 63.8±14.3 years, median (IQ range) dialysis duration 19 (4-55) months, BMI 25.5±5.8 Kg/m2, median follow-up time 19 months (IQR 9-27).

Results: In the whole study cohort, 12567 patients experienced the combined endpoint BFs/death and 7.538 patients, with available data on hip fractures (HFs) had the HFs/death outcome. A significant (P≤0.002) and inverse effect modification by age on the relationship between PPI treatment and the incidence rate of BFs and HFs was found, the effect of PPI being progressively lower from 35 years of age onwards (Fig. 1). Both crude and adjusted effect modification analyses considering the competitive risks of mortality fully confirmed these results, the effect of PPI on the combined outcomes BFs/D and HFs/D being closely and inversely dependent on age (Fig. 1).

Conclusions: In this study, the association between PPI use and bone fracture risk was clearly confirmed in the dialysis population especially in younger patients. In addition, we could demonstrate a combined increased risk of bone fractures and death, again higher in younger patient, indicating a remarkable and avoidable adverse effect of PPIs in this population.

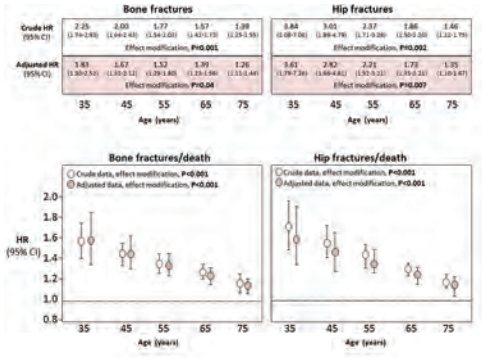

Fig. 3

Effect modification by age on PPI use

The Regina CKD-MBD Study Bhanu Prasad,[2] Shelley Giebel,[3] Thomas Nickolas.[1] *[1]Columbia University Medical Center, New York, NY; [2]None, Regina, SK, Canada; [3]Regina QuAppelle Health Region, Regina, SK, Canada*.

Background: Recent studies have demonstrated that measurement of areal bone mineral density (BMD) by dual energy X-ray absorptiometry predicts fractures in patients with chronic kidney disease (CKD). However, whether fracture risk prediction by BMD is enhanced by assessment of biochemical markers of CKD-mineral and bone disease or clinical risk factors is not clear. We hypothesized that in a selected cohort of patients managed in a CKD clinic, that combining T scores with biochemical markers would optimize fracture discrimination than using DXA alone.

Methods: We conducted a retrospective review of 374 consecutive patients who underwent mandatory DXA imaging at the point of entry into our multidisciplinary CKD program. BMD measurements were obtained from DXA scan reports from the Nuclear Medicine Department. BMD data were collected at four sites: the lumbar spine, total hip, mean of left and right femoral neck, and the 1/3- radius. We collected data on demographic, lab markers of mineral metabolism and fractures (identified through self-reported questionnaires, hospital electronic medical records and physician billing records.

Results: In our cohort, 14.3% of stage 3 CKD, 15.7% of stage 4 CKD and 19.7% of stage 5 CKD experienced a clinical fracture during the study period. In an unadjusted model, each standard deviation decrease in total hip T-Score was associated with a 47% higher odds of fracture (OR=1.47, 95%CI: 1.18-1.82, p=0.0006). After adjustment for clinical risk factors (age, sex, BMI and diabetes) the odds of fracture remained unchanged (OR=1.47, 95%CI: 1.14-1.89, p=0.0028), and after adjustment for clinical risk factors and markers of CKD-MBD, BMD remained a significant predictor of fracture (OR=1.52, 95%CI: 1.17-1.99, p=0.0018). In the final model, additional adjustment for eGFR did alter the relationship between total hip T-Score and fracture (OR=1.53, 95%CI: 1.17-1.99, p=0.0017). Neither clinical risk factors nor markers of CKD-MBD were related to fracture in multivariate models and there was no interaction between total hip T-score and eGFR (p=0.5).

Conclusions: We conclude that measurement of BMD by DXA scans predicts fractures in stages 3-5. However, fracture risk prediction was not further enhanced by the addition of biochemical markers of CKD-MBD.

SA-PO911

Risk Factors of Fragility Fracture in Patients with CKD Mark A. Kleman,[2] Waleed Zafar,[1] Alex R. Chang.[3] *[1]Geisinger, Dnville, PA; [2]Geisinger Health System, Danville, PA; [3]Geisinger Medical Center, Danville, PA*.

Background: Management of chronic kidney disease-mineral and bone disorder (CKD-MBD) focuses mainly on parathyroid hormone (PTH), phosphorus, and calcium. However, little is known about fragility fracture risk factors in CKD patients.

Methods: The study population included 5,733 patients in the Geisinger Health System with CKD [estimated glomerular filtration rate (eGFR) < 60 ml/min/1.73m^2, or urine albumin/creatinine ratio >=30 mg/g], intact PTH measurements, and no prior history of fragility fracture or use of osteoporosis medications. Fragility fracture was defined by ICD-9 codes for wrist, humerus, hip, and clinical spine fracture.

Results: Over a median follow-up of 5.0 (3.4-7.5) years, 609 (10.6%) CKD patients experienced an incident fragility fracture. Median (interquartile range) values for age, eGFR, intact PTH, alkaline phosphatase (ALP) were 70 (60-78) y, 43 (31-54) ml/min/1.73m^2, 57 (37-90) pg/ml, and 77 (63-97) IU/L. and 68.0 y, 52.7% were female, 98.1% were white, mean eGFR was 44.8 (22.1) mL/min/1.73m^2, and median Elevated alkaline phosphatase (ALP) >= 100 IU/L was associated with increased risk of incident fragility fracture; intact PTH, 25-hydroxyvitamin D, serum phosphorus and bicarbonate levels were not. Other significant risk factors included older age, female gender, body mass index (BMI) < 20 kg/m^2, serum albumin < 4 g/dl, and history of non-fragility fracture **(Table)**.

Conclusions: Several routinely collected clinical factors are associated with increased risk of fragility fracture in patients with CKD. Future clinical trials aimed at improving bone health and reducing fracture risk may consider using clinical factors to identify CKD patients at high risk of fragility fracture.

	HR	P value
Age (per 1-y increase)	1.04 (1.03-1.05)	<0.001
Female	1.36 (1.12-1.67)	0.002
White	2.47 (0.79-7.71)	0.1
Current smoker	1.16 (0.82-1.64)	0.4
BMI <20 kg/m2	2.23 (1.42-3.50)	0.001
Hx Stroke	1.18 (0.95-1.47)	0.1
Hx non-fragility fracture	1.56 (1.21-2.01)	0.001

SA-PO912

Influence of Vitamin D Receptor Polymorphisms on Biochemical Markers of Mineral Bone Disorders in South African Patients with CKD Bala Waziri,[2] Saraladevi Naicker.[1] *[1]University of the Witwatersrand, Johannesburg, South Africa; [2]Internal Medicine, Charlotte Maxeke Johannesburg Academic Hospital, Johannesburg, South Africa*.

Background: It remains unclear whether genetic factors may explain the reported variation in the levels of biochemical markers of chronic kidney disease mineral and bone disorders (CKD- MBD) across ethnic groups. Therefore, the aim of this study was to examine the influence of VDR polymorphisms on secondary hyperparathyroidism and its association with vitamin D levels in black and white South African study participants.

Methods: This was a cross sectional study involving 272 CKD stage 3- 5D patients and 90 healthy controls. The four common VDR polymorphisms (*Bsm 1, Fok 1, Taq 1, and Taq 1*) were genotyped using the polymerase chain reaction- restriction fragment length polymorphism (PCR –RFLP) method. In addition, the biochemical markers of CKD-MBD were measured to determine their associations with the four VDR polymorphisms.

Results: With the exception of *Taq I* polymorphism, the distribution of the VDR polymorphisms differs significantly between blacks and whites. In hemodialysis patients, the Bb genotype was significantly associated with moderate secondary hyperparathyroidism (OR, 0.3.12; 95 CI 1.11-8.83, p=0.03) and severe hyperparathyroidism (OR, 2.55; 95 CI 1.19-5.47, p=0.02). This was consistent with the observed higher levels of median PTH and mean phosphate in patients with Bb genotype. This candidate risk genotype (Bb) was over represented in blacks compared to whites (71.0 % versus 55.6 %, p <0.0001). In an unadjusted regression model, *Fok Ff* genotype was found to be significantly associated with the risk of developing severe vitamin D deficiency < 15ng/ml (OR, 1.89; 95 CI 1.17-3.07, p=0.01).

Conclusions: The VDR Bb genotype is an independent predictor of developing secondary hyperparathyroidism in patients with end stage renal disease. In addition, study participants with the *Fok Ff* genotype are at increased of developing severe 25(OH) D deficiency

SA-PO913

Integrative Point-of-Care Ultrasound (POCUS) Curriculum Imparts Diagnostic Skills Relevant to Nephrology Surekha U. Mullangi, Stephen M. Sozio, Steven Menez, Tariq Shafi. *Johns Hopkins University School of Medicine, Baltimore, MD*.

Background: The utility of POCUS has been expanding as a multipurpose diagnostic tool for nephrologists. However, a clear, nephrology-specific, curriculum has not been established. We have developed and implemented a POCUS curriculum that teaches focused skills to nephrology fellows. The goal of our study is to describe our initial experience with this innovative program.

Methods: The Johns Hopkins Renal Fellowship POCUS curriculum is a two-week elective that provides focused training to assess the following: heart (ejection fraction, pericardial effusion, chamber size), lungs (pulmonary edema, effusion, pneumothorax), inferior vena cava (diameter, collapsibility), kidney (size, echogenicity, hydronephrosis), bladder (volume), and fistula (depth, diameter). We teach these skills using a combination of didactic lectures, guided scanning, and independent scanning. We grade both image interpretation skills using a Qualtrics-based test and image acquisition skills using an POCUS-Objective Structured Clinical Examination (OSCE). Pre-tests and post-tests were administrated prior to and after completion of the program. Comfort with ultrasound skills was gauged using a 5-point Likert scale.

Results: 12 fellows and trainees have so far started the course; 4 have completed all modules and the remaining are continuing training. Of the 4 who completed training, fellows were mean (sd) 7.3 (2.2) years after graduation from medical school. 25% of fellows had used POCUS before for diagnostic purposes, but none were formally trained in use. The fellows that completed the course reported significant improvement ($p < 0.05$) in assessing kidney pathology, bladder volume, ejection fraction, and pericardial effusion. Comparing pre-test to post-test scores, fellows felt significantly more comfortable identifying and assessing pathology across all domains following the course (2.40 (0.87) to 4.20 (0.65), $p < 0.001$). At the end of the course, 100% of fellows agreed or strongly

agreed that POCUS was easy to obtain, improved assessment of patients, should be a part of the fellowship, and that other nephrology colleagues and faculty should be trained.

Conclusions: A 2-week nephrology-specific P OCUS c urriculum i s f easible and enhances fellows' learning experience.

SA-PO914

Nephrology Practice and Training in the Intensive Care Unit: Results of a United States Survey Paul J. Mccarthy,[2] kemsha Z. Huslin,[1] Farhan Ali.[1] *[1]Smithsburg, MD; [2]University of Maryland, Baltimore, MD.*

Background: Renal pathology is common in the intensive care unit (ICU). Understanding of the entire ICU patient is optimal. We completed a survey looking at opinions of intensivists and nephrologists regarding renal replacement. There was agreement on many issues and disparity in some areas. We completed a second survey on ICU nephrology to identify potential areas for future study and imrpovements in our training program.

Methods: A survey on renal replacement was emailed to training program directors in critical care medicine and nephrology and to nephrologists from a department database. A second survey was emailed to program directors in nephrology and nephrologists from a department database with questions on practices and nephrology training related to the ICU. Questions in the second survey were the result of responses from the first survey.

Results: Respondents were from both academic and non-academic settings, large and small centers and were from all parts of the country. The 1st survey showed agreement among nephrologists and intensivists on indications to start renal replacement and dosing for CRRT. There were differences based on specialty in volume assessment and rounding patterns. Half of responding to the second survey stated that up to 50% of their patients are in the ICU. Most respondents report that they place dialysis catheters, manage hemodialysis, CRRT and half prescribe pheresis. 75% have not participated in a continuing medical education (CME) activity specific to ICU nephrology in the last year. Rarely respondents round on patients at night. For training programs, less than half reported a minimal of proctored CRRT cases are required. 40% of training programs give renal fellows specific training in hemodynamic monitoring and 15% or less of programs report training fellows in ultrasound, mechanical ventilation or require a formal rotation as part of an ICU team.

Conclusions: Nephrologists spend a good portion of time seeing ICU patients. Most place dialysis catheters, manage hemodialysis, CRRT and many manage pheresis. 75% have not participated in a CME specific to ICU nephrology in the last year. Most nephrology training programs have no minimum requirement of proctored CRRT cases and most programs do not train fellows in hemodynamic monitoring, ultrasound, mechanical ventilation or require dedicated time as an ICU team member.

SA-PO915

Assessing Teaching Practices in Percutaneous Kidney Biopsy among Pediatric Nephrology Training Programs Shamir Tuchman,[1] John D. Mahan.[2] *[1]Children's National Medical Center, Washington, DC; [2]Nationwide Children's Hospital, Columbus, OH.*

Background: Standardized approaches for teaching kidney biopsies in pediatric nephrology fellowship training have not been established. To date, there has not been a comprehensive assessment of kidney biopsy teaching practices among pediatric nephrology training programs. The purpose of this study was to determine common practice patterns for teaching kidney biopsies for pediatric nephrology trainees.

Methods: An online survey was piloted and administered to training program directors (TPD's) at 40 ACGME accredited pediatric nephrology training programs in the United States.

Results: 28 (70%) of TPD's completed the survey. Trainees performed the majority of all kidney biopsies at 73% of the institutions with the majority (63%) of kidney biopsies performed by 1st year trainees. A supervising attending nephrologist was uniformly in attendance in the procedure area. Less than 50% of programs used didactic instruction or simulations in teaching obtaining consent and performing kidney biopsies. "Observation" was uniformly employed (100%) as the primary teaching modality for these purposes. All institutions used ultrasound localization for kidney biopsies. In 22% of the institutions, the trainee performing the biopsy was responsible for ultrasound guidance of the biopsy needle. 86% of the programs that have the nephrologist performing simultaneous ultrasound provided formal instruction in ultrasonography to their trainees. There was a broad range in the number of kidney biopsies performed by each trainee through training ranging from 10 to 150 biopsies with 10-80% of these performed in renal allografts. Among TPD's, the minimum number of kidney biopsies felt to be sufficient to attain competency for independent practice was 10 with the majority (57%) of TPD's feeling that 20-40 biopsies were necessary for a trainee to achieve competence. 92% of training programs provide teaching in the interpretation of kidney biopsies using a combination of didactic instruction (73%), renal pathology conferences (93%), and formal rotations with pathology within or outside their institutions (63%).

Conclusions: Despite a lack of formalized guidance or national standards, pediatric nephrology training programs employ common practices in teaching pediatric nephrology trainees to competently perform kidney biopsies in children and adolescents.

SA-PO916

Virtual Patient Simulation Improves Clinical Decisions for Hyperkalemia Treatment in Patients with Heart Failure Susan Gitzinger, Donald Blatherwick, Douglas Blevins. *Medscape, Lexington, KY.*

Background: This study was conducted to determine if an online, virtual patient simulation-based continuing medical education (CME) intervention could improve performance of nephrologists and cardiologists in the management of patients with heart failure and hyperkalemia.

Methods: The CME intervention comprised 2 cases presented in a virtual patient simulation (VPS) platform, allowing learners to choose from lab tests, diagnoses, and treatments matching the scope and depth of actual practice. Learner clinical decisions, entered using open field entries, were analyzed using a sophisticated decision engine; tailored clinical guidance (CG) was provided based on current evidence and expert recommendation. Decisions were collected post-CG and compared with each user's pre-CG data using a 2-tailed paired t-test to determine *P* values. Data is reflective of learners who participated in the assessment from 2/23/17 to 4/21/17.

Results: Significant improvements include: *Case 1 (n=86 nephrologists, n=126 cardiologists):* Nephrologists and cardiologists demonstrated statistically significant changes from pre-CG to post CG in (all P<0.001): Diagnosis of hyperkalemia (3% vs 37% of nephrologists; 0% vs 45% of cardiologists) Orders for patiromer (1% vs 29% of nephrologists; 1% vs 36% of cardiologists) Orders for a preferred beta-blocker (12% vs 51% of nephrologists; 26% vs 56% of cardiologists) Orders for an ACEi (12% vs 40% of nephrologists; 30% vs 56% of cardiologists) Orders for influenza vaccination (0% vs 35% of nephrologists; 0% vs 36% of cardiologists) *Case 2 (n=68 nephrologists, n=102 cardiologists):* Nephrologists and cardiologists demonstrated statistically significant changes from pre-CG to post CG in (all P<0.001): Orders for patiromer (35% vs 68% of nephrologists; 21% vs 63% of cardiologists) Orders for sacubitril/valsartan (10% vs 46% of nephrologists; 19% vs 59% of cardiologists) Orders for influenza vaccination (0% vs 46% of nephrologists; 0% vs 40% of cardiologists) Orders for pneumococcal vaccination (0% vs 49% of nephrologists; 0% vs 43% of cardiologists)

Conclusions: This study demonstrated the success of online, VPS-based education that engages nephrologists and cardiologists for an authentic and practical learning experience that can improve evidence-based clinical decisions in the management of hyperkalemia in patients with heart failure.

CKD-Related Hyperkalemia: Effectiveness of Online Medical Education on Clinical Decision-Making Susan Gitzinger,[1] Karen Badal,[2] Donald Blatherwick.[1] *[1]Medscape, Lexington, KY; [2]WebMD, New York, NY.*

Background: Inhibition of the renin-angiotensin-aldosterone system (RAAS) has become a cornerstone of evidence-based therapies in chronic kidney disease (CKD), diabetes, and heart failure. Despite this, RAAS inhibitors remain widely underutilized in current clinical practice. We sought to determine if participating in a case-based online educational intervention related to CKD management improves clinical decision-making of nephrologists and cardiologists in the United States.

Methods: An interactive, case-based, online CME activity was developed. The educational effects were assessed using a repeated pairs pre-assessment/post-assessment study design. For all questions combined, the McNemar's chi-squared test assessed whether the mean post-assessment score differed from the mean pre-assessment score. P values are shown as a measure of significance; P values <.05 are statistically significant. Cramer's V was used to calculate the effect size (0.06-0.15 is a small effect, 0.16-0.30 medium, and >0.30 large). The activity launched on December 19, 2016, and data were collected through January 24, 2017.

Results: Improved clinical-decision making was seen among nephrologists (n = 130) and cardiologists (n = 107) pre- to post-assessment in (all *P*<.001): Causes of CKD progression in individual patients (nephrologists: 73% to 92%, V=0.242; cardiologists: 53% to 81%, V=0.299) Optimization of RAAS inhibitors in CKD (nephrologists: 55% to 87%, V=0.355; cardiologists: 55% to 79%, V=0.259) Alternative options for management of hyperkalemia and safe polypharmacy in patients requiring maximization of RAAS inhibition (nephrologists: 64% to 83%, V=0.218; cardiologists: 43% to 68%, V=0.254)

Conclusions: Participation in this interactive, case-based, online CME activity resulted in improved clinical decision-making by nephrologists and cardiologists in the management of patients with CKD particularly in regard to safe and appropriate maximization of RAAS inhibition. Significant improvements were seen in considering causes for CKD progression, the importance of effective RAAS inhibition and RAAS inhibitor maximization, and alternative management strategies in patients with hyperkalemia.

SA-PO918

Success of CME at Improving Physicians' Knowledge of Diagnosis and Treatment of Hepatorenal Syndrome Susan Gitzinger,[1] Donald Blatherwick,[1] Julia A. Muino.[2] *[1]Medscape, Lexington, KY; [2]Medscape, LLC, New York, NY.*

Background: Timely diagnosis and intervention are critical for improving outcomes for patients with hepatorenal syndrome (HRS), yet most specialists are not fully confident in their ability to identify and classify HRS, or to select appropriate pretransplant

therapies. We sought to determine if continuing medical education (CME) improves physician knowledge of the diagnosis and treatment of HRS.

Methods: The CME activity consisted of an online video roundtable discussion among leading experts in HRS. Participants completed a 4-question survey before and after the activity to identify changes to knowledge, competence or confidence in relation to a specific clinical situation. A repeated pairs pre-assessment/post-assessment study design was used. The analysis included: - A paired, 2-tailed t-test to assess differences between mean pre- to post-assessment scores - McNemar's chi-square test assessed differences from pre- to post-assessment; P values <.05 are statistically significant - Cramer's V to determine effect size Survey data were collected from March 29, 2017 through May 2, 2017.

Results: In total, nephrologists (n=127) and gastroenterologists (n=139) improved their understanding and competence in several specific topic areas including (data expressed as % correct pre-assessment vs % correct post-assessment; all $P<.001$): - The link between HRS and ascites (88% vs 99% of nephrologists and 85% vs 96% of gastroenterologists) - Characteristics of type 1 HRS (72% vs 98% of nephrologists and 69% vs 93% of gastroenterologists) - Appropriate first-line therapies for patients with type 1 HRS awaiting liver transplantation (52% vs 80% of nephrologists and 60% vs 84% of gastroenterologists) Overall, the educational effect size was medium, indicating a noticeable effect on participants' ability to choose correct responses (nephrologists: V=0.285; gastroenterologists: V=0.251). In addition to these gains in clinical knowledge. 46% of nephrologists and 52% of gastroenterologists indicated that they felt more confident in their ability to properly diagnose HRS after participation in this education.

Conclusions: This study demonstrates that a well-designed online CME initiative can have a positive effect on both nephrologists and gastroenterologists, resulting in significant improvements ($P<.05$) in clinical knowledge and competence seen in both audiences on all topics presented.

SA-PO919

Best Practices in Social Media Xavier F. Parada, Miguel A. Cota, Arvind Conjeevaram, Basu Gopal, Fernanda Arce, Jose E. Lopez-Almaraz, Krishnam R. Penmatsa, Rolando Claure-Del Granado, Sonia Rodriguez, Tejas P. Desai. *@ISNeducation, Brussels, Belgium.*

Background: Nephrology societies have begun to use social media (SoMe) during meetings. However live coverage is limited, decentralised & disorganised

Methods: We compare 3 SoMe operations to identify successes & flaws. The NKF & ISN deployed vanguard SoMe strategies: The NKF's Social Media Ambassador Program asked volunteers to participate in #SCM17 campaign if they agreed to 6 stipulations. The ISN's Social Media Task Force assigned specific tasks to members giving full support to broadcast the #WCN2017 campaign. These were compared to the #KidneyWk 2016 campaign that employed no known strategy, analyzing the Activity, Diversity, & Vibrancy using NOD Analytics

Results: #KidneyWk contained 8032 tweets but had a 1-day greater duration. It's 5-day-best activity was only 1% greater than #WCN2017. Participants in #WCN2017 & #KidneyWk came from 55 nations. #WCN2017 represented Latin American, Caribbean, & African nations the best. #SCM17 & #KidneyWk represented the Middle East the best. Nearly 45% of tweets in #SCM17 were vibrant. #WCN2017 followed closely w/43% & #KidneyWk w/38% vibrant tweets

Conclusions: A strategy of assigned tasks and organizational support offers the best balance of activity, diversity, and vibrancy. #WCN2017 earned a high global reach (55 nations) and vibrancy (43% of tweets) while not sacrificing activity (-1% from the top campaign)

Improvement in Self-Perceived Clinical Competence among Indiana University Nephrology Fellows after Intersession Ayman Hallab, Michael T. Eadon, Ranjani N. Moorthi, Brian S. Decker. *Indiana University School of Medicine, Indianapolis, IN.*

Background: The first year of Nephrology fellowship training is a clinically intensive experience in the USA. Our Nephrology fellowship program introduced an Intersession for first-year fellows during the academic year 2016-2017. We hypothesized that an intersession will improve fellows' self-perceived competence in core nephrology disciplines.

Methods: A 2-week intersession included hands-on training in home hemodialysis, peritoneal dialysis, and temporary catheter placement. Instruction in acute kidney injury management, hypo/hypernatremia, acid-base disorders and resistant hypertension was conducted via didactics, independent readings, and case-based discussions. Small-group workshops emphasized consultant professionalism. Fellows were exempt from clinical duties with the exception of their once weekly continuity clinic. An anonymous survey of 8 questions was conducted before and two weeks after the intersession to rate self-perceived competence. A scale of 1 to 5 was used to assess self-competence.

Results: All five first-year fellows participated in the Intersession. Five pre-surveys and 4 post-surveys were collected. One pre-survey was not adequately filled and excluded from the analysis. The average competence pre- and post-intersessions are shown in table 1. There was an increase in competence in AKI, acid-base, hypertension, and home hemodialysis management ($p<0.05$ for all). There was an increase in overall competence ($p<0.05$).

Conclusions: An intersession for first-year nephrology fellows significantly improves self-reported competence. It is expected that intersessions will be continued in the following years in the Nephrology fellowship program and longer term outcomes will be available.

Table 1- Self-reported competence pre- and post-intersession

	Pre	Post	p-value
Acute Kidney Injury	3.25	4.33	0.045
Hypo/hypernatremia	3.25	3.75	0.390
Acid-base disorders	2.75	3.75	0.030
Temporary catheter insertion	3.50	4.50	0.356
Hypertension	2.50	4.25	0.004
Home hemodialysis	1.75	3.00	0.002
Peritoneal Dialysis	2.75	3.25	0.207
Consultant Professionalism	4.25	4.75	0.207
Overall Competency	3.00	3.95	0.010

SA-PO921

Comparison of Five Methods of Measuring Specific Gravity in Mock Urine Solutions Heidi Saxton,[3] Nirupama Ramkumar,[2] Martin C. Gregory.[1] *[1]Salt Lake City, UT; [2]University of Utah, Salt Lake City, UT; [3]University of Utah School of Medicine, Salt Lake City, UT.*

Background: Urine specific gravity (SG) is commonly used as an indicator of urine concentration in the clinical nephrology setting. SG measurements can aid in distinguishing pre-renal etiologies from acute tubular necrosis, although the accuracy of these measurements by different methods remains unknown. Our main objective in this study was to compare five methods of measuring SG in solutions that resemble normal and pathologic urine specimens.

Methods: We measured the SG and osmolality of solutions with varying concentrations of salts, glucose, urea, albumin, and intravenous contrast using the methods of hydrometry (urinometer), refractometry, reagent strips, and pycnometry. Samples were also sent to the hospital clinical laboratory for measurement by automated refractometry. Slope of SG versus osmolality and Pearson's correlation coefficient was calculated for each method.

Results: Slopes of SG by hydrometry correlated most closely with slope of specific gravity by pycnometry across all solutions (r value of 0.996). Slopes of SG by refractometry and clinical laboratory methods correlated moderately well (r values of 0.950 and 0.927, respectively), while slopes of SG by reagent strip correlated very poorly (r value of -0.434).

Conclusions: As mock urine solutions become more concentrated, the method of hydrometry correlates most closely with pycnometry. Refractometry manually and by clinical laboratory have moderate accuracy, while the method of reagent strip performs very poorly. This latter method may have poor clinical utility, especially in pathologic urine from patients with kidney disease.

Correlation of slope of specific gravity against calculated osmolality with pycnometry slope

	Refractometry	Reagent strip	Hydrometry	Clinical laboratory
All solutions	0.9499	-0.4341	0.9963	0.9265
NaCl, Urea, Albumin/urea, Glucose/urea	0.9701	-0.1686	0.9984	0.9494

SA-PO922

Patient Impressions of Hemodialysis and Peritoneal Dialysis
Kristin M. Corapi,[1] Warissara Sorat,[3] Ishir Bhan.[2] *[1]Massachusetts General Hospital, Boston, MA; [2]None, West Newton, MA; [3]university of Massachusetts Lowell, Lowell, MA.*

Background: It is established that the more a patient knows about peritoneal dialysis (PD), the more likely he is to select it. At our center, patients with advanced chronic kidney disease (CKD) are referred to a dialysis options visit with a nurse educator to learn about PD and hemodialysis (HD). In the current project, we spoke to CKD patients to collect feedback about the visit.

Methods: Patients with stage 4 or 5 chronic kidney disease (CKD) were invited to a semi-structured interview immediately following their education visit. The interviews were recorded and transcribed. Qualitative content analysis was conducted by two staff members using NVivo 11 software. Basic demographics were collected.

Results: The mean age of the 10 CKD patients interviewed was 62 years (SD = 9.4). 60% were female, 40% were married, and 40% were Caucasian. 40% were not educated beyond high school, 60% reported an annual income of < $20,000. Most patients did research before their education appointment. This typically involved an internet search (n=7), however others also spoke to dialysis patients, talked with their doctors/nurses, and one patient visited a unit. Only three patients said they knew nothing about dialysis before the visit. The patients interviewed displayed a preference for HD because of the perceived ease of therapy. The major advantages described were the schedule (with days off) and the fact that the therapy was delivered by others (the notion of just needing to show up). Only a minority of patients identified shortcomings of HD. One patient described the time commitment as a disadvantage and a few patients voiced concerns about the need for a fistula and needles. PD in contrast was overwhelmingly viewed as a burdensome therapy. Patients were dismayed by the need to store supplies at home, to complete dialysis daily on their own, and the potential for infection. A couple of patients did not want the nurse to explain PD. Only two patients seemed to be considering PD as an option.

Conclusions: The patients interviewed displayed little confidence they would be able to successfully complete PD and were left with a negative impression. In contrast, there was little perceived downside to HD. These results may reflect the shortcomings of our current model of education. Further research is needed to determine different styles of education can overcome these barriers and improve utilization of PD.

Developing Partnerships to Advance Renal Care and Ameliorate "Brain-Drain" in Haiti
Brian D. Remillard,[2] Philip C. Cleophat,[3] Robert S. Brown.[1] *[1]Beth Israel Deaconess Medical Center, Boston, MA; [2]Dartmouth Hitchcock Medical Center, Lebanon, NH; [3]Hôpital Universitaire de Mirebalais, Mirebalais, Haiti.*

Background: Immediately following the earthquake in Haiti (Jan 2010), BR provided acute hemodialysis (HD) for several patients with acute kidney injury (AKI). This involved major support and equipment from the Dartmouth community and Partners in Health/Zanmi Lasante. Once the earthquake crisis ended, we recognized that it would require a concerted effort and multiple partnerships to bring ongoing renal care to Haiti. Furthermore, despite Haiti investing years of free training of health care professionals, over 80% leave the country creating a "brain-drain" due to lack of jobs, low pay, little ongoing medical education and few resources to provide adequate patient care.

Methods: Two academic institutions, DHMC and BIDMC, have established partnerships with Bridge of Life, Sustainable Care Kidney Foundation, Partners in Health and Zanmi Lasante and our new charity, TORCH, along with NxStage Medical, Inc, to initiate treatment of AKI with HD at HUM. We have effectively used teleconferencing between DHMC and HUM to provide education, biomedical support, train staff, and build relationships. We subsequently have developed a "mini" fellowship program inviting Haitian physicians and nurses to DHMC and BIDMC for short (2 week) training venues to provide specific skill development and ongoing mentoring.

Results: With the help of our partners, nurses and residents came from HUM to the USA for specific training in HD, central line placement, urinalysis, AKI diagnosis, echocardiography, and peritoneal dialysis treatment and complications. Teleconferencing has been used to provide ongoing contact and reinforce training. Since 2014, 41 patients with AKI have been treated with HD at HUM with 25 patients surviving.

Conclusions: The development of industry/academic/NGO partnerships was able to build a successful program for treating AKI. Long-term relationships with nurses and residents at HUM via teleconferencing and "mini" fellowships has advanced renal patient care, supported the physicians and nurses at HUM, and may provide a partial answer to the problem of "brain-drain" that impairs Haitian medical care.

Conflicts of Interest in Nephrology Clinical Practice Guidelines
Madhuri Chengappa,[2] Sandra Herrmann,[1] Saurabh Gupta,[3] Thejaswi Poonacha.[3] *[1]Mayo Clinic, Rochester, MN; [2]Mayo clinic, Rochester, MN; [3]University of Minnesota, M Health, Minneapolis, MN.*

Background: Clinical practice guidelines (CPG) are evidence-based guidelines, which serve as a standard of care in practice, quality improvement and reimbursement. The extent of conflicts of Interest (COI) in Nephrology CPG's has not been well studied. Our study evaluated the extent of COI in the Kidney Disease Improving Global Outcomes (KDIGO) practice guidelines. We also attempted to correlate this to the level of evidence and strength of recommendations outlined in KDIGO guidelines.

Methods: We examined 9 of the most recent KDIGO's CPG which developed between 2008 and 2013. Using disclosure lists, we catalogued COIs for participants in each CPG work group. The categories included : Advisor/ consultant, Honoraria, Travel stipend, Grant/ Research support, Speaker, Equity interest, Employee, Board of trustees, Royalties, Board of Directors, Employment, Ownership interests, Data monitoring committee, Expert testimony and Development of education materials. We reviewed COIs for members of the evidence review team (ERT) as well. We cataloged the companies/ institutions involved in each disclosure. Episode describes 1 instance of participation of an individual in 1 company in 1 category of each guideline. "Company" describes a commercial, industry or institute affiliation reported by an individual in each episode. We correlated this data to a previously published article: A systematic review of evidence underlying KDIGO guidelines (Am J Kidney Dis.2016 Mar; 67(3):417-22)

Results: 93 (65.9%) of a total of 141 individuals reported COIs. A total of 758 episodes were disclosed. Being a consultant/ advisor was the most common category (31%) followed by Grant/ research support (29%). The % of episodes varied between CPGs (6.3%-19.5%). A total of 127 companies were associated with COI disclosure. 1 company was the most frequently reported company involving 82 (10.8%) of the 758 episodes. Only 1 member in the ERT reported 1 COI. The guideline with the maximum episodes (19.5%) had 3% recommendations as Category 1A and 33% as 2C. Guideline with lowest number of episodes (6.33%) had the highest number of recommendations category 1A (19%)

Conclusions: COIs are prevalent in KDIGO guidelines with up to 2/3rd of participants disclosing COI. The ERT however had only one COI to report. We were not able to clearly correlate the strength of recommendations in each guideline with COI in the same guideline.

SA-PO925

Knowledge and Practice Patterns in the Diagnosis, Evaluation, and Management of Mineral Bone Disease in CKD among Primary Care Physicians and Nephrologists
Brittany L. Schreiber, Flor Espinoza, Omar A. Aleter, Hania Kassem. *University of Texas Medical Branch, Galveston, TX.*

Background: Mineral bone disease in chronic kidney disease (CKD-MBD) is a systemic disorder encompassing mineral, bone, and calcific cardiovascular abnormalities that develop as a complication of CKD and contribute to morbidity and mortality in these patients. Despite the availability of guidelines, there continues to be a disparity in practice patterns contributing to therapeutic inertia. Our aim was to identify gaps in knowledge and variations in clinical practice among primary care providers in comparison to nephrologists regarding the diagnosis, evaluation and management of CKD-MBD especially in earlier stages of CKD when patients might not be followed by a nephrologist.

Methods: This study was conducted using a questionnaire which was distributed to residents, fellows and faculty in primary care specialties and nephrology. Questions were derived from the 2009 practice guidelines from the Kidney Disease Improving Global Outcomes work group and the 2003 National Kidney Foundation's Kidney Disease Outcomes Quality Initiative Clinical Practice Guidelines for Bone Metabolism and Disease in Chronic Kidney Disease.

Results: Nephrologists scored higher than primary care physicians in all areas tested including pathophysiology of the disease, screening parameters and intervals, target levels and treatment strategies. The difference in score was statistically significant in the majority of those areas. Overall, primary care specialists (n of 51) scored an average of 31.7 % while nephrologists (n of 11) scored an average of 80.3 % (p-value <0.01).

Conclusions: Our investigation showed there is a significant discrepancy in knowledge between primary care physicians and nephrologists regarding diagnosis and management of CKD-MBD. It is necessary to improve primary care physicians' knowledge and practice in this field to provide high quality of care to patients. Our next steps include physician education and creation of best practice advisory alerts using the electronic medical record system which will include criteria for appropriate nephrology referral for this subset of patients.

SA-PO926

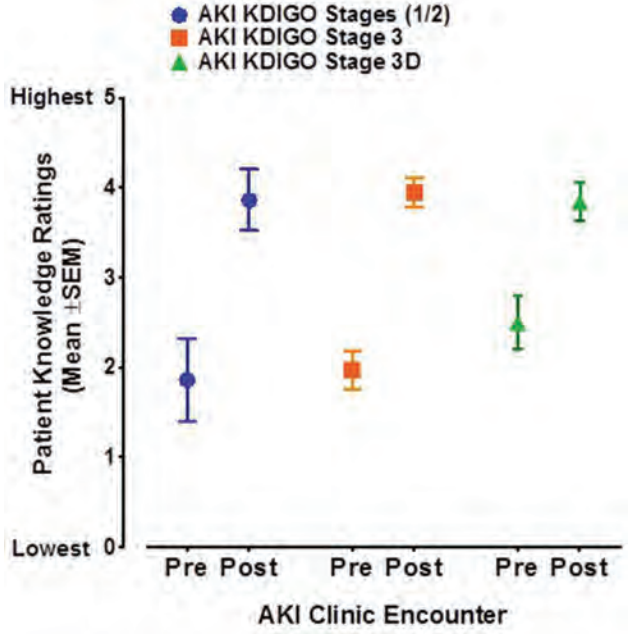
Examining Patients' Knowledge about AKI in Hospital Survivors Followed in a Dedicated AKI Clinic
Victor M. Ortiz-Soriano,[1] Joseph L. Alcorn,[1] Fabiola G. Gianella,[1] Brian S. Armentrout, MS, PA-C,[1] Taha Ayach,[1] B. Peter E. Sawaya,[2] Hartmut H. Malluche,[1] Javier A. Neyra.[2] *[1]University of Kentucky, Lexington, KY; [2]University of Kentucky Medical Center, Lexington, KY.*

Background: Acute kidney injury (AKI) survivors are at high risk of adverse outcomes. There are few clinics dedicated to improving the care of AKI survivors. Specialized post-discharge nephrology care may improve AKI literacy and prevent renal and non-renal complications. We examined self-rated AKI knowledge in AKI survivors followed in a specialized AKI Clinic.

Methods: This is a prospective study of 62 non-dialysis dependent AKI survivors. Patients self-rated the level of knowledge about their AKI diagnosis and the level of severity of their AKI at two time-points: pre and post their first clinic encounter. AKI was defined by KDIGO criteria. Patients' ratings (scale: 1 lowest to 5 highest) were compared by KDIGO stages and by the occurrence of renal recovery (ratio of the first clinic encounter serum creatinine (SCr)/baseline SCr ≤1.5). Mixed-model ANOVAs were utilized.

Results: Mean (SD) age was 54 (14.7) years; 51.6% were males and 87.1% whites. Patients' ratings of their knowledge about AKI significantly increased following the clinic encounter (p=0.001 for each KDIGO stage [**Figure 1**] and each renal recovery group). Patients with AKI KDIGO Stages 1 and 2 rated their AKI as less severe than patients with AKI Stage 3 (p=0.049) and Stage 3D (p=0.002). There were no differences in the level of severity of AKI ratings by renal recovery status.

Conclusions: Post-discharge specialized nephrology care increased patients' self-assessed knowledge about their AKI diagnosis. Patients with higher KDIGO stages rated the severity of their AKI as more severe than those with lower KDIGO stages, indicating that the survey has face validity. Future studies should examine the impact of patients' AKI literacy on patient-centered outcomes.



SA-PO927

Talking Animated Videos to Educate Patients with Kidney Disease Jonathan Slater. *Longmeadow, MA.*

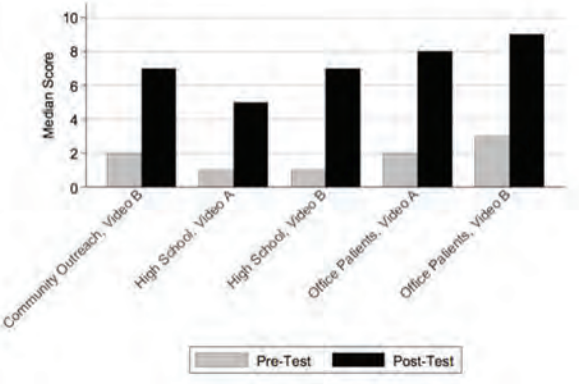
Background: Improved patient understanding of their disease state promotes engagement and facilitates partnership and shared decision making. Digital Health education utilizing animated videos (AV) are gradually being incorporated into EMRs (e.g. EMMI, EPOCH, etc.) to help fill this need; however, there is very limited data on their effectiveness in educating both low and high healthcare literate patients. Kidneyman (KM) had its beginngs 7 years ago with a mission for patient education. It has now created a library of AV for patient kidney education. This study provides a preliminary assessment of the efffectiveness of these AV in educating different sub-populations.

Methods: The following AVs from the library of KM were used for this study: Understandig Chronic Kidney Disease (A) and Treamnt Options for patients with ESRD (B). The AVs, which are 5-7 minutes in length, were shown to different sub-population incuding: high-schoolers heath class ; attendees to communty outreach Kidney Program and indivdual patients being seen in Nephrologists outpatient office. Viewers of the videos were given the same specific questionaire, designed for that particluar AV, before and after watching the videos and the results were culminated and analyzed. Videos can be watched by going to kdneyman.co

Results: The results for the Outreach to the Community participants for Video B, the high-schoolers for Video A and B as well as the office patients for both videos all showed significant improvement in number of correct answers after watching the video (see Table and Graph).

Conclusions: The results from this study do support these AVs as being effective in educating 3 different sub-group of populations. The style and format of all the AVs in the Kidneyman library have been specifically desinged to reach both low and high healthcare literate people and further testing to validate this is ongoing.

Group	Pre-test Median [25th, 75th percentile]	Post Test Median [25th, 75th percentile]	p-value from the Wilcoxon matched-pairs signed-rank
Outreach to community; Video B; N = 25	2 [1,3]	7 [4,9]	<0.001
High School; Video A; N = 15	1 [1,2]	5 [4, 8]	<0.001
High School; Video B; N = 28	1 [1, 2]	7 [6, 8]	<0.001
Office Patients; Video A; N= 5	2 [2,2]	8 [7, 9]	0.04
Office Patients; Video B; N = 5	3 [3, 4]	9 [9,10]	0.04



SA-PO928

Enhancing Learning and Interest in Nephrology among United States Medical Students Hitesh H. Shah, Nupur N. Uppal, Kenar D. Jhaveri. *Hofstra Northwell School of Medicine, Great Neck, NY.*

Background: Interest in nephrology careers remains low among United States (US) medical graduates. The type of nephrology elective that US medical students experience may play an important role in creating and enhancing interest in nephrology career.

Methods: A redesigned 4-week nephrology elective was created at our institution for US medical students. Our redesigned elective included both 2-week inpatient (IP) and 2-week outpatient (OP) nephrology experiences. The OP rotation included 10 half-days of various nephrology clinic experiences, 2 half-days of immediate post-transplant clinic, 1 half-day of kidney donor evaluation clinic, 2 half-days of PD clinic and 3 half-days of outpatient HD rounding. Our redesigned elective also included educational conferences. To evaluate the elective experience, all medical students were asked to complete an on-line survey following the completion of their rotation.

Results: From July 2012 to April 2017, nineteen 4th year medical students (from 14 different US medical schools) completed our redesigned elective. All students responded to our survey. All reported adequate OP nephrology experience during their elective. 84% of the students had worked with 1 or 2 faculty members during the IP setting. In comparison, 90% were exposed to at least 4 different faculty members during the OP experiences. All students had interacted with at least 3 fellows. All reported that the elective experience enhanced their exposure and knowledge in nephrology. They also thought that this elective structure provided them with a better insight into what nephrologists do in practice. 84% of the students reported that this elective experience created an interest in nephrology career. Majority (68%) of the students responded that they would consider nephrology as one of their 3 top career choices as a result of this elective experience.

Conclusions: Measures to enhance learning and interest in nephrology among medical students are needed. We believe that the restructured elective provides the medical student with a much needed and realistic exposure to nephrology careers. Based on our experience, we recommend nephrology training programs to consider this elective structure for medical students.

SA-PO929

CKD Patient and Provider Feedback Surrounding Dialysis Modality Education Kristin M. Corapi,[1] Warissara Sorat,[3] Ishir Bhan.[2] *[1]Massachusetts General Hospital, Boston, MA; [2]None, West Newton, MA; [3]university of Massachusetts Lowell, Lowell, MA.*

Background: Both hemodialysis and peritoneal dialysis impact patients' lifestyles. In an effort to help patients make an informed choice, the nephrology community is

encouraged to provide education about dialysis options. At our hospital, this involves a one on one visit with a nurse educator. In the current project, we talked with patients and providers to get feedback on our dialysis education.

Methods: Patients with chronic kidney disease (CKD) stage 4/5 and providers were invited for semi-structured interviews. The interviews were recorded and transcribed. Qualitative content analysis was conducted by two staff members using NVivo 11. Basic demographics were collected.

Results: The mean age of the ten CKD patients enrolled was 62 years (SD = 9.4). 60% were female and 40% were Caucasian. 40% were not educated beyond high school and 60% reported an annual income of < $20,000. The providers interviewed (n=11) were 5 MD's, 4 RN's, 1 social worker, and 1 one dietician. The mean age of providers was 49 years (SD= 13.1) with an average of 18 years in practice (SD = 9.1). 64% were Caucasian and 64% were female. Following the visit, half of the patients reported feeling scared, confused or disappointed to learn they might need dialysis. Similarly, staff depicted patients as in denial, resigned, overwhelmed, and stressed. The majority of patients felt that the single visit provided all of the information needed to choose a modality. The remaining patients (n=4) asked for additional information about diet, lifestyle changes, and how to slow further CKD progression. Staff agreed that diet and lifestyle changes are difficult for patients to understand and might be topics that would benefit from more explanation. Patients recommended the use of videos, written material, emails, and talking to peers as strategies to help improve their understanding. Staff agreed that the addition of a patient network would be beneficial. Staff also suggested having more than one visit, group classes, multi-disciplinary involvement, and introducing dialysis earlier in the CKD trajectory would help patients choose a dialysis modality.

Conclusions: The referral to dialysis education is stressful to patients as they begin to accept the severity of their disease. Employing various educational styles, venues, and peer support may help ease these emotions and help patients to choose the modality best for them.

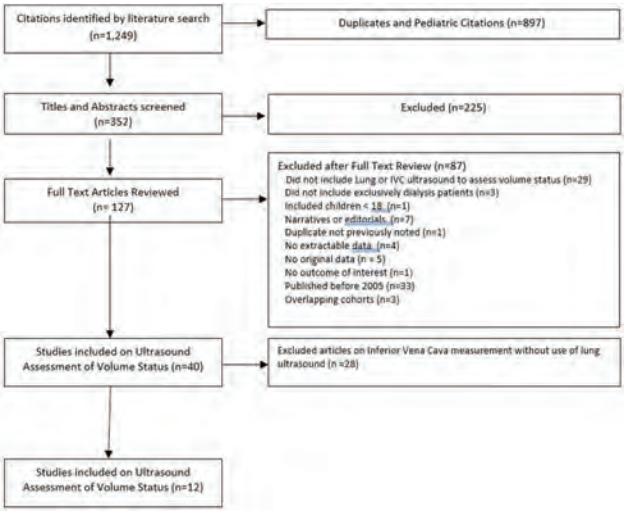
Lung Ultrasound in ESRD: Moving from Evidence to Practice Daniel W. Ross,[5] Mohammed Abbasi,[2] Kenar D. Jhaveri,[1] Mala Sachdeva,[3] Richard L. Barnett,[3] Mangala Narasimhan,[6] Anna Mathew.[4] *[1]Hofstra Northwell School of Medicine- Northwell health system, Great neck, NY; [2]Montefiore Medical Center, Bronx, NY; [3]None, Great Neck, NY; [4]North Shore-LIJ Health System, Great Neck, NY; [5]Medicine, Division of Nephrology, Hofstra Northwell School of Medicine, Great Neck, NY; [6]Northwell, Sleepy Hollow, NY.*

Background: Lung ultrasound (US) allows for enhanced ability to detect extravascular lung water compared to traditional physical exam or standard chest XRay. This is extremely important for our CKD and ESRD patients to assess volume status. Training in using point of care US that includes lung US is vital in this era for our fellows and faculty. We conducted a review of lung US use in dialysis patients and assessed how it was taught to researchers.

Methods: We conducted a strategic search in Medline, Embase, Cochrane, and Web of Science. Eligibility criteria for included studies were: (1) 5 or more adults (age ≥ 18) with ESRD on chronic dialysis; (2) measured and reported lung US findings; and (3) reported another comparator outcome measure of volume status. Articles that looked at only IVC and not lung US were excluded. Titles and abstracts were screened by a single reviewer and the remaining full texts were reviewed independently by two reviewers. Discrepancies were resolved by a third reviewer.

Results: We identified 1,249 articles of potential interest. After title and abstract screening, we reviewed 352 full-text articles. We identified 12 studies where lung US was used to detect extravascular lung water in dialysis patients. In two studies nephrologists were trained but in most studies residents were trained. Reported training time varied from 2 to 3 hours. Time to perform lung US ranged from 6 to 15 minutes. All studies reported high concordance between novice and expert sonographers.

Conclusions: Lung US can be reliably taught to learners in a short 2 to 3-hour training course. Teaching lung US to our nephrology trainees is an important step to improve care collaboration with our critical care and emergency medicine colleagues and improving volume assessment in our CKD and ESRD patients.



SA-PO931

Patient Engagement in ESRD: Do Patients Know Who Their Nephrologist Is? Arjun Sekar,[1] Leslie P. Wong.[2] *[1]Cleveland Clinic Foundation, University Heights, OH; [2]Cleveland Clinic, Solon, OH.*

Background: Patient engagement describes how involved patients are in their care. We observed that some hospitalized dialysis patients are unable to describe their care, including who their nephrologist is. We hypothesize that patients unaware of these basic details may not actively participate in their care. We performed a survey to assess perceptions of the patient-doctor relationship and dialysis care.

Methods: We included hospitalized adult ESRD patients requiring hemodialysis. Intensive care, peritoneal dialysis and non-English speaking patients were excluded. Subjects completed a questionnaire about routine aspects of their dialysis care. We did a descriptive analysis of their responses and attempted to identify trends based on whether or not they knew their nephrologist's name.

Results: Of 66 patients approached, 44 completed the survey. Over one-fifth (23%) did not know their attending nephrologist and 54% said a different nephrologist also rounded on them at dialysis. 74% felt their nephrologist answered their concerns promptly; 44% raised their health concerns with the nephrologist all the time. Only 24% were aware of palliative options. While 93% felt maintaining their dry weight was important to their health, only 60% knew their dry weight. Though 90% thought fluid restriction was important, only 60% stated they were compliant. Most (86%) thought controlling phosphorus was necessary but fewer (64%) were aware of its adverse effects. Sub-analysis of responses (Table) was done based on whether or not patients knew their attending nephrologist.

Conclusions: This study aimed at assessing patient engagement in ESRD. A number of patients reported disjointed perceptions of their dialysis care, including an inconsistent relationship with an attending nephrologist. This might impact discussions about palliative care and willingness of patients to follow advice. Better awareness and focus on the patient- nephrologist relationship in dialysis is needed.

RESPONSES BASED ON WHETHER PATIENTS KNEW THEIR NEPHROLOGIST

	YES=34	NO=10
DIFFERENT NEPHROLOGISTS ROUNDING ON THEM	58%	40%
LIKELY TO FOLLOW NEPHROLOGISTS ADVICE	86%	56%
AWARE OF PALLIATIVE CARE	28%	10%
KNOW THEIR DRY WEIGHT	66%	33%
COMPLIANT WITH FLUID RESTRICTION	91%	88%
AWARE OF ADVERSE EFFECTS OF PHOSPHORUS	74%	30%
THINK DIALYSIS IMPROVES QUALITY OF LIFE	74%	71%

SA-PO932

Penile Calciphylaxis: Suspicion Is the Key Olanrewaju A. Olaoye,[2] Abhilash Koratala.[1] *[1]Gainesville, FL; [2]University of Florida, Division of Nephrology, Gainesville, FL.*

Background: Calciphylaxis or calcific uremic arteriolopathy (CUA) is a rare and potentially fatal condition that presents with skin ischemia and necrosis, typically seen in end stage renal disease (ESRD) patients on dialysis. Histologically, it is characterized by medial calcification of dermal arterioles. CUA commonly involves legs, abdomen and gluteal region. Herein, we present a case of CUA of the glans penis.

Methods: An 81-year old white man with history of hypertension and CKD stage 5 was admitted to the hospital for uremic symptoms necessitating initiation of haemodialysis. He complained of pain and redness of the glans penis that first appeared 3 weeks ago. At that time, he was treated for possible balanitis with antibiotics and had partial relief. He denied having any fever, chills, difficulty urinating or discharge from the urethra. On examination, he had purpuric patches, erosions and superficial necrosis of penile glans with minimal tenderness [Figure 1A]. His labs were significant for serum

creatinine of 12.7 mg/dl, phosphate 8.4 mg/dl, calcium 9.8 mg/dl, albumin 2.6 g/dl, and parathyroid hormone 1131 pg/ml. CT scan of the abdomen showed extensive calcification of the aorta and pudendal vessels [Figure 1B]. Based on the clinical features and imaging evidence of vascular calcification, we diagnosed him with CUA of the penis

Results:

Conclusions: While the definitive diagnosis of CUA requires skin biopsy, it is not routinely recommended for penile lesions because of the risk for progression of necrosis. Risk factors for CUA include White race, CKD-MBD axis abnormalities, obesity, hypercoagulable conditions including protein C and S deficiency, diabetes mellitus, hypoalbuminemia, warfarin use and longer dialysis vintage of over 6-7 years. Management includes intensification of dialysis regimen, phosphate and PTH lowering therapy, and intravenous sodium thiosulfate therapy. Clinicians should be aware of rare presentations of CUA for prompt diagnosis and appropriate treatment

SA-PO933

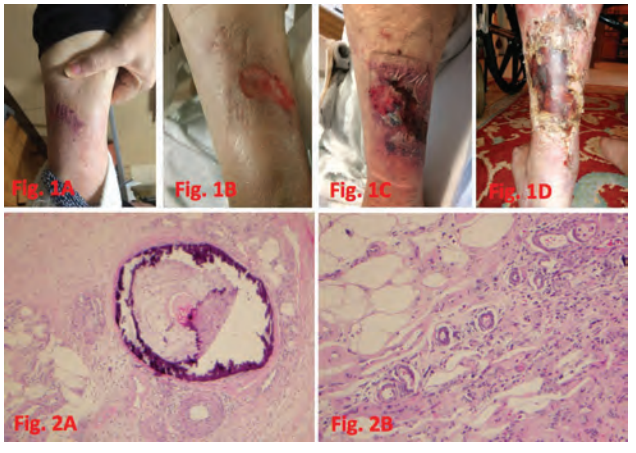
A Wolf in Sheep's Clothing: Calciphylaxis, Innocuous at First Glance Stefan C. Hemmings, Derek M. Fine. *Johns Hopkins University School of Medicine, Baltimore, MD.*

Background: Calciphylaxis is a debilitating skin condition with high mortality seen in patients on dialysis who are at particular risk due to disordered calcium and phosphorus metabolism. Its early features are unfamiliar to many clinicians.

Methods: A 61 year old woman with diabetes on peritoneal dialysis for 5 years with adequate clearance by Kt/V was noted to have an erythematous painful lesion on the left leg (fig. 1A), which was diagnosed as shingles by her primary physician. She presented 2 days later to hospital for complaints of abdominal pain and was noted to have shallow ulceration of the lesion (fig.1B). She was evaluated by dermatology who felt that is was most consistent with venous stasis. Labs results: Calcium 10mg/dL, Phosphorus 6.4mg/dL, Cal-Phos product 58, iPTH 244pg/dL and 25-hydroxy vit D 47.5ng/mL. She was on 30mg cinacalcet for hyperparathyroidism. She followed up in dermatology clinic a few days after discharge and the ulceration had deteriorated as shown in fig. 1C. Concern for its progression prompted a skin punch biopsy that confirmed the diagnosis of calciphylaxis with histopathological features of vascular medial calcification (figs. 2A and 2B). She was readmitted and transitioned to hemodialysis for aggressive therapy with sodium thiosulfate. Despite this, the area of involvement progressed extensively in the left leg and new lesions on the fingers developed. After 10 weeks of treatment the leg lesion appeared to stabilize with eschar formation and healing skin at the borders (fig. 1D).

Results:

Conclusions: Nephrologists and internists alike need to be aware of the initial innocuous presentations of calciphylaxis that may not raise clinical suspicion. The classic eschar is oftentimes a late feature. Early recognition can prevent the morbidity and mortality related to infections and amputations associated with delayed treatment, as the condition can progress rapidly. High vigilance for painful skin lesions is required in patients on dialysis.



SA-PO934

A Rare Case of a Large Calcified Mass in a Calciphylaxis Patient Raju A. Patil,[3] Jason Cobb,[4] Peter Daring,[1] Carol A. Gray,[2] William Mckinnon.[5] *[1]Colorado College, Decatur, GA; [2]Emory Healthcare, Atlanta, GA; [3]Emory University, Decatur, GA; [4]Emory University School of Medicine, Atlanta, GA; [5]Peachtree Vascular Surgery, Atlanta, GA.*

Background: Calciphylaxis is a rare clinical disorder in patients with ESRD and is characterized by painful skin ulcerations due to ischemia and necrosis of the skin and subcutaneous adipose tissue. The disorder carries a mortality rate of 80% in the first year, and death is often due to recurrent infections leading to sepsis. The pathogenic mechanism is not clearly understood and therapeutic options are limited. We present a rare case of a calcified tumor from a patient suffering from calciphylaxis measuring 23.0 x 22.0 x 6.5 cm and 27 x 26 x7.5 cm on the medial aspect of the thigh.

Methods:

Results: A 58 year old black female with ESRD due to a collapsing glomerulopathy, diabetes, developed symptoms of pain and skin ulcerations over her bilateral lower extremities and abdomen. A tissue biopsy of the lesions revealed necrotic ulcerations of the epidermal and dermal layers, and focal calcium deposition in the subcutaneous adipose tissue. She presented to the hospital with symptoms of fever, weakness and pain, with large areas of induration and skin ulcerations (the largest measuring 20 cm) over the inner aspects of the thigh bilaterally. Examination revealed a large area of induration and skin ulcerations with a large firm mass. Lab levels included PTH <100 pg/ml (she presented on cinacalcet), serum phosphorus within normal limits, and unfortunately she had been on long-term warfarin due to chronic dialysis access thrombosis. She was transferred to our hospital for further management of calciphylaxis which included wound care, surgery debridement, and hyperbaric oxygen therapy. Vascular surgery excised 27 x 26 x 7.5 cm and 23.0 x 22.0 x 6.5 cm masses from the right and left inner thigh. Histopathology examination confirmed vascular calcifications, fat necrosis with fibrosis, inflammation, and subcutaneous calcification classically described in calciphylaxis. Approximately one month after surgery the patient subsequently succumbed to sepsis.

Conclusions: Although calciphylaxis most commonly presents with skin ulcerations and calcified deposition under the skin, this is an unusual case of calciphylaxis which manifested in the form of a large calcified mass. This is rarely described in the literature and one of the first cases of an excised mass with a pathological diagnosis. The pathogenesis of this proliferation of tissue in calciphylaxis needs to be further identified and studied.

SA-PO935

Acute Esophageal Necrosis (Black Esophagus) Complicating Calcific Uremic Arteriolopathy Jawed Akhtar,[1] Vijaya Kumar Gorantla,[1] Barry M. Wall.[2,1] *[1]UTHSC, Memphi, TN; [2]Veterans Affairs Medical Center, Memphis, TN.*

Background: Calcific uremic arteriopathy (CUA) is associated with medial arterial calcification with vascular thrombosis and necrosis. While skin manifestations predominate, CUA rarely involves the gastrointestinal tract.

Methods: A 76-year-old male receiving chronic hemodialysis for 7 years presented with severe penile pain with ulceration due to phimosis and balanitis, requiring surgical debridement. Pathology confirmed medial artery calcification and tissue necrosis, consistent with CUA. He later developed nausea and melena. Endoscopy revealed black, friable mucosa of nearly the entire esophagus with a clear transition to viable tissue at the gastroesophageal junction. Pathology confirmed necrosis and the diagnosis of acute esophageal necrosis was made. He was placed on IV proton-pump inhibitors (PPI) and TPN. Workup for vasculitides was negative. HIV, fungal, HSV-2, and CMV tests were also negative. Calcium (11.4 mg/dL) and parathyroid hormone (PTH; 525.6 pg/mL) were noted to be elevated. Parathyroid scan confirmed tertiary hyperparathyroidism. Patient received non calcium phosphate binders, pamidronate and sodium thiosulfate with dialysis. Patient declined daily dialysis or parathyroidectomy. Cinacalcet was started when oral intake improved. Follow up: PTH improved to 390 pg/ml, calcium 9.0 mg/dl an PO4 3.5 mg/dl. Repeat endoscopy revealed significant improvement with persistent severe esophagitis in the distal and middle third of the esophagus with a normal proximal third. He was started on a clear liquid diet and transitioned to oral PPI. TPN was discontinued 5 days later. He was discharged to a rehabilitation center, receiving oral liquid nutritional supplement (1800 cal/day) with no further gastrointestinal symptoms or bleeding.

Results:

Conclusions: Gastrointestinal manifestations of CUA include mucosal edema, diffuse ulcer formation, and bowel perforation arising from bowel infarction. Gastrointestinal bleeding is a common presentation. Acute esophageal necrosis, a rare cause of upper gastrointestinal bleeding is found in patients with significant morbidities and is associated with high mortality. To our knowledge, there have been no prior reports involving coexistence of these conditions.

Native Kidney Osseous Metaplasia – Incidental Finding or a Disease to Treat Gyongyi Okechuku,[1] Saed Shawar,[1] Jingyin Yan.[2] *[1]Baylor College of Medicine, Houston, TX; [2]None, Houston, TX.*

Background: Osseous metaplasia is an atypical phenomenon involving the formation of the bone tissue outside the skeletal system. This pathologic process may occur in sites such as the skin, subcutaneous tissue, and skeletal muscle, occasionally seen in visceral

organ like intra-abdominal sites. We describe a case of osseous metaplasia in a native kidney.

Methods: We present a 26 year old African American woman with biopsy proven minimal change disease (MCD) at age of 5. Her disease course is significant for been steroid dependent initially with multiple relapses upon steroid taper and partial remissions. She had 3 renal biopsies in childhood. All 3 were consistent with minimal change disease. Her treatment regimen consisted of steroids, cellcept, started after she had side effect from cyclosporine and Lisinopril. She presented to our Nephrology clinic with worsening SOB, orthopnea and PND. Physical examination was significant for fine crackles in lungs, and 3+ bilateral pitting pedal edema. Labs showed serum calcium 8.2, phosphorus 4.1, vitamin D 34, and bicarbonate of 28, BUN of 15 and creatinine of 0.6. Her white cell count was 6.8, with hemoglobin 6.6, Platelets were 113. Her urinalysis was notable for 2+ proteinuria. C3 and C4 were normal. Negative RF; negative ANA; normal serum protein electrophoresis and light chain assay, dsDNA, ANCA were negative. A renal sonogram was unremarkable. A repeat renal biopsy was done findings suggested Minimal change disease. However, we found unmineralized osteoblast within 1 glomerulus.

Results: Osseous metaplasia (OM) pathophysiology is not well known, but many factors have been incriminated including chronic ischemia, trauma, and chronic inflammation. The pathphyisology of this finding is not well understood. Osseous metaplasia has been described in some transplant allograft, and associated with malignacies affecting the kidney, some leukemias and basal cell carcinoma. Ectopic calcifications are different entities. OM is asymptomatic and probably often confounded with ectopic calcifications since their radiological aspects are identical. Treatment usually is watchful waiting approach.

Conclusions:

SA-PO937

Perioperative Acute Systolic Cardiac Dysfunction as Complication of Parathyroidectomy Itunu O. Owoyemi,[3] Angie G. Nishio-Lucar,[4] Sundararaman Swaminathan,[3] Karen M. Warburton,[1] Gayle M. Vranic,[2] Peter I. Lobo,[3] Alden M. Doyle.[1] *[1]Charlottesvilee, VA; [2]University of Virginia Health System, Charlottesville, VA; [3]University of Virginia, Charlottesville, VA; [4]University of Virginia HS, Charlottesville, VA.*

Background: Several factors including hypocalcemia have been incriminated in the pathogenesis of abnormal cardiac function in End Stage Kidney Disease (ESKD).

Methods: We report a case of a 57 yo woman with ESKD due to hypertension, failed kidney transplant graft from BK nephropathy 8 years ago referred for management of severely elevated parathyroid hormone levels (PTH). Patient had undergone subtotal parathyroidectomy 5 years prior. Despite intensive therapy with calcitriol and cinacalcet, her PTH levels had remained around 2000 pg/mL. She had stress test done 2 months prior to operation that showed no evidence of inducible myocardial ischemia and preserved ejection fraction. Her evaluation included a sestamibi scan with showed activity within the mediastinum prompting the decision for resection and auto-transplantation. A day prior to surgery, she recieved IV calcitriol during dialysis and was down to her target weight. Cinacalcet was discontinued. Her surgery was uncomplicated. She received 1 g of IV calcium chloride. She was extubated quickly in the recovery room and initially did well. Over the next hour, she developed acute shortness of breath with hypercapneic respiratory failure. A stat chest X-ray revealed left pleural effusion and mild cardiomegaly, which were new findings compared to chest X-ray done a day before surgery. Pertinent laboratory findings prior to this episode include hemoglobin 10.7mg/dL, ionized calcium 3.9 mg/dL, and phosphorus 7.7 mg/dL. PTH was 190 pg/mL, down from 1399 pg/mL at beginning of surgery, troponin – 0.03 with no EKG changes. An Echocardiogram done showed decreased left ventricular systolic global function and small pericardial effusion adjacent to the right ventricle. A protocol for prevention of hypocalcemia was immediately embarked upon to prevent further episodes of hypocalcemia which resulted in good control of serum calcium and phosphorus levels. Her cardiac dysfunction resolved prior to discharge and she has done well since.

Conclusions: Modifications of myocellular calcium interactions or sensitivity which may alter relaxation and contribute to cardiac dysfunction. Patients with severe hyperparathyroidism are at risk in the early post-operative period and should be monitored closely for hypocalcemia and, less commonly, acute cardiac dysfunction.

SA-PO938

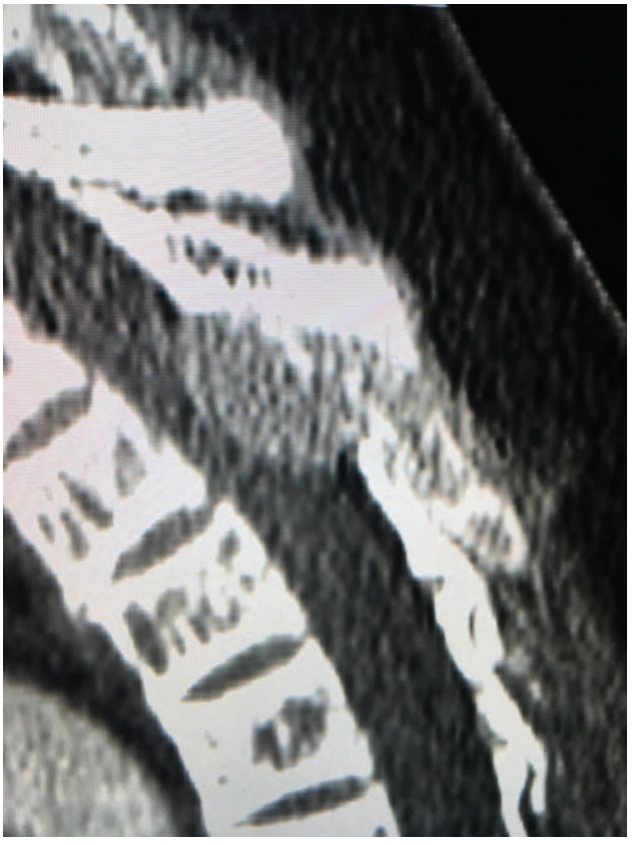
Acute Neurological Syndrome Complicating Secondary Hyperparathyroidism Ravina Patel,[1,3] Michael R. Wiederkehr.[2] *[1]Baylor University Medical Center, Dallas, TX; [2]Dallas Nephrology Associates, Dallas, TX; [3]Methodist Dallas Medical Center, Dallas, TX.*

Background: Long-term severe secondary hyperparathyroidism in dialysis patients can lead to formation of "brown tumors," a benign but locally aggressive neoplasm of predominantly osteoclast-like giant cells in a fibrous stroma. They present as single or multiple lesions and are locally destructive by their lytic and expansive properties. Parathyroidectomy is preferred over medical management. Here we describe a case of acute cord compression caused by a brown tumor.

Methods: A 33-year-old Hispanic female, dialysis dependent for 9 years, presents with progressive lower extremity weakness and back pain. She had many years of uncontrolled hyperparathyroidism. Levels of iPTH were consistently above 2000, but recently up to 5500. Addition of cinacalcet improved PTH but it remained above 3000. Hypercalcemia indicated development of tertiary hyperparathyroidism. Imaging now revealed numerous lytic lesions through the spine, ribs, and sternum, and two expansive masses at T3 and T12 with severe spinal cord compression at T3 with associated cord edema (see image), moderate spinal canal stenosis at T12. She underwent emergent T2-T4 laminectomy with resection of the tumor, followed by subtotal parathyroidectomy one week later. Intraoperative PTH dropped from 2358 to 268, and to 11 the following day.

Results:

Conclusions: Spinal cord compression by a brown tumor is a rare complication of secondary or tertiary hyperparathyroidism and poses a treatment dilemma as regression of brown tumor after parathyroidectomy has been well described. Given her acute presentation with cord edema at T3 we decided on neurosurgical intervention. The brown tumor at T12 caused spinal stenosis but no cord compression. We are now following expectantly as we monitor the T12 mass and lytic bone lesions in anticipation of resolution post parathyroidectomy.



SA-PO939

Nephrocalcinosis and Nephrolithiasis in Renal Allograft during Cinacalcet Treatment for Severe Hyperparathyroidism Anshul Bhalla, Marwa El-Sabbahy, Monika Pilichowska, Nitender Goyal. *Tufts Medical Center, BOSTON, MA.*

Background: Hyperparathyroidism (HPT) is commonly associated with ESRD and resolves with kidney transplant (KTx). Elevated parathyroid hormone (PTH) levels may persist post-KTx causing hypercalcemia. Cinacalcet use is common in these patients, but reportedly increases the risk of nephrocalcinosis (NC) and nephrolithiasis (NL), due to hypercalciuria.

Methods: A 61 year old female with lupus nephritis causing ESRD, on dialysis for 8 years, underwent deceased donor KTx with immediate graft function. Basiliximab was used for induction and Tacrolimus, Mycophenolate and Prednisone for maintenance immunosuppression (IS). Hypercalcemia early after transplant prompted Cinacalcet initiation and its persistence required dose up-titration on follow up. A 3.5 gland parathyroidectomy (PTX) performed 4 months after KTx was complicated by post-op acute kidney injury, with moderate hydronephrosis and distal ureter obstructing calculus seen on allograft imaging. Impacted stones in the ureteral orifice were partially removed by cystoscopy, but stent placement was unsuccessful requiring percutaneous nephrostomy. Serum creatinine (SCr) improved. Kidney biopsy was performed 6 months post-KTx for elevated SCr, BK Viremia and de-novo donor specific antibody to DR14 and DR52 HLA antigens. Morphologic examination revealed acute tubular epithelial cell injury in addition to luminal depositions of calcium phosphate, consistent with NC, with no evidence of rejection or BK nephropathy. Allograft function stabilized after percutaneous nephrolithotripsy and nephrouretral catheter placement. Stone analysis revealed calcium oxalate (20%) and calcium apatite (80%).

Results:

Conclusions: Resorption of soft tissue calcification, higher allograft Vitamin D production, severe HPT and Cinacalcet use cause renal calcium loading, increasing the risk of NC and NL, which are otherwise rare post KTx. We postulate that a combination of these factors contributed to kidney stones in our patient. Early PTX in KTx recipients with persistently high PTH levels and hypercalcemia might prevent this complication.

Laboratory Data Pre and Post Kidney Transplant

Disseminated Bartonellosis Masquerading as PTLD in a Renal Transplant Recipient Srijan Tandukar, Christine Wu. *University of Pittsburgh Medical Center, Pittsburgh, PA.*

Background: A solid organ transplant recipient is at high risk for infections due to immunosuppression. We report a case of a renal transplant recipient presenting with diffuse lymphadenopathy concerning for PTLD who was found to have disseminated bartonellosis.

Methods: A 32 year old male presented 11 months following his renal transplant (CMV +/-, EBV +/+) with complaints of malaise, drenching night sweats and fever to 101.8 F while on tacrolimus and mycophenolate mofetil. Review of systems was positive for a cat scratch on his knee several months back. He was hemodynamically stable on presentation. On exam, he had tender right inguinal lymphadenopathy. Urinalysis, chest x-ray and blood cultures were negative. His WBC count was 6,700/mm^3 and creatinine was 1.6 mg/dl (baseline 1.2 mg/dl). CT scans showed left supraclavicular, axillary, retroperitoneal and iliofemoral lymphadenopathy with hypodense lesions in the liver, spleen and renal allograft. PCR showed 110 copies/ml EBV and no CMV. Serologies for Bartonella henselae were positive for IgG (1:512) and IgM (1:80). Lymph node biopsy showed necrotic areas, neutrophilic abscesses with focal positivity for Bartonella and large abnormal cells that were EBV positive. He was treated with azithromycin and doxycycline for 8 weeks. His symptoms, along with lymphadenopathy, splenic and liver lesions on repeat CT scan resolved completely. His creatinine stabilized at 1.5-1.7 mg/dl.

Results:

Conclusions: PTLD is characterized by lymphoid proliferation of B cells that may be monoclonal or polyclonal in origin and affects up to 1-2% of kidney transplant patients. As in our case, patients with PTLD often present with fever, malaise and lymphadenopathy. Bartonella henselae is a bacterium that is transmitted from cats to humans from a scratch or bite. Infected patients often present with fever, lymphadenopathy and night sweats. Dermatologic and neurologic findings may also be present. In an immunocompromised patient, the features may be more severe, with dissemination to other organs. In our patient, complete resolution of symptoms and CT findings following antibiotic treatment confirmed the diagnosis of bartonellosis. Disseminated bartonellosis should be considered in transplant patients presenting with fever and lymphadenopathy.

SA-PO941

Rapid Onset Donor Cell Transformation into Plasmacytoid Post-Transplant Lymphoproliferative Disorder (PTLD) in a Kidney Transplant Recipient Mahmoud A. Mahmoud,[1] Barry M. Wall,[2] Manish Talwar.[1] *[1]University of Teneessee Health Science Center, Memphis, TN; [2]Veterans Affairs Medical Center, Memphis, TN.*

Background: Post-transplant lymphoproliferative disorder (PTLD) is a complication of both solid organ transplant and allogeneic bone marrow or stem cell transplants. PTLD is most often of recipient B cell lineage and is typically associated with Epstein-Barr Virus (EBV) infection.

Methods: A 56-year-old AA male with ESRD secondary to hypertension received a kidney transplant from a 9 year-old deceased female donor. Donor and recipient EBV IgG was positive. He received induction with thymoglobulin and maintenance therapy with mycophenylate, tacrolimus, and prednisone. Hospital discharge serum creatinine was 4.9 mg/dl and 1.8 mg/dl on post-op day 15. Allograft biopsy (Figure1), performed on post-op day 48 due to rising creatinine and fever, revealed a massive plasma cell infiltrate which was negative for EBV, but strongly CD138 positive with monotypic lambda light chain expression by in situ hybridization, consistent with PTLD. Recepient EBV IgM and early D antigen were negative posttransplant, and EBV serum PCR was <500. There was no evidence for cellular or vascular rejection. FISH studies revealed a female cell population comprising the plasmacytoid infiltrate. Recipient bone marrow examination was negative for PTLD. Immunosuppression was withheld and treatment was attempted with bortezomib and cyclophosphamide; however, renal function declined and he resumed hemodialysis. Allograft nephrectomy showed diffuse hemorrhagic necrosis of parenchyma with presistent plasma cell infiltrates.

Results:

Conclusions: FISH studies performed on the preserved kidney tissue showed a predominant female cell population comprising the atypical plasmacytoid infiltrate, confirming that PTLD was donor derived. There has been no evidence of persistent PTLD in the patient during 10 months of followup. Recipients of other organs from the same donor have not developed PTLD after 10 months of followup.

SA-PO942

A Rare PTLD Presenting as Autonomic Dystonia: Who Would Have Thought Sathish Karmegam,[2] Kosunarty Fa,[2,1] Jose A. Castillo-Lugo.[2,1] *[1]Dallas Nephrology Associates, Dallas, TX; [2]Nephrology, Methodist Dallas Medical Center, Dallas, TX.*

Background: Introduction: Post Transplant Lymphoproliferative Disorders (PTLD) are life threatening complications of transplantation. Chronic use of immunosuppressive agents to prevent allograft rejection increases the long-term risk of malignancy. This is a report of a rare case of Diffuse Large B Cell Lymphoma presenting with autonomic dysfunction as a paraneoplastic syndrome.

Methods: Case Description: A 40 y/o Caucasian man with PMH of Living Unrelated Kidney Transplant (about 15 months ago), acute vascular rejection 2B (within 6 months of transplant), and HTN presented with fatigue and bloody diarrhea. His medications were tacrolimus, MMF, prednisone and lisinopril. He had severe orthostatic hypotension with recurrent syncopal episodes on admission. Hgb and chemistries were normal. Lisinopril was discontinued. He received aggressive volume expansion, oral fludrocortisone, and midodrine. Infectious stool work up was negative. CMV viral load was weakly positive. He was started on IV ganciclovir empirically. His adrenal axis, cardiac function and CT of abdomen were normal. CMV adrenalitis was ruled out and ganciclovir discontinued. His EBV PCR turned out to be strongly positive. IV acyclovir was started. Chest CT showed no central lymphadenopathy but small left axillary lymphadenopathy. A colonoscopy showed 'multiple shallow ulcers throughout the colon with heaped up margins'. Biopsy was negative for CMV inclusion bodies. Colonic mucosa showed atypical large cell lymphoid infiltrate in the lamina propria consistent with 'Diffuse large B-Cell Lymphoma' (DLBC). Axillary lymph node excision biopsy was consistent with 'Diffuse large B-cell lymphoma and T-lymphocytes with positive CD-20. MRI of the brain was negative. MMF was discontinued and tacrolimus dose was decreased. Hematology service recommended R-CHOP chemotherapy. His autonomic dysfunction improved with treatment.

Results:

Conclusions: Discussion: Lymphomas are among the most common complications of transplantation and many are related to EBV infection. The incidence is highest in the first post-transplant year due to high immunosuppression. Autodystonia is a well-known paraneoplastic syndrome of CNS and Hodgkin's lymphomas. High level of suspicion is required to make diagnosis and initiate treatment early. DLBC lymphoma presenting with autodystonia is extremely rare and no other cases have been reported until now.

SA-PO943

Familial Anti-GBM Disease in Zero Human Leukocyte Antigen Mismatch Siblings Nicola Lepori,[1,2] Andrea Angioi,[1,2] Wisit Cheungpasitporn,[1] Sanjeev Sethi,[3] An S. De Vriese,[4] Fernando C. Fervenza.[1] *[1]Nephrology and Hypertension, Mayo Clinic, Rochester, MN; [2]Division of Nephrology, Ospedale Brotzu, Cagliari, Italy; [3]Anatomic Pathology, Mayo Clinic, Rochester, MN; [4]Division of Nephrology, AZ Sint-Jan, Bruges, Belgium.*

Background: Familial anti-GBM disease is extremely rare. The single gene mutations that may play a role in the development of familial anti-GBM disease are currently unidentified.

Methods: A 65-year-old woman presented to our institution with hemoptysis, gross hematuria and oliguria. Physical examination revealed bilateral diffuse wheezes and edema of the lower extremities. The patient was a smoker and had a family history positive for serologic and renal biopsy-proven anti-GBM disease in 2 of her 15 siblings; morover she had been exposed to kerosene during her childhood. Laboratory testing showed hemoglobin (Hb) of 10.2 mg/dL and serum creatinine (sCr) of 12.0 mg/dL. Urinalysis showed 1+proteinuria and hematuria. Serology demonstrated positive anti-GBM IgG antibody test at 2.1 units and negative ANCA. Kidney biopsy showed a crescentic and necrotizing glomerulonephritis, with linear staining of IgG (3+) along the glomerular basement membranes on the IF, consistent with anti-GBM disease. Patient was started on IV metilprednisolone and daily plasmapheresis sessions, followed by oral cyclophosphamide plus prednisone. Nevertheless, due to uremic symptoms, hemodialysis was started. 3 weeks after treatment, anti-GBM IgG antibody became negative and at 3-month follow-up visit renal function had improved and hemodialysis was discontinued. The patient continued to do well with negative anti-GBM antibodies at 15-month follow-up visit with sCr of 1.4 mg/dL without significant proteinuria. HLA typing from the

patient and one of her affected brothers showed they had identical HLA typing (0 of 6 HLA mismatch) and were homozygous for HLA-DR15.

Results:

Conclusions: HLA-DR15 is associated with an increased risk of anti-GBM disease, but HLA types in familial anti-GBM disease cases have never been reported. We present the first case of familial anti-GBM disease involving 3 siblings in the same family with a potential link of HLA-DR15 in the development of familial anti-GBM disease.

SA-PO944

One Drug's Promise Leads to an Unavoidable Complication Andrew Kowalski,[2] Daniel Fantus,[1] John J. Friedewald.[2] *[1]Comprehensive Transplant Center, Northwestern University, Chicago, IL; [2]Northwestern University, Lombard, IL.*

Background: CMV is a major pathogen for immunocompromised patients, especially including solid organ transplant recipients resulting in a broad range of syndromes and inducing organ rejection. This case study examins the course of denovo CMV infection in the setting of immunosupression with belatacept.

Methods: 48 yo male, with a history of CKD stage V due to IgA nephropathy who underwent a successful living related kidney transplant in 7/2015. Due to his HLA status he received a steroid protocol induction and then transitioned to mycophenolate mofetil and tacrolimus. In the next few months he was transitioned to belatacept and off tacrolimus based on a study protocol. A year later he presented with complaints of vague abdominal pain and diarrhea. He was found to have a CMV viral load of 439,804 IU/mL, and placed on ganciclovir. His viral load decreased and then rose to 55,678 IU/mL the following month despite continued ganciclovir. He complained of worsening gastrointestinal symptoms and his viral load was 152,305 IU/mL. Belatacept was stopped and tacrolimus was restarted. His creatinine was at baseline and foscarnet was started. He presented with complaints dyspnea, new onset hematuria and fevers. His creatinine was 4.45mg/dL and urine analysis had a large amount of blood and protein. Foscarnet was then held. He underwent a renal biopsy that was consistent with foscarnet induced renal toxicity. Creatinine remained stable at 4.7mg/dL, repeated CMV viral loads were undetectable and foscarnet was discontinued. His creatinine had then peaked at 10mg/dL. His abdominal symptoms returned and his CMV viral load had increased to 41,332 IU/mL. He was readmitted for cidofovir. His creatinine had risen to 13.9mg/dL. Mycophenolate was discontinued to boost his white cell count and his CMV viral load decreased to 7000 IU/mL, but his creatinine increased to 17. He was then started on dialysis.

Results:

Conclusions: Belatacept binds to CD80 and CD86 receptors and blocks the required CD28 mediated interaction between APCs and T cells needed to activate T lymphocytes. The nature of belatacept prohibits the body to mount a response against EBV leading to an increase in PTLD. We recommend that this concern be extended to CMV negative patiens as this case shows that the use of belatacept hinders the ability of the body to mount a response leading to uncontrolled infection and nessecitating the use of nephrotoxic medications.

SA-PO945

Disseminated Adenoviral Infection with Nephropathy in a Kidney/Pancreas Transplant Recipient Natalie Nesmith, Meghan E. Kapp, Agnes B. Fogo, Paisit Paueksakon, Gowri Satyanarayana, Heidi M. Schaefer, J.H. Helderman, Beatrice P. Concepcion. *Vanderbilt University Medical Center, Nashville, TN.*

Background: Adenovirus (AV) is a commonly encountered viral pathogen with self-limited infection in immunocompetent hosts. In immunocompromised hosts more serious complications can occur. We report a kidney/pancreas (KP) transplant recipient who developed disseminated adenoviral infection with nephropathy which was successfully treated with cidofovir.

Methods: A 32 year old man with Type I Diabetes Mellitus with diabetic nephropathy, retinopathy, and peripheral vascular disease underwent simultaneous KP transplant in 10/2016. He was induced with solumedrol and alemtuzumab. Maintenance therapy included three drug regimen with tacrolimus, prednisone and mycophenolate mofetil. Two months later he developed gross hematuria, high-grade fevers, and acute kidney injury (sCr 1.46 mg/dL vs baseline sCr 0.8 mg/dL). Amylase/lipase were normal. Serum (>2million copies/mL) and urine AV PCR were positive with positive AV nasal swab. He underwent transplant biopsy which showed multifocal tubulocentric necrotizing granulomas with viral cytopathic nuclear changes in tubular epithelial cells and podocytes, the latter associated with a cellular crescent with fibrinoid necrosis and apoptotic debris. Electron microscopy demonstrated focal crystalline viral particles in tubules. Immunohistochemical stains were diffusely positive for AV and negative for SV40. There was no evidence of concomitant acute cellular rejection and no diagnostic evidence of antibody-mediated rejection with negative C4d by immunofluorescence. He was started on cidofovir/probenecid with resolution of fevers after two doses and ultimately received eight doses. Four months later, serum AV PCR was negative and sCr was 1.5 mg/dL.

Results:

Conclusions: While disseminated adenovirus is rare amongst KP transplant recipients, it can cause serious complications including multi-organ dysfunction, graft loss, and death. Severe disease including AV nephropathy warrants treatment with cidofovir despite its nephrotoxicity.

SA-PO946

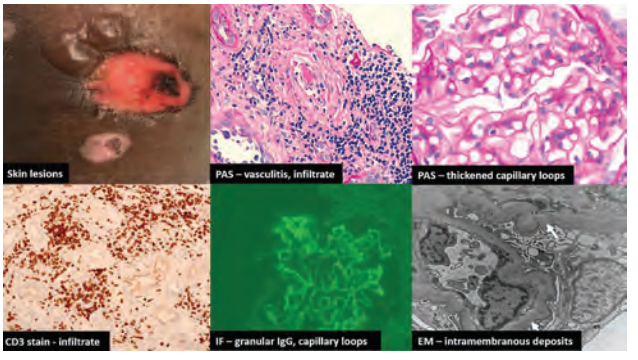
Bullous Pemphigoid and Renal Transplant Rejection: More Than a Mere Coincidence? Abhilash Koratala,[2] William L. Clapp,[2] Olanrewaju A. Olaoye,[1] Alfonso Santos.[2] *[1]University of Florida, Division of Nephrology, Gainesville, FL; [2]University of Florida, Gainesville, FL.*

Background: Bullous pemphigoid (BP) is an autoimmune blistering disease characterized by subepithelial blister formation and deposition of immunoglobulins and complement in the epidermal and/or mucosal basement membrane zone. There are few case reports on the association between BP and allograft rejection, and membranous nephropathy (MN). We report a unique case of BP associated with both acute cellular rejection (ACR) and de novo MN in a renal transplant recipient.

Methods: A 63-year-old man with a history of ESRD secondary to MN, status post living related kidney transplant 5 years ago who has been compliant with his immunosuppressant regimen was admitted for worsening skin rash that started 3 weeks ago and acute kidney injury. Skin exam revealed multiple scattered bullae with clear fluid and erosions with a collarette of scale on the neck, chest, back and limbs. His serum creatinine (Scr) was 7.3 mg/dL at presentation (baseline ~1.5). Urine exam showed 45/hpf RBC, 1/hpf WBC and an albumin-creatinine ratio of ~0.5 g/g. BK virus, CMV, Herpes simplex and Varicella zoster serologies were negative. Skin biopsy revealed BP. His Scr minimally improved with supportive measures and allograft biopsy showed Banff 2A ACR with de novo MN and ~50% interstitial fibrosis and tubular atrophy (IFTA). He was treated with pulse corticosteroid and antithymocyte globulin but his Scr remained unimproved after 1 month. Further immunosuppression was not attempted due to the severity of IFTA on repeat biopsy. His skin lesions eventually improved with high-dose steroid therapy.

Results:

Conclusions: Though the possibility of multiple distinct autoimmune processes cannot be excluded, allograft rejection-induced immune stimulation or anti-basement-zone antibody interactions are possible unifying mechanisms for the simultaneous skin and renal involvement. Whether the diagnosis of BP in a renal transplant recipient warrants kidney biopsy remains unanswered.



SA-PO947

Long-Term Outcome after Treatment of Plasma Cell-Rich Rejection of the Kidney in Simultaneous Kidney and Pancreas and Kidney and Liver Transplant Recipients Ksenija Vucur,[2] Zeljka Jurekovic,[2] Branislav Cingel,[2] Danica G. Ljubanovic,[1] Mladen Knotek.[2] *[1]University of Zagreb School of Medicine, Clinical Hospital Dubrava, Zagreb, Croatia; [2]Department of Nephrology, University of Zagreb School of Medicine and University Hospital Merkur, Zagreb, Croatia.*

Background: Although plasma cells (PC) participate in the kidney graft rejection, their major involvement (i.e. plasma cell rich rejection - PCRR) is rare. We identified three cases with PCRR among simultaneous kidney-pancreas (SPKT) and liver-kidney (SLKT) recipients in our center.

Methods: Case I: A 35-yr old Caucasian male who had SPKT in 2006 presented three mths posttx with renal dysfunction. Kidney biopsy (bx) showed acute cellular rejection (ACR) IB with infiltrate consisting of 17% of PC. Donor-specific antibodies (DSA) were negative. After treatment with steroid boluses there was only a mild decrease in serum creatinine, and the second bx revealed again PCAR. Treatment with high-dose (2 g/kg) IVIG and boluses of steroids led to normalization of renal function. On a follow-up bx at 1 yr, there were no signs of rejection. Eleven yrs later, both graft function is excellent. **Case II:** A 55-yr old Caucasian male who received SLKT in 2006 presented two yrs after tx with renal dysfunction. Kidney bx revealed ACR IB. The infiltrate consisted of 27% PC. After treatment with high-dose IVIG and steroid boluses, a repeat bx showed no signs of acute rejection. Subsequently, the patient had persistent stable renal dysfunction. He died in 2012 from sepsis. **Case III:** A 36-yr old Caucasian male presented in 2009, four yrs after SPKT with worsening of renal function. Kidney bx revealed acute PCRR with microvascular injury (MVI) that was treated with steroid boluses. At that time he had DSA against DQ and DR. Subsequent two bx showed persistent ACR and the treatment included high-dose IVIG. Afterwards renal function improved, but five yrs later serum creatinine increased again, and on biopsy PCRR with MVI was again diagnosed. It was treated with bolus of steroids and high-dose IVIG and was followed by creatinine decrease. On the last visit in 2017 patient had both graft function stable with creatinine 155 μmol/L.

Results:

Conclusions: We showed that in SPKT or SLKT PCRR may affect only kidney function and was only partially associated with DSA and MVI. Combined treatment with high-dose IVIG and pulse steroids may be effective in treatment of PCRR resulting in a good long-term graft survival. To our knowledge, this is also the first report of PCRR in a patient with SLKT.

SA-PO948

AKI Post Kidney Transplant Associated with Macroscopic Glomerular Hematuria Secondary to Rivaroxaban Magdi H. Abdelrahman,[2,1] Muhammad R. Mustafa,[2,1] Praveen N. Chander.[1] *[1]New York Medical College, Valhalla, NY; [2]Westchester Medical Center, West Harrison, NY.*

Background: Reversible AKI secondary to macroscopic glomerular hematuria (MGH) has been described in IgA nephropathy, Anticoagulant-related nephropathy (ARN) and rarely in Thin GBM disease in the native kidneys. Acute tubular damage and widespread intraluminal obstructive RBC casts are salient histologic features. ARN is classically caused by warfarin; however other anticoagulants have been reported to cause it. We report a case of reversible AKI associated with rivaroxaban post heart and kidney transplantation.

Methods: A 51 yo male with a history of non-ischemic cardiomyopathy and ESRD due to ANCA-associated vasculitis underwent combined heart and kidney transplantation from a deceased donor. He received Induction with basiliximab and methylprednisolone. Post-operative course was complicated by the development of catheter-related intra-jugular vein thrombosis and he was started on intravenous heparin. His maintenance immunosuppression was prednisone, Tacrolimus and Mycophenolate mofetil. He was switched to rivaroxaban when his serum creatinine (SCr) improved to 1.5 mg/dl. Two weeks after his transplant, his SCr increased to 2.8 mg/dl. Tacrolimus level was 11.6; ANCA titer was 1:640. Large numbers of RBCs were detected on urinalysis. A transplant kidney biopsy showed a small segmental epithelial crescent in 1/11 glomeruli and numerous RBCs in the Bowman's space of another, without any necrotizing or other significant lesions. Widespread intraluminal obstructive casts were present in tubules. The degree of renal impairment and tubular RBC casts were disproportionately greater than the glomerular disease suggesting coexistent ARN. Rivaroxaban was stopped; the patient was treated with rituximab, and pulse steroids. SCr dropped to 1.6 mg/dl in 2 weeks.

Results:

Conclusions: Common etiologies of renal dysfunction in the early period post-transplantation are acute rejection, recurrent primary disease, or calcineurin inhibitor nephrotoxicity. To our knowledge, this is the first case of AKI post combined heart and kidney transplantation due to ARN (rivaroxaban). In conclusion, MGH of any etiology obstructing renal tubules should be considered in the differential diagnosis of early post-transplant acute kidney injury especially in patients on anticoagulants. Renal histology can be of help in evaluating such cases.

SA-PO949

A Case of Kaposi's Sarcoma Developed during the Intensive Immunosuppression Therapy against T Cell-Mediated Rejection, but Resolved Rapidly after Adding mTOR Inhibitor Kosuke Sako,[1] Yosuke Nakagawa,[1] Yudai Isozaki,[1] Chiaki Kawabata,[1] Naoto Hamano,[1] Hiroaki Ishida,[2] Masahiro Koizumi,[1] Go Ogura,[3] Takehiko Wada,[1] Masafumi Fukagawa,[1] Michio Nakamura.[2] *[1]Division of Nephrology, Endocrinology and Metabolism, Tokai University School of Medicine, Isehara, Japan; [2]Department of Transplantation Surgery, Tokai University School of Medicine, Isehara, Japan; [3]Department of Pathology, Tokai University School of Medicine, Isehara, Japan.*

Background: Incident renal allograft rejections have been decreasing in number due to dramatic advance in immunosuppression therapies for kidney transplantation (KT). In contrast, infections and *de novo* neoplasms associated with those therapies have become an important issue. Here, we report a case of Kaposi's sarcoma developed during the intensive immunosuppression therapy against T cell-mediated rejection, but resolved rapidly after adding mTOR inhibitor, everolimus.

Methods: A 44-year old Mongolian woman, who had been on hemodialysis for 4 years with end stage renal disease due to autosomal dominant polycystic kidney disease, received a kidney transplant from her husband. Because of ABO-incompatible KT, she had received rituximab 100 mg twice, double filtration plasmapheresis and intravenous immunoglobulin as pre-transplantation conditioning. Initial immunosuppression consisted of tacrolimus, mycophenolate mofetil, basiliximab and steroids. Her serum creatinine level was decreased to 1.26 mg/dL at minimum, however, it was elevated to 1.69 mg/dL again at 2 months after KT. The findings of a graft biopsy were compatible with T cell-mediated rejection, which was successfully treated with steroid pulse therapy and gusperimus hydrochloride. Immunosuppression therapy was intensified by increasing the dose of tacrolimus and her serum creatinine levels persisted 1.6-1.8 mg/dL thereafter. However, there appeared aggregated dark reddish nodules on her skin at nose and between eyebrows at 6 months after KT. They did not resolve with topical corticosteroid and tacrolimus but rather grew gradually. Skin biopsy demonstrated monomorphic spindled cells with HHV-8-positive nuclei and capillary proliferation, which provided the diagnosis of Kaposi's sarcoma. Everolimus was added to immunosuppression therapy regimen and then the sarcoma was significantly reduced.

Results:

Conclusions: Kidney transplant patients with Kaposi's sarcoma are supposed to increase in number with the progress of immunosuppression therapies. Everolimus, which is expected to have an anti-angiogenic effect, may be one of therapeutic options for Kaposi's sarcoma associated with immunosuppression therapies.

SA-PO950

The "Conn" Artist: An Unlikely Cause of Post-Kidney Transplantation Hypertension Laila S. Lakhani,[2] Angelina Edwards.[1] *[1]University of Texas at Houston Health Science Center, Houston, TX; [2]Internal Medicine, University of Texas Health Science Center at Houston, Houston, TX.*

Background: Hypertension among the post-renal transplant population is largely due to pre-existent essential hypertension in end stage renal disease (ESRD). Other transplant-specific causes of hypertension include the use of Calcineurin inhibitors and Corticosteroids, Renal artery stenosis or Graft Versus Host Disease. Secondary causes of hypertension are rarely reported in the literature. We report an interesting case of a patient with a non-secretory adrenal adenoma pre-transplant, which became functional post-transplant, leading to resistant hypertension and metabolic derangements.

Methods: 60 year old female with ESRD secondary to hypertension and diabetes mellitus type 2, underwent evaluation for transplant at our Center. Abdominal imaging revealed a 8 mm left adrenal nodule, however biochemical evidence for a secretory adenoma was negative. She underwent a deceased donor renal transplant, with basiliximab induction and maintenance immunosuppression with cyclosporine, mycophenolate mofetil and prednisone. She had excellent allograft function with nadir creatinine of 1.4 mg/dL but was noted to have uncontrolled blood pressures, despite maximum doses of 5 antihypertensive agents. Laboratory parameters were significant for hypokalemia and metabolic alkalosis. A workup for secondary causes of hypertension was pursued (Table 1). Repeat abdominal imaging at this time showed an enlarged left adrenal adenoma, 1.3x1.9 cm. Labs showed elevated aldosterone levels and adrenal vein sampling localized the secretion to the left adrenal gland (Left: 979ng/dL vs Right: 18 ng/dL). She was started on an aldosterone antagonist with only mild improvement of her blood pressure, subsequently requiring a left adrenalectomy. Post- surgery, she had complete resolution of hypokalemia and stability of her blood pressure, requiring minimal antihypertensive therapy.

Results:

Conclusions: Hypokalemia and resistant hypertension from primary hyperaldosteronism can be easily masked in the ESRD population. Although it remains a common problem, medically refractory hypertension post renal transplant should prompt a work up for secondary causes, including hyperaldosteronism.

Table 1: Laboratory findings pre and post-Transplant.

	Pre-Transplant	Post-Transplant
Aldosterone/PRA ratio	22	310
Metanephrines	39	2085
Cortisol	11.7	13.9

SA-PO951

Nocardiosis in a Renal Transplant Patient: A Case Report and Review of Literature Mohit Gupta,[1] Irtsam Shahid,[2] Rupesh Raina.[2] *[1]Internal Medicine, Cleveland Clinic Akron General, Akron, OH; [2]Internal Medicine, Cleveland Clinic Akron General, Akron, OH.*

Background: Nocardiosis is a rare and systemic disease that occurs in up to 5% of renal transplant recipients. Amongst patients with Nocardiosis, Central Nervous System involvement is seen in approximately 50% of cases. We report a patient with remote history of renal transplantation who was found to have multiple brain abscesses consistent with Nocardia infection.

Methods: A 66 year-old male with prior history of living donor renal transplant approximately 4 years ago presented for evaluation of progressive dizziness, nausea and vomiting. MRI revealed the presence of a peripherally enhancing lesion in the medial right cerebellum in addition to 2 smaller lesions in the right frontal lobe. CT Scan of the Chest done also revealed the presence of several small pulmonary nodules in both lungs. With the use of Mycophenolate Mofetil and Tacrolimus, there was a concern for brain abscess versus malignancy. The patient was started on IV Trimethoprim – Sulfomethaxozole in addition to Vancomycin and Ceftazidime with plan for aspiration and culture. Immunosuppression was modified due to concern for worsening kidney function thought to be due to calcineurin toxicity. However, false elevation in Creatinine secondary to Trimethoprim was also considered. Aspirate of the culture revealed the presence of branching gram positive organisms consistent with Nocardia. Vancomycin was switched to Linezolid and Ceftazidime to Imipenem with a plan to continue IV antibiotics for 6 weeks.

Results:

Conclusions: Nocardiosis is an opportunistic infection that occurs in up to 5 % of renal transplant recipients. It is seen commonly in the intense immunosuppression period after renal transplantation (which is 1-6 months) or after high dose therapy is used to treat rejection. The primary site of involvement is the pulmonary system, but spread to the CNS can also occur. Risk factors for development of Nocardia include multiple rejection episodes, worsening kidney function as well as high dose immunosuppression. Empiric antimicrobial therapy is often recommended as it is very slow growing. Trimethoprim-Sulfomethaxozole is first line therapy for management of Nocardia brain abscess due to good penetration of sulfonamides. The mortality rate in immunosuppressed patients has been reported to be up to 50%. Hence, a high degree of clinical suspicion is necessary when such CNS findings are observed in renal transplant recipients.

SA-PO952

Hidden, Donor-Derived Malignancy: A Tale of Two Kidneys Amaleswari Pamarthy,[2] Pradeep Vaitla.[1] *[1]Madison, MS; [2]UMMC, Madison, MS.*

Background: PTLD (Post-transplant lymphoproliferative disorder) is a relatively common malignancy but rarely donor derived. PTLD includes clinical syndromes ranging from uncomplicated post-transplant infectious mononucleosis to true malignancies that contain clonal chromosomal abnormalities which may or may not be associated with EBV infection. Most cases occur in the first year. Mortality is as high 50-80% in monoclonal form. High index of suspicion and clinical vigilance is critical since patients can present with nonspecific symptoms & signs. Pathophysiology is not well understood. Hence anticipation and prevention of PTLD remains a challenge.

Methods: Mate kidneys obtained from EBV and CMV IgG negative donor were transplanted to 69-year-old male and 68-year-old female who were positive for EBV IgG and CMV IgG. Kidney and spleen biopsies were done at procurement. Both patients received induction with Anti-thymocyte globulin and maintained on Tacrolimus, Mycophenolate mofetil, Prednisone. Kidney biopsies at the time of transplant did not show any evidence of disease process. Post-transplantation, pathology of donor's spleen revealed plasmacytoma. Hence both recipients called in for further work. SPEP was unremarkable, serum free light chains showed a mild increase in lambda light chains, which were followed regularly. One patient developed abdominal pain 4 months post transplant and imaging revealed 10cm mass arising from transplant kidney, the biopsy confirmed plasmacytoma. The second patient presented with urinary retention and imaging revealed a large para-aortic lymph nodal mass. Biopsy confirmed plasmacytoma as well. Both patients were started on chemotherapy and doing fairly well now.

Results:

Conclusions: Despite having a normal kidney biopsy at the time of transplant, donor-derived malignancy can be transmitted through lymphatics of the donor organs. If suspicion for PTLD is high, more aggressive screening and high clinical vigilance is indicated. Negative bonemarrow biopsies might not preclude from having PTLD. If high suspicion for EBV-related PTLD present, prophylactic therapies, including antiviral agents and immunoglobulins were proposed but need to be tested in randomized, placebo-controlled trials to determine their true efficacy. Decreasing the immunosuppression is the cornerstone and might help with regression of the PTLD, sometimes aggressive chemotherapy is indicated as presented above.

SA-PO953

An Unusual Case of Renal Cell Carcinoma (RCC) with Sarcomatoid Changes in a Renal Transplant Allograft Muhammad O. Saleem, Laura L. Mulloy, Carlos F. Zayas, Rajan Kapoor. *Augusta University, Medical College of Georgia, Augusta, GA.*

Background: Renal transplant recipients are at a higher risk of developing RCC than general population. RCC in renal transplant allograft is unusual. We present a rare case of highly agressive RCC with sarcomatoid changes in an allograft.

Methods: A 69-year Caucasian female with CKD stage 5 due to Autosomal Dominant Polycystic Kidney Disease (ADPKD) received a preemptive deceased donor kidney transplant. She presented 2 years post transplant with persistent hematuria. CT scan revealed 3.4 x 2.9 x 2.3 cm hypo-enhancing structure concerning for malignancy in the transplant allograft in addition to multiple simple and hemorrhagic cysts in both native ADPKD kidneys. She underwent a percutaneous biopsy of suspicious renal allograft mass, which was negative for malignancy and revealed only bland myofibroblastic proliferation. A repeat biopsy, which was also negative for malignancy was done 2 weeks later to confirm pathological findings and to eliminate any sampling error. A plausible diagnosis of persistent hematuria from her native polycystic kidney ruptured cysts was made. She presented about a year later with significant weight loss of 25 lbs and anorexia for two months duration. Repeat CT showed significant increase in the size of renal transplant mass. A MAG3 scan showed a fistula formation from the allograft mass to ileum. Patient underwent an exploratory laparotomy and an en bloc resection including transplant allograft nephrectomy and ileo-cecectomy was performed. Histopathology showed poorly differentiated RCC with sarcomatoid changes of allograft invading into the bowel wall. Staging CT showed multiple pulmonary metastases as well.

Results:

Conclusions: Renal transplant patients are at increased risk of developing RCC of the native kidneys. RCC can occur in transplant allograft as well but incidence is extremely low. A tumor registry reported incidence as low as <0.01% in allograft. RCC with sarcomatoid changes is extremely rare and only a few cases have been reported. Patients with ADPKD have higher incidence of sarcomatoid changes in RCC (33% vs 1 to 5%) as compared to general population. Our case is an unusual scenario due to findings of extremely rare and highly aggressive form of RCC with sarcomatoid features in a transplant allograft. We suggest an aggressive approach to diagnose renal allograft mass particularly in patients with ADPKD.

SA-PO954

Transitional Cell Carcinoma Involving Graft Kidney in a Kidney Transplant Recipient: A Case Report Seong il Jo, Yoon-Kyung Chang, Suk young Kim, Yu ah Hong. *College of Medicine, The Catholic University of Korea, Seoul, Korea, Daejeon, Republic of Korea.*

Background: Kidney transplantation (KT) is the treatment option for patients with end stage renal disease (ESRD) to prolong survival and improve quality of life. Although the use of potent immunosuppressive agents increases graft survival in kidney transplantation recipients (KTRs), it may lead to the development of malignancy, including transitional cell carcinoma (TCC). TCC developing in the pelvis of graft kidney is very rare in KTRs

Methods:

Results: A 40-year-old male visited hospital with complaints of nausea, vomiting and gross hematuria. Eleven years ago, he was diagnosed ESRD of unknown origin, and received a living related KT from his father one year later. Radiologic findings showed a huge polypoid mass in the pelvis of graft kidney with pelvo-calyceal dilation and a 3.3 cm-sized nodule in aortocaval chain and a 2.5 cm-sized nodule in right external iliac chain. Sonography-guided percutaneous needle biopsy of pelvis mass in the graft kidney revealed a low grade urothelial cell carcinoma. Radical graft nephroureterectomy was performed and histopathological diagnosis confirmed as a low grade urothelial carcinoma of graft pelvis and ureter lumen, which invaded to perirenal fat and renal parenchyma with lymphovascular presence (pT3N0M0). The patient started with adjuvant concurrent chemo-radiation therapy and returned to regular hemodialysis.

Conclusions: We report a rare case of TCC in the pelvis of graft kidney with already advanced disease at diagnosis in a young KTR. For the early diagnosis of TCC in KTRs, exposure history to Chinese herb or analgesics should be investigated before KT and high risk population in KTRs should be tightly performed regular postoperative surveillance for TCC and considered of less calcineurin inhibitor-based immunosuppressant protocol.

SA-PO955

Successful Kidney Transplantation and Chronic Lymphocytic Leukemia: A Case Report Mohammed Nazmul,[2] Clifford D. Miles,[2] Vamsi Krishna Chilluru,[1] Ryan Mullane,[2] Scott G. Westphal.[1] *[1]Omaha, NE; [2]University of Nebraska Medical Center, Omaha, NE.*

Background: Active malignancies are typically considered as contraindication to kidney transplantation. Chronic lymphocytic leukemia (CLL) has variable prognosis; many have indolent course, with median survival up to 10 years, and some centers are considering the role of kidney transplantation in patients with active CLL who develop advanced kidney disease. Concerns related to transplantation include influence of immunosuppression on disease progression, possibility for leukemic infiltration of the allograft and increased risk of infectious complications. Few cases of kidney transplantation into patients with CLL have been described, however allograft and patient outcomes have been discouraging with high rate of graft failure and mortality. We report a patient with CLL treated with Bruton Tyrosine Kinase inhibitor, ibrutinib, underwent successful renal transplantation with relatively uncomplicated post-transplant course.

Methods: A 50-year-old man was diagnosed with CLL/small lymphocytic lymphoma Rai stage 0 with favorable cytogenetics. He was managed conservatively initially, but later treated with cyclophosphamide and maintenance rituximab due to declining renal function. Kidney biopsy revealed IgA nephropathy with CLL renal involvement characterized by lymphocytic interstitial infiltrate. He progressed to end-stage kidney disease requiring hemodialysis. He completed two years of rituximab and was later transitioned to maintenance therapy with ibrutinib which controlled his CLL with stable WBC counts and no infections. Given clinical stability and favorable prognosis, he was approved for kidney transplantation and received a deceased donor kidney transplant (KDPI 67%) with basiliximab induction followed by maintenance immunosuppression including tacrolimus, mycophenolate sodium and prednisone. He is now 1.5 years out from his transplant and had a successful allograft outcome with serum creatinine 1.0 mg/dl (eGFR 76 ml/min) at last check. There have been no infectious complications. He has maintained a persistent lymphocytosis, but has not had adverse allograft injury related to his CLL.

Results:

Conclusions: Patients with CLL have often been excluded for consideration for kidney transplantation, newer therapies and improved understanding of favorable prognostic markers may allow for safe kidney transplantation in carefully selected patients.

SA-PO956

Long Term Function of Pediatric En Bloc Kidneys: A Single Center Study Amr Habbach, Kalathil K. Sureshkumar. *Westpenn Allegheny Health Network, Pittsburgh, PA.*

Background: Pediatric en bloc kidneys are considered "marginal" and many transplant centers are reluctant to use them. However, these kidneys double the number of nephrons and previous studies have shown that when exposed to adult hemodynamics these kdineys grow to adult size within first year. We aimed to compare extended long term function of pediatric en bloc kidneys to living donor kidneys performed at our institution.

Methods: This is a single center restrospective study of pediatirc en bloc and living donor kidney transplants performed at our center between January 1990 and December 2001 who had functiong graft beyond 5 years. Graft survival, yearly serum creatinine and

estimated GFR using modified MDRD equation were calculated and compared between en bloc and living donor kidney recipients.

Results: There were 72 patients in the en bloc and 75 in the living donor group who were transplanted during the study period. Maximum available follow up for serum creatinine value was 17 years following transplantation. Kaplan-Meier survival analysis showed no difference in graft survival between the groups over 27 years of follow up (long rank p 0.78). However on regression analysis, allograft function was found to be superior for en bloc vs. living donor kidney recipients longitudinally as evidenced by higher estimated GFR (33.0 ± 7.8 ml/min, p<0.0001) as shown in figure.

Conclusions: Our single center study showed simlar graft survival but superior long term graft function as measured by estimated GFR among pediatric en bloc kidneys compared to living donor kidneys. This could be related to increased "nephron dose" among en bloc kidneys which could likely make them less susceptible to hyperfiltration injury in the long term. Our study encourages more widespread use of en bloc kidneys which can alleviate organ shortage while providing excellent long-term function. Strengths of our study include relatively large number of study patients and extended available follow up.

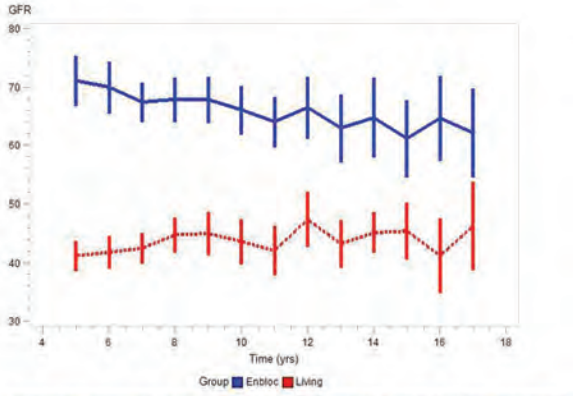


Figure 1: Plot Means with Standard Error Bars for GFR stratified by Pediatric En Bloc Renal Transplant vs Living Donor transplant

SA-PO957

Experience with Interleukin-1 Blockade in Three Renal Transplant Patients with Severe Gout Arthritis Vega Goedecke,[1] Gunilla Einecke,[2] Hermann G. Haller,[1] Annette D. Wagner.[3] *[1]Hannover Medical School, Hannover, Germany; [2]Medical School Hannover, Hannover, Germany; [3]Medizinische Hochschule Hannover, Hannover, Germany.*

Background: Hyperuricemia and gout are common comorbid conditions experienced by up to 28% of kidney transplant recipients. Reasons include reduced excretory renal function, intake of diuretic medication as well as side-effects of immunosuppressant drugs such as calcineurin-inhibitors. Treatment of gout in these patients remains a challenge, as uricostatic drugs such as allopurinol have a narrow therapeutic range in patients with impaired renal function whereas uricosuric medications such as benzbromarone are less effective due to reduced excretory renal function. Allopurinol and febuxostat are contraindicated when azathioprine is given, as they can cause severe drug interactions. Also, allopurinol therapy may increase cyclosporine plasma levels. Interleukin 1 (IL-1) plays a crucial role in gout arthritis and its blockade with selective IL-1 inhibitors such as canakinumab or anakinra has shown promising results in the treatment of gout. Canakinumab was shown to be effective in preventing gout attacks in patients who had contraindications or were unresponsive to colchicine and/or non-steroidal inflammatory drugs. Data on the use of IL-1 blockade as treatment for gout in renal transplant patients are limited, therefore we present our experience with interleukin 1 blockade in 3 patients after renal transplantation. All of them had refractory gout arthritis despite various treatment regimens prior to starting IL-1 blockade therapy.

Methods: We present our clinical experience with anti-interleukin-1-antibody treatment in three renal transplant patients with gout arthritis. All of them had refractory gout arthritis despite various treatment regimens prior to starting IL-1 blockade therapy. Two patients improved significantly and have had no gout symptoms since starting IL-1 blocking therapy. One patient suffered from pneumonia 1 month after starting therapy. Therefore, IL-1 blocking therapy was discontinued and the patient was started on rasburicase therapy.

Results:

Conclusions: Overall, therapy was well tolerated and symptoms improved in 2/3 patients. Therefore, Il-1 blocking therapy with canakinumab or anakinra is an option for treating refractory gout arthritis in renal transplant patients, even with chronic kidney disease stage 4. Infection was the main complication of therapy observed in our patients, therefore, close monitoring is recommended.

SA-PO958

Renal Allograft Malakoplakia: A Rare Cause of Allograft Failure Payaswini Vasanth,[1] Jeffy Kenny Thomas,[1] Thomas E. Rogers,[2] Sharon M. Graves.[1] *[1]Nephrology, Emory Univeristy, Atlanta, GA; [2]Emory University, Atlanta, GA.*

Background: Malakoplakia is an unusual granulomatous inflammatory disorder associated with diminished bactericidal action of leukocytes. Cases of renal allograft malakoplakia are rare and are generally associated with a poor graft and patient survival. We present a case of renal allograft malakoplakia triggered by repeated UTIs in the setting of recent increase in immunosuppression.

Methods: 50-year-old female with history of pediatric en bloc kidney transplant with baseline allograft function ranging between 2-2.5mg/dl on immunosuppression regimen of low dose Tacrolimus (trough between 3-5), low dose MMF due to history of UTIs and BK viremia and prednisone. Her post transplant was complicated by recurrent *E.coli* UTIs and mesangioproliferative-type glomerulopathy, with prominent staining for IgM and C3 which is a variant of focal segmental glomerulosclerosis (FSGS), and hence her immunosuppression was increased to high dose prednisone with prolonged taper. Soon after she developed *E.coli* UTI and acute kidney injury, her creatinine increased to 9.5mg/dl. She was treated with IV Antibiotic rocephin and transitioned to oral Levoquin for 3 weeks. Her creatinine trended down to 4.2mg/dl and a biopsy was performed that showed epithelioid histiocytes with basophilic inclusions called Michaelis-Gutmann bodies suggestive of malakoplakia with severe IFTA. Her creatinine remained at 4mg/dl and we maintained her on low immunosuppression in the setting of malakoplakia.

Results:

Conclusions: Renal parenchymal malakoplakia is a rare cause of renal allograft failure. Currently, malakoplakia is thought to be associated with infection, *E.coli* is the most common. Therefore, agents targeting Gram negative bacteria with high bioavailability in macrophages are most commonly chosen, such as quinolones and sulfamido groups. In malakoplakia, macrophage dysfunction and persistent antigens within cells cause progressive delivery of cytokines, resulting in renal inflammation and further injury. If the early interstitial injury is not controlled, renal injury continues to deteriorate and even progresses to interstitial fibrosis even when bacteria is removed and is associated with poor graft outcome, as demonstrated in this case.

SA-PO959

Pazopanib (Votrient) Induced Podocytopathy in a Transplant Kidney Massini Merzkani,[2] Kenar D. Jhaveri,[2] James M. Pullman,[1] Rimda Wanchoo.[2] *[1]Pathology, Montefiore Medical Center, Bronx, NY; [2]Nephrology, Hofstra Northwell School of Medicine, Great Neck, NY.*

Background: Glomerular endothelial cell injury and podocyte damage, resulting in glomerular disease including thrombotic microangiopathy(TMA) and focal segmental glomerulosclerosis, are well recognized complications of tyrosine kinase inhibitors(TKI) used in targeted therapy for cancers. TKI use in kidney transplant recipients is not well described. We report a case of nephrotic syndrome in a kidney transplant recipient with metastatic renal cell cancer treated with the TKI- pazopanib(Votrient).

Methods: A 58 year old male with a living unrelated renal transplant 15 years ago was diagnosed with metastatic renal cell cancer (RCC). Immunosuppression was changed to minimal dose mycophenolate mofetil, tacrolimus was replaced with sirolimus, and low dose prednisone was continued. Renal function was normal without proteinuria. The TKI pazopanib was started to treat the metastatic RCC. Within three months of starting treatment, he developed worsening hypertension, edema and nephrotic range proteinuria (7 gms/day) with low serum albumin (3.4g/dl). A kidney biopsy revealed podocytopathy and early glomerular endothelial damage. There was no evidence of T- cell or antibody mediated rejection. Proteinuria improved with discontinuation of sirolimus and pazopanib but worsened again with re-initiation of pazopanib alone. We therefore conclude that pazopanib caused the podocytopathy as well as the endothelial injury. Without other options for RCC treatment, pazopanib was continued with conservative management of proteinuria by angiotensin receptor blockade and blood pressure control.

Results:

Conclusions: We report the first case of biopsy proven podocytopathy with endothelial injury secondary to the TKI pazopanib in a kidney transplant recipient. Nephrologists, transplant physicians and oncologists need to be aware of complications of this and other targeted therapies in transplant recipients.

SA-PO960

Transplant Associated Thrombotic Microangiopathy (TA-TMA) in a Child with Neuroblastoma and Complement Factor Deletion: A Novel Association Amirtha Chinnadurai,[2] Ali Y. Suliman,[3] Michael Kent,[1] Alda Tufro.[4] *[1]Yale University, New Haven, CT; [2]Pediatric Nephrology, Yale University School of Medicine, New Haven, CT; [3]Yale univeristy School of medicine, Hamden, CT; [4]Yale University School of Medicine, New Haven, CT.*

Background: TA-TMA is an increasingly recognized morbidity following stem cell transplantation. It is uncommon in autologous stem cell transplantation (auto-SCT). Risk factors for TA-TMA following auto-SCT include specific malignancies such as neuroblastoma, platinum based chemotherapy, total body irradiation and infections. To our knowledge, there are no previous reports of genetic predisposition as a cause of TMA in neuroblastoma following auto-SCT.

Methods: A 3-year-old hispanic boy with stage IV poorly differentiated neuroblastoma, received 6 cycles of high dose chemotherapy, primary tumor resection

and underwent auto-SCT two months later. His post-stem cell transplant course was complicated with septic shock with multi-organ dysfunction including respiratory failure, recurrent supraventricular tachycardia and acute kidney failure requiring continuous renal replacement therapy, which subsequently resolved and the neuroblastoma remained in remission. Two months after auto-SCT, he developed refractory hypertension on multiple anti-hypertensive therapy, seizures associated to acute posterior reversible leukoencephalopathy syndrome, recurrent acute kidney injury and severe thrombocytopenia and anemia, dependent on daily transfusions. The diagnosis of TMA was then established with the presence of schistocytes, low serum haptoglobulin, elevated lactate dehydrogenase, negative Coombs, normal ADAMTS13, marked decrease in CH50 and complement component 5 activity. Complement gene panel revealed homozygous deletion of CFHR1 gene. He received weekly eculizumab for two months leading to normalized renal function, eGFR of more than 100ml/min/1.73m2 (modified schwartz), resolved hypertension, proteinuria, anemia and thrombocytopenia. Eculizumab therapy was tapered as all TMA signs resolved, and remains in remission to date (23 months from onset), while receiving Eculizumab every two months.

Results:

Conclusions: We report for the first time a case of TMA in a child with neuroblastoma harboring a complement genetic mutation known to cause TMA or atypical hemolytic uremic syndrome. It resolved upon Eculizumab and remains in remission after extending the therapy interval to 8 weeks. We hypothesize that complement genetic variants may constitute a risk factor for sporadic TA-TMA.

SA-PO961

Kidney Transplantation in a Patient with Severe Pulmonary Hypertension on Macitentan Therapy Sandhya L. Kommana,[1] Erik L. Lum.[2] *[1]Harbor ULCA MEDICAL CENTER, Harbor City, CA; [2]UCLA Ronald Reagan Medical Center, Westwood, CA.*

Background: Pulmonary Hypertension (PH) is associated with a significant reduction in patient survival and graft function following kidney transplantation. Patients with severe pulmonary hypertension, defined as a 6 minute walk test < 300 meters or ventricular systolic pressure (RVSP) > 55 mmHg, are at increased risk for peri-operative complications and is considered a contraindication to kidney transplantation. Here we report a case with severe PH on maintenance Macitentan (Endothelin receptor antagonist) therapy who underwent successful kidney transplantation.

Methods: A 65-year-old male with ESRD secondary to autoimmune vasculitis was evaluated for kidney transplantation. His past medical history was notable for dermatomyositis, interstitial lung disease, pulmonary hypertension, and coronary artery disease. Two years prior to evaluation he was noted to have increasing dyspnea. A CT scan of the chest revealed pulmonary fibrosis. Pulmonary function tests revealed restrictive lung disease with FEV1 75% predicted, FEV1/FVC 57% and significant DLCO impairment of 28%. An Echocardiogram showed RVSP of 70 mmHg and was started on nocturnal oxygen therapy. His symptoms continued to worsen and was started on Macitentan, with improvement in his pulmonary pressures (32 mmHg) and nocturnal oxygen was discontinued. One year prior to transplantation he developed worsening dyspnea as a result of pulmonary edema in association with progression of his renal disease and was initiated on hemodialysis. His symptoms improved and he was cleared for kidney transplantation. The patient underwent living unrelated kidney transplantation without complications. His Macitentan was continued during the perioperative period. We used caution not to use Diltiazem or Fluconazole postoperatively due to drug interaction with Macitentan. He is currently 3 months post kidney transplantation and has good allograft function with S Cr of 1.2 mg/dl.

Results:

Conclusions: The prevalence of pulmonary hypertension in ESRD patients has been estimated between 9-15% and when severe may preclude patients from getting kidney transplantation. However, the recent development of effective pharmaceutical therapies for PH may improve these outcomes. To our knowledge, this is the first reported case where kidney transplantation was performed in a patient with pulmonary hypertension on drug therapy.

SA-PO962

Acyclovir Neurotoxicity Occurring in Two Patients on Peritoneal Dialysis with Varicella-Zoster Virus Encephalitis Xunxi S. Guo,[1] Vesh Srivatana.[2] *[1]NYP/Cornell, New York, NY; [2]The Rogosin Institute, New York, NY.*

Background: Acyclovir neurotoxicity which can have varying symptoms including agitation, delirium, myoclonus, and coma are known to appear more commonly in end-stage renal disease (ESRD) patients. The kidney is the major route for acyclovir elimination and in ESRD patients, hemodialysis (HD) eliminates an estimated 45% of the drug during a 3-hour treatment, however in continuous ambulatory peritoneal dialysis (CAPD) clearance is 22 times lower compared to HD. We report 2 cases of acyclovir neurotoxicity in peritoneal dialysis (PD) patients with varicella-zoster virus (VZV) encephalitis with improved mental status after transitioning to HD.

Methods: Case 1: A 56 year-old female with ESRD on CAPD for 3 months, recently started on valacyclovir for 2 days for herpes zoster opthalmicus presents with acute onset of confusion. She was started on IV Acyclovir upon admission. Cerebrospinal fluid (CSF) analysis showed 3,500 Varicella DNA copies/mL. Her encephalopathy worsened and neurological evaluation with EEG and MRI/MRA was unrevealing. On hospital day 4, she underwent HD with subsequent improved mental status. Acyclovir level was 3.1 mcg/mL pre-HD and none detected post-HD. She was treated with 2 weeks of IV Acyclovir and intermittent HD with return to normal mental status and transitioned back to CAPD at discharge. **Case 2:** A 50 year-old female with ESRD on automated PD for 6 years presents with worsening mental status in setting of zoster ophthalmicus and superimposed cellulitis. She had been on valacyclovir for 2 days and continued on IV Acyclovir. Her mental status quickly deteriorated, only grimacing to pain. CSF analysis showed 81,700 Varicella DNA copies/mL. Acyclovir level was 8.1 mcg/mL. On hospital day 3, she was started on HD. Her course was complicated by troponinemia, hypotension, and reduced ejection fraction attributed to VZV myocarditis and was briefly on continuous renal replacement therapy. Her mental status returned to baseline 5 days after start of HD. She completed a course of acyclovir and was transitioned back to PD at discharge.

Results:

Conclusions: We present two unique cases of acyclovir neurotoxicity in PD patients with VZV encephalitis. They highlight that acyclovir even at appropriate dosing can lead to toxic levels and neuropsychiatric effects in the PD population due to no appreciable clearance.

SA-PO963

A Unique Case of Valganciclovir Associated Reversible Azoospermia in a Renal Transplant Patient Al J. Lee, Myriam C. Vela-Ortiz, Karthik M. Ranganna, Sandeep Aggarwal. *Drexel University College of Medicine, Philadelphia, PA.*

Background: Azospermia with secondary infertility has not been reported as an adverse effect associated with valgancyclovir. We present a case of reversible azospermia in a renal transplant patient associated with valgancyclovir therapy.

Methods: 30y/o male with past medical history of surgically corrected Tetralogy of Fallot whom developed dialysis dependent renal failure post cardiac surgery and required renal transplant 11 years ago. Patient presented for routine outpatient transplant appointment with complaints of inability to conceive. He denied genitourinary trauma, ED dysfunction, family history of infertility, or exogenous use of androgens. He was a well-nourished, well developed male who appeared as stated age and had an unremarkable physical exam. Referral was made to fertility clinic. The patient's semen analysis results are: semen volume 3.8mL and no sperm identified. Diagnosis of primary male infertility secondary to azopsermia was made. At this time the patient was on stable immunosuppression with tacrolimus 1mg BID and prednisone 5mg daily and valgancyclovir 900mg BID (for 3 years)secondary to persistent EBV viremia. Autoimmune, hormonal, and radiological workup for infertility was negative. In an attempt to uncover medication related azospermia, valgancyclovir was stopped. 1 month later repeat semen analysis results were: semen volume 2.9mL, sperm concentration 21mil/mL, total sperm number 60.9mil/ejac, progressive motility 41%, total motility 63%, vitality N/P, sperm morphology 3%, pH 8, leukocyte <1. There were no further other medication changes. Patient was able to conceive a child and had semen cryopreserved. Patient currently not on valgancyclovir with stable EBV PCR of 7272 copies/mL; unchanged since initial stoppage of valgancyclovir 10 months prior.

Results:

Conclusions: In animal studies gancyclovir has been a potent inhibitor of spermatogenesis but to our knowledge this is the first h uman r eported c ase of valgancyclovir associated azospermia. Further studies needed including careful post-marketing analysis to confirm this association.

SA-PO964

Rapidly Growing Mycobacteria (RGM) – An Unusual Cause of Peritoneal-Dialysis Associated Mycobacterial Peritonitis Nasir Khan,[2] Valerie Jorge Cabrera,[2] Neera K. Dahl.[1] *[1]Madison, CT; [2]Yale School of Medicine, New Haven, CT.*

Background: Non-tuberculous mycobacteria are a rare but serious cause of peritoneal dialysis-related peritonitis. *M.chelonae*, a member of the rapidly growing non-tuberculous mycobacteria (RGM) group, is an atypical organism mostly found in soil and water and known to cause skin and soft tissue infections. We present a case of *M.chelonae* infection manifested with chronic skin lesions and peritonitis in a diabetic peritoneal dialysis patient.

Methods: A 54 year old African American male developed 2 nodular lesions on the mid abdominal area. His past medical history included diabetes, hypertension and end-stage renal disease due to diabetic nephropathy. He had been started on peritoneal dialysis (PD) around 2 years ago. Over the course of 7 months these nodular skin lesions developed intermittent purulent discharge. Wound cultures, including fungal and acid-fast bacilli (AFB) cultures were repeatedly negative. Several days prior to admission, his peritoneal effluent became cloudy without any systemic symptoms. Two ulcerated nodules with purulent drainage were noted on the mid abdominal area. Peritoneal fluid cell count showed 4256 nucleated cells. Computed tomography (CT) of the abdomen confirmed the lesions to be interconnecting. A discrete 1.5 x 2.5 cm collection was also reported along the peritoneal catheter track. Four days later preliminary peritoneal fluid cultures revealed gram-positive acid fast bacilli, later identified as *M.chelonae*. The PD catheter was surgically removed and the patient was transitioned to hemodialysis. Deep wound cultures obtained in the operating room also confirmed the diagnosis. He was started on a 4-month course of Tigecycline and Amikacin based on culture sensitivities.

Results:

Conclusions: *M.chelonae* characteristically causes chronic nodular lesions with a purple discoloration. Very few cases of *M.chelonae* peritoneal dialysis-related peritonitis have been reported. Mainstay of treatment is removal of the source as well as antibiotics. A high level of suspicion for organisms such as fungi and non-tuberculous mycobacteria should be maintained in peritoneal dialysis patients with routine negative dialysate cultures who are unresponsive to standard empirical antibiotics.

SA-PO965

Peritonitis Following Fecal Microbiota Transplantation (*2) via Colonoscopy in a Peritoneal Dialysis Patient Shree R. Mulay, Sana Waheed. *University of Wisconsin, Madision, Madison, WI.*

Background: Fecal microbiota transplantation (FMT) is commonly utilized in the treatment of recurrent Clostridium difficile (C. diff) infection. However, there is no consensus on how best to manage these patients who are on peritoneal dialysis (PD) regarding administration of prophylactic antibiotics prior to FMT. We share our experience with one such case requiring an FMT who subsequently developed peritonitis.

Methods: A 50-year-old female on peritoneal dialysis for end stage renal disease secondary to ANCA vasculitis and recurrent C. diff infection was admitted with abdominal pain and severe diarrhea. She was found to have another C. diff infection and since she had already failed treatment with oral vancomycin and fidaxomicin a decision was made to proceed with FMT via colonoscopy. Given the concern that she may not have a successful FMT if given prophylactic antibiotics, she was not given any antimicrobial prophylaxis and all antibiotics were held 48 hours prior to the procedure. She resumed peritoneal dialysis after the procedure and her fluid remained clear. However, 2 days later her diarrhea and abdominal pain recurred. She had an extensive GI work up and no alternative explanation could be found for her abdominal pain and her C. diff remained positive. She underwent another FMT considering the fact that there could be a 5-10% failure rate with the procedure. Again, she was not given prophylactic antibiotics. Her PD fluid turned cloudy the next day and she had low grade fever and her PD fluid cell count showed a total of 404 nucleated cells with 29% polymorphic neutrophils. Her PD culture grew Enterococcus faecalis and she was treated with intraperitoneal daptomycin daily for a total of 3 weeks. Her abdominal pain and diarrhea have not recurred since the second FMT.

Results:

Conclusions: FMT can be used to successfully treat patients on peritoneal dialysis with recurrent C. diff. However, our patient developed peritonitis as a result of the procedure which can be a risk if prophylactic antibiotics are not administered. We suspect she developed peritonitis from the second FMT because it was associated with a more thorough diagnostic (exploratory) colonoscopy. We recommend that the risk of peritonitis be discussed in detail with patients who are on peritoneal dialysis undergoing FMT.

SA-PO966

Klebsiella pneumonia Renal Abscess and Peritonitis in a Peritoneal Dialysis Patient: A Novel Route of Infection Miten Dhruve,[2] Joanne M. Bargman.[1] [1]*Toronto General Hospital, Toronto, ON, Canada;* [2]*Nephrology, University Health Network, Toronto, ON, Canada.*

Background: We present a route of bacterial translocation leading to peritoneal dialysis (PD) peritonitis never before reported in the literature.

Methods: A 60 year old patient with newly-diagnosed CKD of uncertain cause underwent a kidney biopsy inadvertently performed during an episode of Klebsiella urosepsis. The biopsy was consistent with advanced diabetic nephropathy and after appropriate education and preparation, a PD catheter was placed and training commenced. The patient presented soon thereafter with abdominal pain and cloudy effluent consistent with PD peritonitis. Imaging revealed a renal abscess at the biopsy site. Microbiology from the PD effluent and from needle drainage of the renal abscess were both positive for *Klebsiella pneumoniae*.

Results:

Conclusions: We propose that the PD peritonitis was the result of seeding of the peritoneal cavity across the retroperitoneum with bacteria from the renal abscess. Successful treatment was achieved through drainage of the abscess and intraperitoneal antibiotics. The patient's course is consistent with a novel route of bacterial entry into the peritoneal cavity culminating in PD peritonitis.

SA-PO967

Atypical Presentation of Acute Type A Aortic Dissection in a Peritoneal Dialysis Patient – A Case Report Waqas J. Siddiqui,[1] Muhammad Aslam,[2] Abu Bakar,[2] Hasan Arif,[1] Sandeep Aggarwal,[1] Ellie Kelepouris.[1] [1]*Division of Nephrology and Hypertension, Drexel University College of Medicine, Philadelphia, PA;* [2]*Dow University of Health Sciences, Karachi, Pakistan.*

Background: Clinical presentation in dialysis patients if often atypical. A commonly encountered clinical sign of dyspnea in dialysis patients is often secondary to fluid overload, but this generalization can often times lead to delay in diagnosis of important underlying causes. We present a case of acute aortic dissection (AoD) in a peritoneal dialysis (CCPD) patient with dyspnea refractory to fluid removal as the only presenting clinical symptom.

Methods: 53 year old man with a history of HIV, ESRD on CCPD awaiting renal transplant, hypertension, cardiomyopathy and recent culture negative peritonitis presented with 3 days of exertional dyspnea and orthopnea. He is compliant with his CCPD exchanges and medications, having recently started Furosemide 40 mg orally for better volume control. His vitals at presentation were: BP = 140/80 mmHg, heart rate = 100/minute (min), temperature = 98.0 °F orally, respiratory rate = 18/min and O_2 saturation on room air = 98%. His EKG showed prolonged QTc = 530 milliseconds. Remaining EKG and blood workup were unremarkable. Chest x-ray revealed mild congestion. The patient was misdiagnosed with fluid overload likely due to CCPD failure. Later he desaturated to 90% on room air requiring high flow O_2 at 6L/min. He was transferred to MICU and started on PD for 4 hours with Dianeal 4.25% solution resulting in net ultrafiltration of 1.2L. His SBP peaked at 158 mmHg. Next morning on cardiac auscultation, loud III/IV diastolic murmur was heard at a left parasternal border. Urgent echo and CT chest with contrast confirmed severe aortic regurgitation with Type-A AoD. An emergent surgical repair was done. Post operatively he received Continuous Veno-venous Hemodialysis, later on, transitioned to intermittent hemodialysis and subsequently discharged.

Results:

Conclusions: Acute AoD is a rare but potentially life-threatening vascular catastrophe with a high associated mortality. This case reminds us that dialysis patients can have an atypical presentation of acute AoD and should be considered if a patient is not improving with conventional treatment. Patients at risk of acute AoD include patients with T2DM, advanced age, atherosclerosis, high BUN, connective tissue diseases and uncontrolled hypertension.

SA-PO968

Successful Placement and Follow Up of ESRD Patient on Peritoneal Dialysis with an LVAD Valerie S. Barta, Kenar D. Jhaveri, Rimda Wanchoo. *Nephrology, Hofstra Northwell School of Medicine, GREAT NECK, NY.*

Background: Left ventricular assist devices(LVAD)s have been shown to improve cardiac function in patients with advanced congestive heart failure(CHF) that are refractory to medical therapy. LVADs are contraindicated in patients with end stage renal disease(ESRD) on hemodialysis(HD). Peritoneal dialysis(PD) is widely considered a contraindication as well, given the close proximity of the peritoneal catheter to the device as well as risk of systemic infections. We report a successful placement of LVAD in an ESRD patient on PD with short and long term follow up.

Methods: A 52 year old Caucasian male with ESRD secondary to chronic heart failure on PD for five years got evaluated for a heart-kidney transplantation. Due to the patient's worsening heart failure and significant symptom burden, he underwent LVAD (HeartWare) placement while continuing PD. He tolerated the procedure well and there were no infectious complications related to his PD catheter. Post LVAD follow up his PD prescription has not required adjustment and his mean arterial pressures(MAP) have remained > 60 mm hg. As blood pressure monitoring is not possible in LVAD patients, MAP values using arterial Doppler ultrasound are used to assess volume status. His fluid management was adjusted using these MAP values in combination with physical exam. Nine months following the LVAD, the patient remains stable on PD awaiting heart-kidney transplantation.

Results:

Conclusions: Our case highlights that PD can be safely performed in LVAD patients. There were no complications with volume management, interrupted LVAD function or peritonitis in our patient. PD should not be a contraindication for placement of LVADs. Additionally, it is our recommendation that in cases of acute kidney injury requiring initiation of dialysis post LVAD, the option of PD should be offered.

SA-PO969

Can Ferric Citrate Lead to Iron Overload in Peritoneal Dialysis Patients? Luke M. Basdeo, Maulik C. Govani, Nabeel Aslam. *Mayo Clinic Florida, Jacksonville, FL.*

Background: Ferric citrate (FC), a novel oral phosphorus binder, is FDA approved for treatment of hyperphosphatemia in patients receiving dialysis. FC binds to dietary phosphate in GI tract producing ferric phosphate and is excreted in feces. However, small quantity of iron is systemically absorbed. There is limited data about the safety of ferric citrate among peritoneal dialysis (PD) patients. Iron overload with FC in PD patients has not been previously reported. We present a series of three PD patients who developed iron overload while receiving FC.

Methods: Patient 1- 65-years old man with ESRD due to IgA nephropathy, status post failed kidney transplant, on CCPD for 3 years with adequate clearance, started on ferric citrate in 1/2016, dose adjusted to 3 tablets tid with meals and 1 with snack; max total dose of 11 tablets/day resulting in acceptable phosphorus control. No IV iron or transfusion during subsequent 12 months. Iron studies summarized in table. FC discontinued at 12 months. Hematology work up consistent with acquired hemosiderosis. **Patient 2**-51-years old woman with ESRD due to systemic sclerosis, on CCPD for 7 years with good clearance, started on ferric citrate in 1/2016, dose titrated up to maximum of 12 tabs/day with good phosphorus control. No IV iron or blood transfusion during the subsequent 12 months. Iron studies summarized in table. FC discontinued at 12 months. **Patient 3**-72-years old man with ESRD due to AL amyloidosis, on CCPD for 1.5 years with adequate clearance, started on ferric citrate in 10/2016, dose titrated up to max of 11 tab/day with acceptable phos control. No IV iron or transfusion after FC initiation. Iron studies summarized in table. FC discontinued at 6 months

Results:

Conclusions: PD patients may be more prone to developing iron overload with the use of ferric citrate. This may be due to less iron loses in PD patients as compared to HD patients. These cases highlight the importance of close monitoring of iron studies in PD patients while receiving ferric citrate as phosphate binder. Further studies are needed to assess the safety of maximum approved dose of ferric citrate among PD patients.

HbA1c Underestimated Glucose Level in Diabetic PD Patients Compared to Normal Kidney Function Diabetic Patients Hua Zheng. *Peking Union Medical College, Beijing, China.*

Background: HbA1C is widely used as glycemic marker for general DM patients. However, its accuracy has been questioned in ESRD patients for potential effect of renal anemia, EPO usage and uremia on glycation physiology. Most research relevant to the topic was done in hemodialysis. Yet, reports on whether HbA1C underestimated glucose level in PD patients were contradictory. This research aimed to compare HbA1C value adjusted with mean glucose in PD DM and DM patients with normal kidney function (NKF) and the potential cause of the difference.

Methods: Twenty DM PD patients were enrolled in this single-centered prospective research for 72-hour Continuous Glucose Monitoring (CGM). PD patients were matched with twenty DM NKF patients based on 72-hour mean glucose (MG), age and gender who underwent CGM during the same period.

Results: One PD patient was discarded for incomplete data. No significant gender and age difference was detected between PD and NKF patients. For PD patients, mean EPO dose for previous three months was 8002 IU per week. Mean Hgb was 106.8g/L. PD and NKF patients had negligible MG (8.8±1.9 vs 8.7±1.7 mmol/L, p=0.868) with significantly different HbA1C value (6.17%±0.87% vs 6.93%±1.02%, p=0.043). PD patients also had worse linear correlation than NKF patients. Significant different regression formula was found between PD and NKF patients (p for intercept=0.02). PD patients had 0.79% lowered absolute value than NKF patients for HbA1C (6.15% vs 6.94%, $p < 0.001$) at pooled mean MG (8.74mmol/L). Further analysis on regression residuals or residuals over estimated HbA1C found that this difference could not be explained by EPO dose (p=0.733), hemoglobin (p=0.727), urea (p=0.934), creatinine (p=0.648), albumin (p=0.582), residual GFR (p=0.767) or nPCR (p=0.408).

Conclusions: HbA1C significantly underestimated glucose level in diabetic PD patients compared to normal kidney function diabetic patients. The difference might not be simply explained by hemoglobin, EPO injection dose, uremia, residual GFR, albumin, or nPCR.

Hematuria in a Chronic Hemodialysis Patient Anuradha Konkesa,[3] Srikanth Thiruvarudsothy,[4] Neeraj Sharma,[7] Aravindan V. Jeyarajasingam,[1] Sushma Munugoti,[6] Alluru S. Reddi,[5] Farah Piracha.[2] *[1]Swedesboro, NJ; [2]Rutgers NJ Medical School, Staten Island, NY; [3]Rutgers, Morrisplains, NJ; [4]Rutgers NJMS, Belleville, NJ; [5]Rutgers New Jersey Medical School, Newark, NJ; [6]Rutgers UNIVERSITY, Montclair, NJ; [7]Rutgers University, Bloomfield, NJ.*

Background: Spontaneous gross hematuria in a chronic hemodialysis patient is an uncommon finding which can be a consequence of renal cyst rupture, renal cell carcinoma, angiomyolipoma, stones, or vascular diseases. We recently treated a patient on chronic hemodialysis for spontaneous gross hematuria who was found to have renal cysts and renal cell carcinoma.

Methods: A 47-year-old African American man with past medical history of AIDS, hypertension, and ESRD on HD due to HIVAN since 2002 was evaluated for gross hematuria (1 to 2 ml). Hematuria was not associated with flank pain, weight loss, dysuria, or trauma. A CT scan of the abdomen and Pelvis with contrast showed a 6.3x6.2x5.1 cm mass in the mid to upper pole of right Kidney. There were bilateral renal cysts and both kidneys were atrophic. He underwent a right laparoscopic nephrectomy. Histology revealed clear cell renal carcinoma.

Results:

Conclusions: Acquired cystic kidney disease (ACKD) is recognized as a disease of consequence affecting patients on long-term hemodialysis (≥3 years), and the prevalence of ACKD increases linearly with duration of dialysis. Approximately 1- 4% of patients with ACKD develop renal cell carcinoma (RCC), and the development of cysts and their degeneration into carcinoma is poorly understood. The range of patients affected by ACKD-RCC is very narrow. Compared to the general population, the risk of developing RCC in ACKD is increased by more than 100-fold. In general, RCC associated with ACKD is considered to be less aggressive than sporadically occurring RCC. A CT scan should be performed to rule out other causes of spontaneous renal rupture. Recommendation to screen patients with ESRD for ACKD and renal cell cancer has not been uniform because of their limited life expectancy; however we believe screening will be valuable for patients in good general health with a good life expectancy.

SA-PO972

Successful Fecal Microbiota Transplant in an ESRD Patient Jeffy Kenny Thomas,[2] Jason Cobb,[2] Jung W. Suh.[1] *[1]Atlanta Gastroenterology Associates, Atalnta, GA; [2]Emory University School of Medicine, Atlanta, GA.*

Background: The incidence of clostridium difficile (c. difficile) colitis is increasing and there are reports of 10-25% of patients treated with medical therapy (metronidazole or vancomycin) having relapse of colitis despite medical therapy. A treatment option in these refractory or recurring c. difficile colitis cases is fecal microbiota transplant (FMT). There is a paucity of data of c. difficile colitis in patients with kidney disease. We present a case of an ESRD patient with refractory c. difficile colitis that underwent a successful FMT.

Methods:

Results: 60 year-old African-American female with ESRD requiring hemodialysis for 3 years. Her ESRD is due to diabetic nephropathy. She was admitted to an outside hospital in March 2017 for coronary artery disease and atrial fibrillation, and was transferred to our hospital for further cardiac care. She received intravenous antibiotics at the outside hospital for 1 day. Upon presentation to our hospital, she had severe diarrhea which required the placement of a fecal management system. Her stool was positive for c. difficile and due to the severity of her disease oral vancomycin was initiated. Despite treatment for 12 days with oral vancomycin, intravenous metronidazole was added. She continued to have persisting diarrhea despite treatment. She received bezlotoxumab (human monoclonal antibody for the treatment of c. difficile infections) but continued to have severe watery diarrhea. Gastroenterology was consulted and a decision was made to perform a FMT. The patient received a FMT on April 14th and April 25th, 2017. It was performed per colonoscope with 60 ml syringes of fecal material being injected in the terminal ilium and cecum for a total of 240 ml each time. At the time of discharge (14 days after initial FMT) the patient was off antibiotics, off probiotics, and having only one semi-formed stool each day.

Conclusions: This is the first case of an ESRD patient undergoing a FMT and shows that it is a safe treatment option in ESRD patients with refractory or relapsing c. difficile colitis.

SA-PO973

Clinical Picture: Central Venous Catheter-Related Occlusive Disease Jin Wen,[1,3] Yang Yu,[2] Tianlei Cui.[2] *[1]Nephrology and Rheumatology Department, Yongchuan Hospital of Chongqing Medical University, Chongqing, China; [2]Nephrology Department, West China Hospital & Sichuan University, Chengdu, China; [3]Nephrology Department, West China Hospital & Sichuan University, Chengdu, China.*

Background: The central venous catheter (CVC)-related occlusive disease is a major and serious complication of central venous cannulation, posing a huge challenge to end-stage renal disease (ESRD) patients, especially for the growing group of hemodialysis patients when CVC becomes the only available form of access. Herein, we report a successful case of multiple central venous occlusion and thrombosis by percutaneous superior vena cava (SVC) cannulation technique under cross-located fluoroscopy.

Methods: A 50-year-old male with ESRD for 7 years presented with 3 weeks of hemodialysis catheter dysfunction. Before transferred to our hospital, he had undergone a maintenance hemodialysis via a tunneled right femoral vein catheter for 6 months, when other possible vascular accesses had been tried but failed, unfortunately. Physical examination showed collateral tortuous veins in the right chest wall. CT venography of the chest demonstrated chronic occlusion of the entire right brachiocephalic vein (BCV), left BCV and the distal end of SVC. Meanwhile, venography revealed inferior vena cava (IVC) long segment total occlusion with thrombosis (Fig1). Under this situation, we successfully implanted a new tunneled catheter by percutaneous SVC cannulation technique under cross-located fluoroscopy (Fig2), and then removed the previous malfunctioned catheter. The patient discharged 2 days after the new functional catheter establishment.

Results:

Conclusions: The CVC-related occlusive disease is usually so troublesome that leads to increasing mortality of ESRD patients, especially for those who suffer from exhausting hemodialysis vascular access. Although many patients are asymptomatic, some can present with symptoms of venous hypertension, such as edema of upper extremity and collaterals of the chest or abdominal wall, which require our more attention and supervision. However, it remains challenging to deal with such severe CVC-related occlusion when almost all the principal venous are occlusive. Notably, we implanted a new tunneled catheter by percutaneous SVC cannulation technique under cross-located fluoroscopy. Our successful case manifests that this technique may light a new lamp in combating the CVC-related occlusive disease.

SA-PO974

Long-Term Clinical Spectrum and Circulating RAS Evaluation of Anephric Patients on Hemodialysis: A Series of 4 Cases and Literature Review Lin Liu,[2] Yumei Zhang,[1] Fangting Fu,[2] Wenge Li.[1] *[1]China-Japan Friendship Hospital, Beijing, China; [2]Department of Nephrology, China-Japan Friendship Hospital, Beijing, China.*

Background: Blood pressure decline is one of the short-term complications of bilateral nephrectomy mainly due to sharp change of circulating renin-angiotensin system (RAS), but data about long-term outcome of clinical status and the development of circulating RAS of these patients is limited.

Methods: We enrolled 4 Chinese cases with both their kidneys removed for 2, 6, 8 and 8 years, respectively, from 304 patients on maintenance hemodialysis in December 2016 in our center. The blood samples for RAS tests were drawn after the subjects seated for 30 minutes immediately before hemodialysis was started. Radioimmunoassay was performed to assess their circulating RAS. Their ages ranged from 49 to 80, and 3 out of 4 were female. The reasons of nephrectomy included polycystic kidney disease (n=1), cancer (n=2), and hydronephrosis (n=1). Hypotension after surgery occurred in 2 patients, and mostly happened during dialysis. They suffered embolism of arteriovenous fistula, but not any life-threatening complications happened. At present, the SBPs in 24 hours of the 4 subjects were all above 90mmHg,and the lowest SBP of 90mmHg and DBP of 46mmHg occurred during dialysis and at midnight, respectively. Only one patient developed severe hypertension again since 4 years after surgery, whose BP now was not well-controlled despite 6 kinds of antihypertensive drugs including ACEI and ARB. The average hemoglobin level was 103.3±12.3g/L. Two of them complicated with hemorrhage of digestive tract, resulting in the need of high erythropoietin (EPO) dosages. The other two patients without hemorrhage received intravenous EPO of only 4500-8000iu/week. The 3 patients receiving blood tests all presented with extremely low plasma renin activity (PRA) of 0.08±0.03ng/ml, compared with normal range of 0.93-6.56ng/ml. Surprisingly, plasma Angǁ concentration of 71.37±8.28 pg/ml and aldosterone level of 0.17±0.02 ng/ml were within normal limits.

Results:

Conclusions: In conclusion, in 2 to 8 years after surgery, the 4 anephric cases did not suffer life-threatening complications with their hypotension gradually recovered and EPO dosage relatively small. Although their PRA was extremely low, they produced normal Angǁ and aldosterone in plasma, indicating the kidney-independent mechanism of Angǁ production compensated well in 2 years after removement of kidneys.

SA-PO975

Acute Pancreatitis Related to Hemolysis During Hemodialysis Due to Defective or Kinked Blood Tubing Muataz Yaziji, Sobia N. Khan, Leonard A. Arbeit, Kyung Ho Kim, Nand K. Wadhwa. *Stony Brook Medicine/University Hospital, Stony Brook, NY.*

Background: Hemolysis during hemodialysis (HD) may be related to dialysate, extracorporeal circuit or patients' disease. Extracorporeal hemolysis may result from blood pump occlusion, miss-size needle and partial occlusion of catheter in relation to high BFR, and kinked or faulty tubing. We report a case with massive hemolysis during HD related to faulty or kinked blood tubing presenting as acute pancreatitis.

Methods: A 32-year-old man with ESRD due to obstructive uropathy has been on HD since 2014. On his HD day, he started HD at 5:37 AM at BFR 400 ml/min with a 14 gauze needle using right brachiocephalic AV fistula. At 6:08 AM, arterial pressure increased from -80 to -10 mmHg and venous pressure dropped from 170 to 50 mmHg at a BFR of 360 ml/min. He continued HD until 6:43 AM with repeated alarms. He was moved to another HD machine and completed HD for 3.45 hrs with no issues. He presented to ER the next morning with gradual, progressive worsening abdominal and back pain, nausea and vomiting since HD yesterday. On departure, the patient felt well but staff noted that his color had changed to dark red. On way home, he began to feel unwell and progressed until presented to the ER where labs were repeatedly reported hemolyzed. Physical exam: Alert and oriented, BP 122/88 mmHg, HR 98 bpm, RR 18/min, Temp 36.7°c. He was jaundiced with a soft abdomen and mild tenderness. Rest of the exam was normal. Lab data: WBC 6.78 K/uL, Hgb 7.7 g/dl (10.5 g/dL on 2 week prior), hcts 21.6%, platelets 138 K/UL with no schistocytes, Na 135 mmol/L, K 4.3 mmol/L, BUN 69 mg/dL, Cr 9.5 mg/dL, amylase 525 IU/L, lipase 1260 IU/L, T Bili 2.4 mg/dL, D Bili 0.4 mg/dL, LDH 2300 IU/L, haptoglobin 10.3 mg/dl and negative Coombs test. MRI abdomen: Dilated common bile duct with no luminal defect. HIDA Scan: No acute cholecystitis. He received 1 unit of PRBC during HD the next day. He continued to improve in the hospital. He was discharged home on third day to outpatient HD with no further issues.

Results:

Conclusions: Our patient developed severe mechanical hemolysis during HD likely related to blood tubing in view of temporal relation to out-patient HD with repeated alarms. This was supported by a sudden change in his skin color to dark red after HD. His abdominal and back pain were due to acute pancreatitis likely related to toxic effect of free hemoglobin in his blood.

SA-PO976

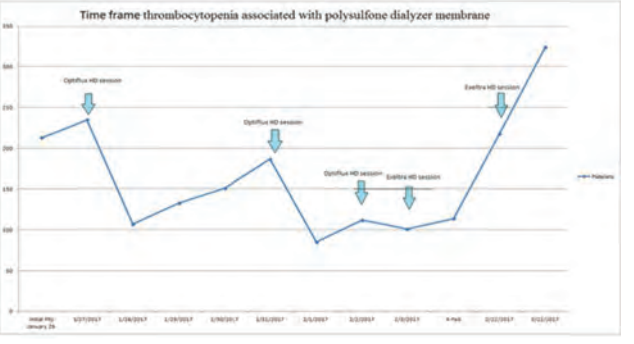
Thrombocytopenia Associated with Polysulfone Dialyzer Membrane Massini Merzkani,[1] Nishita Parikh,[1] Kenar D. Jhaveri.[2] *[1]Northwell Health, New Hyde Park, NY; [2]Hofstra Northwell School of Medicine- Northwell health system, Great Neck, NY.*

Background: Heparin and other drug induced thrombocytopenia are the most common cause of thrombocytopenia in patients with end stage renal disease (ESRD). Dialysis membrane associated thrombocytopenia is extremely rare.

Methods: A 44 year old male with history of ESRD on hemodialysis (HD) was admitted for presumed tunneled HD catheter infection. Over 2 days, the patient grew pseudomonas aeruginosa at the exit site and received piperacilin-tazobactam, vancomycin and eventually cefepime followed by catheter removal. Prior to the first treatment of heparin freeHD (Optiflux 180) on the 1/27/2017 the platelets were $235x10^3/\mu L$. The day after platelets drop $107x10^3/\mu L$. Prior the second HD session (Optiflux 180) was on 1/31/2017, the serum platelets were $187x10^3/\mu L$. The day after HD, the serum platelets dropped to $85x10^3/\mu L$. A presumption of heparin induced antibody was made due to prior use of heparin for deep venous thrombosis prophylaxis and argatroban drip was commenced. Serum heparin induced thrombocytopenia antibodies and serotonin release assay were negative and argotroban was discontinued. Patient was having hemodialysis in the hospital with a dialyzer Polysulfone based (Optiflux 180). Assuming the thrombocytopenia was related to the polysulfone dialyzer given the see-saw effect noted pre and post dialysis (Figure), dialysis was changed to a cellulose base dialyzer (Exeltra 210). Thrombocytopenia resolved as a result of this switch. Following this, the platelets remained to improved and continued in the normal range.

Results:

Conclusions: There have been rare reports of thrombocytopenia associated with dialyzer membranes. As per literature review one of the causes for thrombocytopenic effect of the polysulfone dialyzers is the use of electron beam sterilization. The electron beam modifies the property of polysulfone membranes, increasing their hydrophilicity. Given only monthly blood draws, this entity might not be evident or perhaps, overlooked in the outpatient ESRD units. Our case highlights an important under-recognized cause of asymptomatic thrombocytopenia in the HD patient.



SA-PO977

Dialysis Related Pacemaker Failure Chinonye C. Ogbonnaya-Odor,[3] Dia R. Waguespack,[1] Ali Ziaolhagh.[2] *[1]UTHealth, Houston, TX; [2]University of Texas, Housotn, TX; [3]University of Texas Houston, Houston, TX.*

Background: Dialysis is used in the treatment of electrolyte disorders. Electronic pacemakers are used in the management of arrhythmia's. Failure to capture is a term describing electronic pacemaker pacing, without desired cardiac response. We present a case of unstable bradyarrhythmia due to pacemaker failure to capture, resulting from transient electrolyte changes during hemodialysis.

Methods: An 87-year-old man with CKD III, bradycardia requiring pacemaker placement, and severe hypercalcemia related to left parathyroid adenoma, presented with altered mental status, constipation, and acute kidney injury. He was treated with calcitonin, crystalloids, cinacalcet and hemodialysis. On day 7 parathyroidectomy was performed. Post-surgery, Intact parathyroid (iPTH) trended down rapidly, ionized (iCa) levels gradually decreased, but Creatinine (Scr) increased, and patient became anuric. Labs showed Sodium (Na): 139 mEq/L Potassium (K): 3.9 meq/L Chloride (Cl):102, Bicarbonate (CO2): 21 q/L, iCa of 1.50 mmol/L, Magnesium (Mg):2.4 Mg/dL, Phosphorus: 4.1 Mg/dL. Hemodialysis (HD) was performed with dialysate containing Na: 140 Meq, K: 2.0 Meq, Ca: 1.5 mEq, CO2: 35 mEq. Vitals were stable. After 2 hours of dialysis, patients' heart rate decreased to 20-30 bpm, pacemaker failure to capture was noted on telemetry. Blood pressure (BP) decreased to 75/54, and he became less responsive. HD was discontinued. He was treated with intravenous albumin, crystalloid bolus and atropine with poor response in BP and HR. Transcutaneous pacing was initiated, with appropriate response. Labs revealed iCa: 1.20 mmol/L, K: 3.1 mEq/L, Mg: 1.1 mEq/L, hematocrit: 27%, glucose of 127mg/dL. Pacemaker was interrogated. Findings revealed an acute increase in cardiac pacing threshold during event, which normalized within the next 2 hours. Mg was replaced with intravenous magnesium sulfate.

Results:

Conclusions: Hypocalcemia affects cardiac conduction by increasing phase 2 of cardiac repolarization. The effects are bradycardia and prolonged QTc. Hypomagnesemia can produce similar effects. In this patient, electrolyte flux during dialysis led to pacemaker malfunction. Appropriate treatment for this patient included electrolyte

replacement and changing pacemaker to asynchronous pacing, by placing a magnet on the pacemaker engine.

SA-PO978

Utility of Lung Ultrasound B-Lines in Volume Assessment of ESRD Patients on Hemodialysis Muhammad O. Saleem, Jung Hee Chae, Ahmad A. Kabbani, Jennifer L. Waller, John J. White, N. Stanley Nahman. *Augusta University, Medical College of Georgia, Augusta, GA.*

Background: Volume assessment in end stage renal disease (ESRD) patients on hemodialysis (HD) can be sometimes challenging. Lung ultrasound to look for B-lines, which indicate interstitial edema, is an emerging tool in assessing bedside volume status, and may assist in setting ultrafiltration (UF) goals for dialysis. We performed a quality assurance project to assess the utility of lung ultrasound in determining UF goals.

Methods: ESRD patients were studied before and after HD. Clinical parameters of volume status including systolic blood pressure (SBP) and presence of edema were recorded pre-dialysis, and target UF was set accordingly. We counted the number of B-lines pre and post HD using two portable ultrasound machines, GE V-scan and GE Sonosite. For each patient, the ultrasound probe was placed at the same mid-axillary or mid-clavicular intercostal space to visualize B-lines pre and post HD. Linear regression or ANOVA was used to examine the association between the number of B-lines and fluid removed by UF.

Results: 24 ESRD patients were studied for the number of lung B-lines pre and post HD. B-lines were categorized as 0, 1-2, and 3 or more. For all patients, UF removed trended with the number of B-lines, but there was no significant association. There was a non-significant decrease in the number of B-lines with UF from 3.4±2.1 to 0.7±1.0 (p=0.53). Patients with ≥3 B-lines tended to get more volume removal with mean UF volume of 2.4±0.9L. Mean UF removal in patients with 1-2 B-lines was 1.3±0.9L, and with 0 B-lines was 1.4±0.6L. Interestingly, four patients who did not have any B-lines could not tolerate target UF set pre-HD on the basis of SBP and edema.

Conclusions: Lung ultrasound may be a useful tool for bedside volume assessment of hemodialysis patients and help in deciding UF goals to achieve dry weight. Our pilot project shows a trend that higher number of B-lines may correlate with higher UF tolerance but the data is non-significant. A larger sample size and more sophisticated portable ultrasound machines may give a better idea of any association between B-lines and the determination of UF goals in HD.

SA-PO979

Myoclonus and Altered Mental Status Due to Gabapentin Neurotoxicity in a Patient with Acute on CKD Margaret Ivanov, Ummerubab Syeda, Rakesh Gulati. *Thomas Jefferson University Hospital, Philadelphia, PA.*

Background: Gabapentin neurotoxicity in patients with renal dysfunction continues to be underrecognized in clinical practice, and has been found to be initially suspected in fewer than half of all presenting cases[1].

Methods: A 72-year-old male with a medical history significant for chronic kidney disease stage 4 and non-insulin dependent diabetes mellitus type 2 with severe diabetic polyneuropathy, was admitted to the hospital with septic shock from a urinary tract infection and cellulitis, and acute kidney injury (creatinine 4.2 mg/dL, baseline 1.8 mg/dL). On hospital day 7 despite improvement in his overall condition from a hemodynamic and infectious standpoint, the patient developed agitation and confusion, and was noted on exam to have asterixis and multifocal myoclonus. Of note, his renal function had been steadily declining throughout the hospitalization, with labwork at the time of his deterioration notable for BUN 98 mg/dL, SCr 5.4 mg/dL, and GFR 10 mL/min/1.73m^2. The Nephrology service was consulted with concern for uremic encephalopathy. In reviewing the chart, it was noted the patient had been receiving gabapentin 600mg daily throughout the hospitalization. Although the dose had been reduced from 600mg t.i.d. on admission, it was inappropriately high for his creatinine clearance at the time of his deterioration, and he was found to have a serum gabapentin level of 45.8 mcg/mL (reference range 4.0-8.5 mcg/mL). The patient was started on continuous venovenous hemodialysis filtration with improvement in his mental status and myoclonus by the following morning, and complete resolution of symptoms after 48 hours on CVVHD, with a repeat gabapentin level of 8.6 mcg/mL.

Results:

Conclusions: Due to the occurrence of mental status changes and myoclonus in uremia, the role of neurotoxic medications in patients with renal dysfunction may be overlooked. This case adds to the recent growing body of literature recognizing signs of gabapentin neurotoxicity, and underscores the importance of attentive prescribing of renally cleared medications in patients with fluctuating renal function. [1]Zand L, McKian KP, Qian Q. Gabapentin toxicity in patients with chronic kidney disease: A preventable cause of morbidity. American Journal of Medicine 2010;123:367-373

SA-PO980

Gabapentin Toxicity in a Patient with AKI Lukasz Kiljanek, Al J. Lee, Hasan Arif, Sandeep Aggarwal, Rebecca K. Seshasai. *Drexel University College of Medicine, Philadelphia, PA.*

Background: Gabapentin is a commonly used therapy for the treatment of chronic and neuropathic pain and requires dose adjustment in patients with renal insufficiency. Its toxicity can present as myoclonus and can be managed with hemodialysis.

Methods: 81 year old woman with CKD, baseline creatinine one week prior to admission of 2.4 mg/dl, also hypertension, type 2 diabetes and congestive heart failure admitted after a fall to the trauma service. The patient reports that she fell due to "body jerks" causing loss of balance. As per protocol, she received CT scans with intravenous contrast to rule out acute trauma, all were negative. Creatinine on admission 4.24 mg/dl and rose to 7.27 mg/dl on day 4, at time of nephrology consultation. Patient hemodynamically stable, no episodes of hypotension. On exam she had what appeared almost like dyskinesia, unable to hold her arms, legs or torso steady, as well as myoclonus although mental status was intact. She was diagnosed with contrast induced nephropathy. BMP showed sodium 132 mmol/l, potassium 5.4 mmol/l, bicarbonate 22 mmol/l, glucose 44 mg/dl. Urinalysis unremarkable. She was making < 500 cc urine/day. Renal ultrasound unremarkable. Medication list notable for gabapentin 2200 mg daily, furosemide and losartan. Serum gabapentin level 78 mcg/ml (reference 4-16 mcg/ml). Gabapentin, furosemide, losartan all discontinued. She received two sessions of hemodialysis with full resolution of body movements and myoclonus and recovered from her AKI with a discharge creatinine of 3.09.

Results:

Conclusions: Gabapentin, a 3-cyclohexyl-GABA, is an analogue of GABA able to activate its receptors. Hypoglycemia, myoclonus, and altered mental status have been previously reported as symptoms of gabapentin toxicity. This drug can easily accumulate in patients with impaired renal function. In patients with ESRD on non-HD days elimination half-life of gabapentin is 132 hours, while in the general population it is 5-7 hours. Levels of above 15 μg/mL are considered toxic. Gabapentin can be effectively cleared by hemodialysis. Given its relatively frequent use in patients with renal insufficiency, it is important to remain mindful of potential gabapentin toxicity in patients with neurological symptoms.

SA-PO981

Acquired Erythropoietin (EPO) Deficiency Following Microwave Ablation of Papillary Renal Cell Carcinoma in a Renal Transplant Myriam C. Vela-Ortiz,[2] Joseph H. Brezin,[1] Brian A. Bianco.[3] *[1]Clinical Nephrology VA Associates, LTD, Philadelphia, PA; [2]Drexel University, Philadelphia, PA; [3]Hahnemann University Hospital, Drexel University College of Medicine, Philadelphia, PA.*

Background: Percutaneous microwave ablation of renal malignancies is a novel nephron sparing option for patients who are poor candidates for surgical resection. We present the development of acquired EPO deficiency following microwave ablation of papillary renal cell cancer in a renal allograft.

Methods: A 48-year-old Caucasian female with a PMH of acute post streptococcal glomerulonephritis developed progressive CKD over the next 8 years. She was dependent on recombinant EPO for anemia of CKD for one year prior to renal transplantation in 1995. She received an HLA identical renal transplant from her brother. Her hemoglobin over the next 21 years was normal (12.5-14 gm/dL) without further EPO. The patient was maintained on immunosuppression with cyclosporine, mycophenolate mofetil, and prednisone. Her serum creatinine was 1.5 to 1.7 mg/dl in the first half of 2016. During a work up for resistant hypertension, a 2 x 1.6 cm contrast enhancing mass was found in the lower pole of her kidney transplant. Needle biopsy revealed a low grade papillary renal cell carcinoma. The lesion was treated with microwave ablation as renal sparing therapy. Concurrently the patient was found to have a 7 cm mass of the left native kidney that was treated with laparoscopic radical nephrectomy, also a papillary renal cell carcinoma. Imaging studies 6 months later showed a defect in the lower pole of the renal allograft with no blood flow or contrast enhancement. She developed a normocytic anemia with normal iron studies over the next 3 months and was hospitalized for symptomatic anemia: hemoglobin 6.9 g/dL, WBC 7.3 mm3, platelet count 252, and reticulocyte count 1.4 %. The EPO level was exceedingly low at 7 mlU/L. The bone marrow was hypo cellular on biopsy. She was treated with a blood transfusion followed by judicious recombinant EPO supplementation to avoid further transfusions. Her current hemoglobin is 9.5 gm/dL and her serum creatinine is 1.97 mg/dL.

Results:

Conclusions: Herein we present the case of a patient with papillary renal cell carcinoma of her renal transplant that was successfully treated with microwave ablation. However, she subsequently developed EPO deficiency with severe anemia. We suggest that this may represent a heat related injury to a single functioning kidney that attenuated the production of erythropoietin.

SA-PO1000

Warburg Effect – Unusual Cause of Lactic Acidosis in Cancer Patients Nasir Khan,[1] Lloyd G. Cantley.[2] *[1]Yale School of Medicine, New Haven, CT; [2]Yale University School of Medicine, New Haven, CT.*

Background: Lactic acidosis is the most common cause of anion gap metabolic acidosis in critically ill patients and is associated with significant mortality. While most cases of severe lactic acidosis are from either decreased tissue perfusion or oxygenation (type-A lactic acidosis), other causes should be considered in the differential diagnosis, especially in cancer patients. We present a case of repeated episodes of lactic acidosis, first from tumor lysis syndrome (TLS) and then from anaerobic tumor metabolism in a critically ill patient with Non-Hodgkin Lymphoma (NHL).

Methods: A 75 year old woman with widespread Diffuse Large B-Cell Lymphoma diagnosed three years previously, complicated by severe TLS during induction chemotherapy requiring renal replacement therapy in the past, was admitted with severe metabolic acidemia from lactic acidosis (serum lactate peaked at 30 mmol/L) in the setting of another severe TLS episode triggered by ibrutinib chemotherapy. She was treated with rasburicase and intravenous fluids as well as temporary renal replacement therapy. Her clinical and laboratory parameters improved quickly with resolution of her

lactic acidosis, and she was taken off of renal replacement therapy with return of her renal function to normal. One week later she developed persistent hypoglycemia (glucose values in the 50 mg/dl range despite D10W infusion) followed rapidly by severe lactic acidosis with arterial pH below 7 and serum lactate peak of 29 mmol/L. She remained hemodynamically stable with normal liver and renal function, and her labs did not support TLS: her LDH was only moderately elevated, with normal serum uric acid, calcium and phosphate. Based on her lab findings of persistent hypoglycemia as well as severe lactic acidosis, and CT scan showing progression of her lymphoma, we attributed her lactic acidosis to anaerobic metabolism by her rapidly growing tumor.

Results:

Conclusions: The Warburg Effect, described by Dr *Otto Heinrich Warburg* in 1924, is the metabolic shift of malignant cells to anaerobic glycolysis for ATP production, especially during phases of rapid tumor growth. The resultant inefficient utilization of glucose and generation of large amounts of lactate can lead to clinically significant hypoglycemia and severe lactic acidosis.

SA-PO1001

An Atypical Presentation of Gitelman's Syndrome: Unmasking with Vomiting and Diarrhea

Eric Chang, Jeffrey M. Turner. *Yale University, New Haven, CT.*

Background: Hypokalemia is frequently encountered in the daily practice of nephrology. There are a variety of reasons for hypokalemia, commonly hypomagnesemia, diarrhea or diuretics. Genetic entities such as a salt-wasting tubulopathy like Gitelman syndrome, are rarer etiologies. We report a case of Gitelman syndrome unmasked by vomiting and diarrhea from small bowel overgrowth syndrome.

Methods: A 22-year-old male was referred for persistent severe hypokalemia and hypomagnesemia. He presented with the following electrolyte levels: potassium 2.4-3.4 mmol/L, magnesium 1.2-1.4 mmol/L, and calcium 10.5-10.7 mmol/L. His hypokalemia was noted to occur after acute onset of nausea, vomiting, and diarrhea. His electrolyte abnormalities persisted despite oral potassium and magnesium repletion as well as treatment of small bowel overgrowth syndrome with improved gastrointestinal symptoms. After obtaining additional historical labs, it was noted that he had mild to moderate hypokalemia dating back years prior to his onset of nausea, vomiting, and diarrhea. Our workup revealed a potassium fractional excretion of 11%, magnesium fractional excretion of 7%, aldosterone level of 4, plasma renin activity level of 11.9 (aldo/PRA 0.33). Genetics panel demonstrated compound heterozygous mutations in the SLC12A3 gene. He is now maintained on high dose oral potassium and magnesium supplementation daily with weekly intravenous infusions as well. Adjunctive therapy has been intermittently tolerated due to perceived worsening of his gastrointestinal symptoms. This has included a potassium sparing diuretic, angiotensin receptor blocker, mineralocorticoid receptor antagonist, and NSAIDs.

Results:

Conclusions: Gitelman syndrome is a rare autosomal recessive disorder afflicting 1:40,000 people. Specifically, mutations in the SLC12A3 lead to defective NCC channels in the distal tubules, creating a thiazide-like effect leading to hypokalemia and hypomagnesemia. This case presented a diagnostic challenge as his electrolyte abnormalities initially presented in the setting of severe gastrointestinal illness, which were thought to be the source of his potassium and magnesium losses. This case highlights the critical role of routinely screening for renal wasting of electrolytes even when alternative causes are present.

SA-PO1002

Severe Metabolic Alkalosis After Cystogastrostomy in a Patient with Chronic Necrotizing Pancreatitis

Janewit Wongboonsin,[1,2] Sarah L. Elfering.[1] *[1]Medicine, University of Minnesota, Minneapolis, MN; [2]Medicine, Siriraj Hospital, Mahidol University, Bangkok, Thailand.*

Background: Hospital acquired metabolic alkalosis occurs in the setting of diuresis or other volume depleting conditions. Correction of volume depletion, hypochloremia and hypokalemia results in resolution of alkalosis. We present a case of severe metabolic alkalosis that was an unexpected complication of cystogastrostomy, a common procedure utilized in chronic pancreatitis.

Methods: A 68 year old man was hospitalized for chronic necrotizing pancreatitis managed with abscess drains and cystogastrostomy tube. On hospital day 154, he required restenting of cystogastrostomy tube. Following this, gastric output was 15 L in 5 days with an average net negative balance of 900 ml/day. Physical examination revealed blood pressure of 86/61 mmHg, heart rate at 88/min and normal mental status. Over 5 days, serum bicarbonate rose from 20 to >45 mmol/L and chloride decreased from 118 to 94 mmol/L. Serum creatinine rose from 1.0 to 1.4 mg/dL. Arterial blood gas revealed pH 7.61 pCO2 55 mmHg, pO2 71 mmHg and calculated bicarbonate at 55 mmol/L. Pertinent medications included fludrocortisone 50 mcg for chronic orthostatic hypotension. In addition to his obligate intake of ~4L/day it took aggressive chloride replacement with normal saline (15 L in 3 days) and potassium replacement with 430 mEq over 3 days to resolve the alkalosis.

Results:

Conclusions: Cystogastrostomy is a common procedure that is used to manage walled-off pancreatic fluid collections. Gastric irritation and excessive vomiting are not an expected complication of this procedure. This patient's volume assessment was a challenge due to chronic hypotension with chronic orthostasis. It was not anticipated that he would require an extraordinary amount of isotonic sodium chloride to reverse the alkalemia. Direct chloride loss, volume depletion, hypokalemia and fludrocortisone therapy were likely mechanisms leading to such severe metabolic alkalosis. Neither acetazolamide nor HCl therapy was utilized given excellent response to aggressive fluid resuscitation. This case highlights the need to recognize and correct precipitating and maintenance factors in metabolic alkalosis in order to avoid hypercapnia and respiratory failure.

SA-PO1003

Pseudohyponatremia Secondary to Lipid Infusion

Ankur Shah,[2] Michael Kitchens,[1] Sidney M. Kobrin.[1] *[1]University of Pennsylvania, Philadelphia, PA; [2]Nephrology, University of Pennsylvania, Philadelphia, PA.*

Background: We present the case of a 26 y/o male with a history of bipolar disorder admitted with acute seroquel intoxication (approximately 18000mg) treated with lipid emulsion infusion who developed pseudohyponatremia.

Methods: A 26 year old male with a history of bipolar disorder presented to the emergency department after he called his partner and admitted to taking a full bottle of seroquel pills (calculated to be approximately 18000mg). During his initial evaluation he was noted to be having seizure like activity and thusly he was intubated and started on vasopressors to maintain a MAP > 65. After consultation with poison control he was given an IV lipid emulsion bolus and infusion, 20% in concentration. The total dose of lipid infusion was 720 ml. Prior to infusion his serum sodium was within the normal range. Shortly after infusion he developed hyponatremia with a sodium that nadired at 124. The critical care service attempted to treat this with fludrocortisone and salt tabs prior to consultation with nephrology. Workup revealed normal serum osmolarity at the time of hyponatremia, revealing the diagnosis to be pseudohyponatremia. Fludrocortisone and salt tabs were discontinued.

Results:

Conclusions: It is oft quoted that the most frequently searched topic on uptodate is hyponatremia, here we present a new presentation of a classic disorder. The first step in the workup of hyponatremia is to evaluate the serum osmolarity to confirm that the hyponatremia is truly hypo-osmolar. Common causes of "pseudohyponatremia" include glycine infusion, hyperlipidemia, hyperglycemia, and hyperparaproteinemia. To our knowledge, this is the first reported case of iatrogenic pseudohyponatremia from a lipid emulsion infusion in an adult without an unintentional overdose. As lipid effusion grows as a treatment modality for lipophilic drug intoxication we will likely be seeing more of this entity and the course of treatment of this patient highlights the importance of increasing awareness.

Is Urea Effective in the Management of Oxcarbazepine-Induced Hyponatremia?

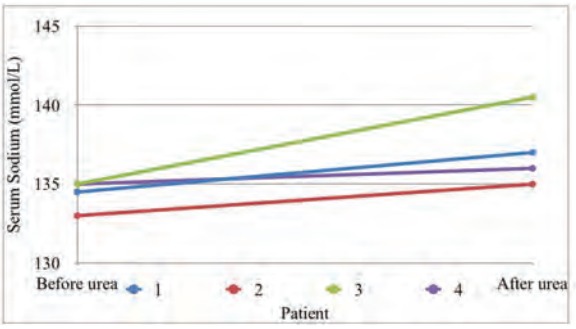
Selasie Goka,[3] Christopher J. LaRosa,[2] Joshua Zaritsky,[2] Divya G. Moodalbail.[1] *[1]Nemours/ Alfred I. duPont Hospital for Children, Wilmington, DE; [2]Nemours/Alfred I. duPont Hospital for Children, Wilmington, DE; [3]Thomas Jefferson University/A.I.Dupont Hospital for Children, Wilmington, DE.*

Background: Oxcarbazepine and carbamazepine, anticonvulsants used to manage partial seizures, are a known cause of hyponatremia largely due to increased tubular sensitivity to ADH. Common ways of addressing this include fluid restriction and sodium chloride (NaCl) supplementation. These can increase the risk of developing nephrocalcinosis/nephrolithiasis in medically complex patients with epilepsy who are largely sedentary. As an alternative, we sought to determine if urea, by osmotic increase in free water excretion, was effective in safely correcting hyponatremia. We present 4 patients whose hyponatremia resolved with the use of urea in place of NaCl.

Methods: The patients, ages 6 to 17 years, were found to have hyponatremia with a nadir between 122 and 131(Figure 1 shows median values) after starting oxcarbazepine. Despite supplementation with NaCl (1-4mEq/kg/day) with some doing fluid restriction; sodium levels remained in the low 130s. The patients were then started on enteral urea (g-tube, j-tube or orally) at 15g to 30g (250-500 mosm) daily. Serum sodium levels normalized within 1-2 weeks of starting urea. Three of the four patients have been successfully weaned off NaCl supplementation with plans to wean the fourth as well.

Results:

Conclusions: Our results show that urea is effective in treating oxcarbazepine-induced hyponatremia. It works to increase urine osmolarity and the excretion of electrolyte-free water. It has been suggested in an animal model to also have neuroprotective effects minimizing risk of osmotic demyelination resulting from rapid correction of chronic hyponatremia. Urea does not potentiate the formation of stones, and as it allows for an electrolyte free-water diuresis it may enable less fluid restriction, help reduce urinary solute concentration and increase urine flow, thereby contributing to stone prevention. It is easy to administer, is not nephrotoxic and can be obtained from retail pharmacies. Given these results, urea may also be a useful alternative for symptomatic hyponatremia in place of hypertonic saline or vaptans.



SA-PO1005

Severe Hyponatremia: A Rapid Correction with Potassium Repletion in a Patient with Lithium-Induced Nephrogenic Diabetes Insipidus Sobia N. Khan, Reena Baharani, Dorothy Rodenbeck, Terence Choy, Muataz Yaziji, Nand K. Wadhwa. *Stony Brook Medicine/ University Hospital, Stony Brook, NY.*

Background: Severe hyponatremia is rare in patients with lithium-induced nephrogenic diabetes insipidus (NDI). This can result from a decreased osmoles intake and acute compulsive water drinking exceeding the capacity of the kidney to excrete free water. Rapid over correction of hyponatremia can occur with potassium repletion. We report a case with bipolar 1 disorder (BD1) with NDI who developed severe hyponatremia with compulsive water drinking on a weight loss diet.

Methods: A 51-year-old woman with BD1, HTN and hypothyroidism presented to the ER with altered mental status, tonic-clonic seizure, lethargy and slurred speech. In the ER, she received IV lorazepam and was intubated for airway protection. Physical exam: Wt 76.4 kg, Temp 35.6ºC, BP 166/92 mmHg, HR 71 bpm. Heart, lungs and abdomen were normal. Six months ago, her serum Na was 140 mmol/L. Lab data: WBC 10.48 K/UL, Hct 30.1%, platelets 232 K/UL, serum Na 105 mmol/L, K 2.1 mmol/L, Cl 65 mmol/L, BUN 7 mg/dL, Cr 0.78 mg/dL, Ca 7.5 mg/dL, Mg 1.3 mg/dL, PO_4 3.1 mg/dL, osmolality 239 mOsm/kg, cortisol 33.2 UG/dL and TSH 2.82 UIU/ml. Urine: Na 48 mmol/L, K 6.0 mmol/L, osmolality 130 mOsm/kg. She received KCl 160 mmol IV and 180 mmol oral, and $MgSO_4$ 4 g IV in first 24 hrs. She received a total dose of DDAVP 16 mcg IV in 24 hours to prevent rapid correction of serum Na. She passed 6600 mL of urine in the first 24 hrs. In the first 12 hrs, her serum Na increased to 117 mmol/L without receiving NaCl solution. With IV infusion of D5W, this rapid increase was reversed and maintained on a serum Na rise of 6-8 mmol/L in 24 hrs. She was extubated the next day. No response to DDAVP was a clue to the diagnosis of NDI. Further history revealed lithium use for 10 years 20 years prior. Her serum Na slowly increased to 133 mmol/L by hospital day 4. She was instructed to eat a regular diet and to drink to thirst with close nephrology and psychiatry follow up. Over a 6 month follow up, her serum Na remained in normal range.

Results:

Conclusions: Hyponatremia is typically not seen in NDI. Our patient was able to maintain normal serum sodium until she began decreasing her oral food intake due to obsessive thoughts about her weight along with compulsive water drinking. In addition, in this case rapid overcorrection of hyponatremia resulted from potassium repletion.

SA-PO1006

Water on the Brain—A Case Report on Crystal Meth-Induced Primary Polydipsia Reema Palankar,[1] Roberto L. Collazo-Maldonado.[2] *[1]UNTHSC Texas College of Osteopathic Medicine, Irving, TX; [2]Dallas Nephrology Associates, Dallas, TX.*

Background: Symptomatic and potentially fatal hyponatremia has been described after ingestion of the designer amphetamine, Ecstasy (MDMA). Along with polydipsia, some studies propose additional mechanisms of MDMA hyponatremia, including induction of an SIADH state and increased activity of aquaporin channels in the medullary collecting duct. Primary polydipsia associated with pure methamphetamine, differing by a methylenedioxy moiety from MDMA, is extremely rare.

Methods: A 36-year-old Hispanic woman with no previous history of systemic illness presented to the ED after suffering an acute-onset seizure that lasted 15 minutes. She was somnolent, disoriented with unintelligible speech. She required intubation on arrival for airway protection. History obtained from her partner revealed crystal meth use earlier that day, after which she drank 10-15 pint sized bottles of water because of "excessive desire to drink water as she was very thirsty." He denied previous history of ongoing excessive water intake, use of ecstasy, or neuropsychiatry conditions. Vitals were stable at admission and she was euvolemic. Workup revealed severe hypotonic hyponatremia (Na 107mmol/L, serum Osm 223 mOsm/kg) with urine Na 79 mmol/L, urine Cl 58 mmol/L, and urine osmolality of 121 mOsm/kg, which was consistent with hyponatremia from primary polydipsia. Head CT revealed diffuse cerebral edema with slit-like ventricles without evidence of herniation. For the symptomatic severe hyponatremia, she received 100 mL hypertonic saline bolus. In addition, she was placed on free water restriction. Repeat CT showed improvement of cerebral edema, which resulted in improvement of mental status and Na levels. She was discharged four days later without any neurological sequelae.

Results:

Conclusions: Cases of methamphetamine-induced primary polydipsia are very rare and probably underreported. It is important to shed light on the prevalence of amphetamine abuse in the teenage/young adult population and the complications of Amphetamine use, including severe hyponatremia, coma and death.

SA-PO1007

Double Trouble with Small Cell Lung Cancer: A Case of Simultaneous Production of Two Ectopic Hormones from a Common Lung Primary Krishna A. Agarwal. *UMMS-Baystate, Chicopee, MA.*

Background: The association of small cell lung cancers (SCLC) with syndrome of inappropriate antidiuretic hormone secretion (SIADH) is well known. Upto 15% cases with SCLC exhibit SIADH but only 1% of patients with SCLC have ectopic ACTH production.

Methods: A 55-year-old cachectic woman with recurrent hospitalizations for weakness, nausea and vomiting was seen in the nephrology office for hyponatremia. SIADH was diagnosed on bloodwork and CT scan of her chest revealed a new hilar mass. Bronchoscopic biopsy and metastatic workup confirmed a small cell type lung cancer with metastasis to her liver, right femur and ribs. Her hyponatremia was treated with water restriction and salt tablets. Two weeks later, she was admitted with right lung collapse and found to have persistent hypertension, metabolic alkalosis, hyponatremia and hypokalemia alongwith elevated ACTH and cortisol. A high-dose overnight dexamethasone suppression test revealed an ectopic non-suppressible source of ACTH and imaging studies ruled out a pituitary or adrenal source of hypercortisolemia. Repeat chest CT showed extensive local infiltration of the lung cancer and widespread hepatic metastasis. Palliative chemotherapy and ketoconazole were trialed in the hopes of reducing tumor burden and improving hypercortisolemia but her clinical status continued to deteriorate and she passed away peacefully.

Results: Case studies have shown that upto 15% of SCLC patients have SIADH and management of hyponatremia improves mortality and therefore palliative chemotherapy is recommended even for extensive disease. Our patient had a unique presentation with both hyponatremia and hypercortisolemia. The median survival time of patients with extensive SCLC is 6-12 months, but it decreases to 7.1 months with concomitant hyponatremia and to 5.5-6.2 months with ectopic ACTH production.

Conclusions: There have only been rare case reports of multiple ectopic hormones being produced from a single primary SCLC. Due to the poor prognosis associated with extensive lung cancer disease and significant worsening with paraneoplastic phenomena like SIADH and ACTH, it is important to diagnose these conditions early and initiate aggressive treatment. Especially, chemotherapy and treatment of hyponatremia because these have been shown to improve performance status and mortality.

SA-PO1008

A Suspected Case of Glycolic Acid Poisoning Daniel Edmonston, Dinushika Mohottige, Jessica D. Morris, Niraj R. Kothari. *Nephrology, Duke University Hospital, Durham, NC.*

Background: The diagnosis of ethylene glycol and other toxic alcohol poisoning is often challenging. Metabolism by alcohol dehydrogenase may result in undetectable ethylene glycol levels in serum. Similarly, the elevation in osmolal gap may not be present once ethylene glycol is metabolized to its charged metabolites. One of the most toxic of these metabolites is glycolic acid. We report a case of suspected recurrent glycolic acid poisoning.

Methods: Our patient was a 38-year-old woman with a history of ethanol abuse and an 8-month span of recurrent admissions for altered mental status in the setting of severe lactic acidosis and acute kidney injury. Investigations including urine toxicology screen, ethanol levels, and volatile acid levels including ethylene glycol, methanol, and isopropyl alcohol were negative during each admission. The patient and family denied any availability of antifreeze and other toxins in the home. Metabolic evaluation for a mitochondrial disorder was negative. She was admitted for nine days for severe lactic acidosis with negative evaluation, which improved with supportive treatment of acidemia. On the day of discharge, her serum bicarbonate was 25 mmol/L. The next day, she became altered again after returning home from the drug store. Her bicarbonate was now 5 mmol/L with arterial pH of 7.13. Her osmolal gap was 5. Again, screening for toxic ingestions was negative. Given high suspicion, she was empirically started on fomepizole and continuous renal replacement therapy was initiated. She remained on pressor support with progressive acidemia, and ultimately died despite aggressive renal replacement therapy. Her autopsy was notable for extensive intravascular and perivascular oxalate crystals in the brain and kidneys. She was also noted to have a transmural acute myocardial infarction of the left ventricle.

Results:

Conclusions: Glycolic acid is found in a myriad of cosmetic products and can be toxic in lethal doses. Unfortunately, the presentation may be difficult to diagnose as the osmolal gap may be normal, lactate markedly elevated (glycolic acid can interfere with certain lab assays for lactate), and ethylene glycol level negative. Even in cases of ethylene glycol poisoning, the glycolic acid level is often a more reliable marker of toxicity. This case highlights the importance of assessment of glycolic acid level in suspected toxic alcohol poisoning.

SA-PO1009

A Known Complication from an Unlikely Source: Propylene Glycol Toxicity Fatima B. Cintron-Rosa, Jannice M. Arroyo, Hector Diaz, Ileana E. Ocasio Melendez. *Nephrology, University of Puerto Rico, San Juan, PR.*

Background: High anion gap metabolic acidosis (HAGMA) in a critically ill patient on vasopressor support could be attributed to the presence of shock. However, this is not specific and additional causes must be investigated. We present an unusual cause of HAGMA and hyperosmolarity in a patient with septic shock and acute kidney injury (AKI), a propylene glycol intoxication.

Methods: A 40-year-old man was admitted due to multiple body trauma secondary to a motor vehicle accident. He required surgery due to bladder rupture with extraperitoneal leakage. Prolonged hospital course complicated with septic shock secondary to multiple nosocomial infections and AKI and was consulted to Nephrology service. Evaluation demonstrated a critically ill patient on mechanical ventilation and vasopressor support, sedated with an intravenous (IV) infusion of lorazepam. Lorazepam was infused at a dose exceeding 0.1 mg/kg/hr. Physical examination revealed fluid overload without oliguria. Laboratory tests supported the clinical impression of AKI and pure HAGMA and acidemia, with a serum bicarbonate concentration of 14.4 mEq/L, an arterial pH 7.214 and a calculated anion gap 27.6. Serum lactic acid level was 39.9 mg/dL. An osmolal gap was present and calculated to be 68 mOsm/kg. Stopping lorazepam IV infusion had no improvement in metabolic acidosis. Patient sedation was changed to an IV midazolam infusion, which is not diluted in propylene glycol. Hemodialysis was initiated and patient showed a rapid improvement in AKI, HAGMA and osmolal gap with withdrawal of hemodialysis therapy after only two sessions.

Results:

Conclusions: This clinical features are classic of propylene glycol toxicity in a patient receiving high doses of lorazepam. Propylene glycol is the diluent used in parenteral formulations of lorazepam and diazepam, which are commonly used sedative medications. This active ingredient is metabolized by alcohol and aldehyde dehydrogenase to D and L-lactic acid, which accounts for the HAGMA with associated elevated osmolal gap not explained by septic shock. Toxicity of propylene glycol is associated to hyperosmolarity, HAGMA, high osmolal gap and AKI and can progress to multisystemic organ failure if severe. Treatment consists of removal of offending agent and dialysis if without improvement, which resulted favorably in our patient.

SA-PO1010

A Preventable Poisoning in Renal Failure Krystahl Z. Andujar, Ileana E. Ocasio Melendez, Fatima B. Cintron-Rosa, Jannice M. Arroyo, Enrique O. Ortiz-Kidd. *Nephrology, University of Puerto Rico, Medical Sciences Campus, San Juan, PR.*

Background: Metformin has become a drug of choice for the treatment of type 2 diabetes mellitus. It has multiple benefits, which include decreasing fasting and post-prandial blood glucose, decreasing body weight and improving lipid profile. However, its use is not without complications and one of the most common toxicities from metformin use is lactic acidosis.

Methods: A 61-year-old man with diabetes mellitus type 2 and arterial hypertension presented to the emergency department after sustaining head trauma. He referred dizziness, nausea and vomiting. Outpatient medications included metformin 1g twice daily. Vital signs revealed hypotension, tachycardia and tachypnea. He appeared uncomfortable, was somnolent but arousable and oriented to person and place. Lungs were clear and extremities without edema. Laboratories showed a creatinine of 13 mg/dL, blood urea nitrogen of 103 mg/dL, bicarbonate of 2.7 mEq/L, glucose of 30 mg/dL and arterial pH of 6.8. Anion gap was 55.3, consistent with a high anion gap metabolic acidosis. Lactic acid levels were elevated at 104 mg/dL. Patient was placed on mechanical ventilation, started on vasopressors and transferred to intensive care unit. A bicarbonate drip was started until hemodialysis was instituted. After hemodialysis, his mental status improved considerably, metabolic abnormalities began to normalize and vasopressors were discontinued.

Results:

Conclusions: Biguanides can lead to the accumulation of lactate by reducing gluconeogenesis and glycogenolysis, inhibiting oxygen consumption and impairing mitochondrial function. This patient had a high risk of metformin accumulation given renal disease. He had a profound acidemia with high anion gap metabolic acidosis and elevated serum lactate levels, consistent with the unusual metformin-associated lactic acidosis (MALA). A case series comparing MALA with other types of lactic acidosis, described only metformin associated with a mean blood pH below 7.0, as in this patient. In patients with severe metformin poisoning, hemodialysis is the preferred approach, which in our patient established hemodynamic stability promptly. However, given the common use of this drug, kidney function and metabolic disturbances should be closely monitored.

SA-PO1011

An Unusual Case of Extensive Brain Infarction and Metabolic Acidosis George Vasquez-Rios, Hani Alkhankan, B. Peter E. Sawaya, Javier A. Neyra. *Nephrology, Bone and Mineral Metabolism, University of Kentucky Medical Center, Lexington, KY.*

Background: Extensive CNS compromise is a rare complication of methanol intoxication that needs prompt recognition.

Methods: A 24-year-old man presented to the ED with a 2-day history of progressive lethargy, diffuse muscular rigidity, and fever. His medical history was relevant for schizophrenia, substance abuse, and essential hypertension. On arrival, his vitals were BP: 169/133 mmHg, HR: 123 beats/min, RR: 25 respirations/min, SatO2: 98% (FiO2: 50%) and T: 38.3 C. Neurological findings included GCS:7, bilateral mydriasis and symmetrical hypoactive reflexes. Laboratory studies revealed severe high anion gap metabolic acidosis (arterial pH 7.21, pO2 100 mmHg, pCO2 8 mmHg and $HC03^-$: 5 mEq/L; anion gap: 36), leukocytosis, mild hyperkalemia, and elevated serum creatinine at 1.36 mg/dl (baseline: 0.96 mg/dl). Calculated and measured serum osmolality were: 302 mOsm/Kg and 297 mOsm/Kg respectively (osmolar gap: 5). After initial workup, sepsis, medication overdose, illicit substance abuse and toxic environmental exposure were excluded. Head CT scan showed extensive bilateral infarctions affecting the lenticular nuclei with hemorrhagic conversion on the right side, along with occipital lobe and cerebellar infarction. Ultimately, his serum methanol level was found to be 40 mg/dL confirming the diagnosis of acute methanol intoxication. Initially, he was aggressively treated with isotonic fluid resuscitation and bicarbonate replacement with mild improvement of his overall clinical status. A 4-hour hemodialysis treatment was administered (delivered single-pool Kt/V: 1.32) to enhance acid/toxic byproduct removal. Intravenous fomepizole (600 mg) and leucovorin (4 doses) were also administered. He was transitioned to continuous venous-venous hemofiltration (CVVH) with an effluent dose of 35 ml/kg/hr to prevent a potential rebound effect. Following 18-hour CVVH therapy, his serum methanol levels were down to 11 mg/dL. His clinical status progressively improved although residual visual impairment and motor deficits were noted upon discharge.

Results:

Conclusions: Extensive cerebral infarction is an unusual presentation of methanol intoxication and may cause a delay in reaching the final diagnosis in a patient with decreased mental status. Rapid recognition and treatment of methanol intoxication are pivotal for survival and attenuation of sequelae.

SA-PO1012

Amantadine Toxicity: An Unexpected Case of Metabolic Acidosis Divya Sharma, Ramapriya Sinnakirouchenan. *Medical College of Wisconsin, Milwaukee, WI.*

Background: Propylene glycol is a solvent used to dissolve a variety of medications and can become toxic when administered in large doses. We present a case of severe metabolic acidosis in a patient taking toxic doses of amantadine, which in some formulations contain the carrier propylene glycol.

Methods: A 66-year-old woman with a history of multiple sclerosis (MS) and end stage renal disease (ESRD) was admitted from Neurology clinic with concerns for MS flare. Her last dialysis was the day prior to admission. Labs revealed BUN 36 mg/dL, Cr 5.81 mg/dL, and bicarbonate 16 mmol/L. That evening she developed severe respiratory distress requiring transfer to the intensive care unit where she was urgently intubated. Arterial blood gas showed pH 6.98, pCO2 <20 mmHg, pO2 104 mmHg, and bicarbonate 3 mmol/L. Basic metabolic panel revealed BUN 59 mg/dL, Cr 7.32 mg/dL, and bicarbonate 4 mmol/L. Other significant labs included lactic acid 20 mmol/L and serum osmolality 322 mOsm/kg. She had an elevated anion gap of 44 mmol/L and an osmolar gap of 18 mOsm/kg. A toxicology screen, including aspirin, acetaminophen, acetone, ethanol, isopropanol, and methanol was negative. The patient underwent emergent hemodialysis for severe acidosis and was extubated the next day.

Results:

Conclusions: It was subsequently found that our patient was started on amantadine 3 weeks prior for MS related fatigue. She was prescribed 100 mg oral twice daily, instead of the recommended dose for ESRD of 200 mg oral weekly. Upon further investigation, we noted that some dosage forms of amantadine contain propylene glycol, which in large amounts can be potentially toxic and be associated with hyperosmolality, lactic acidosis, increased anion gap metabolic acidosis, and respiratory depression. As no other etiology for her acidosis was identified, propylene glycol toxicity was presumed to be the etiology as she was essentially receiving 7 times the dose recommended for her level of renal function. Amantadine was discontinued immediately, and she had no further recurrences of acidosis. This case illustrates the importance of obtaining a thorough history from our patients, including all medications. Not only must we be especially vigilant to dose medications for level of renal function, but to recognize solvents such as propylene glycol that are carriers for a variety of medications and the widespread and potentially harmful effects they may have.

SA-PO1013

Severe Metabolic Acidosis Secondary to Metastatic Melanoma Reoccurrence: The Warburg Effect Sylvester Barnes,[1] Vinod K. Bansal.[2] *[1]Loyola University, Wheaton, IL; [2]Loyola University Medical Center, Maywood, IL.*

Background: The Warburg effect is a phenomenon where a high rate of glycolysis occurs in tumor cells and it uncoupled from aerobic respiration. To keep up with the metabolic demands of the cell, glycolysis increases at the expense of significant glucose utilization and a resultant elevated lactate levels as oxidative phosphorylation does not occur in this process. It is believed this process allows the cell to export various carbohydrate components from the Krebs Cycle to instead promote cell growth.

Methods: The patient is a 85 year old man with CKD stage 3 who presented to the hospital after being seen by his PCP for increasing dyspnea for 6 weeks. The patient has a history of malignant melanoma first diagnosed in 1964 and no sign of recurrence since 2011. Labs were remarkable for a creatinine of 1.54mg/dl, a serum bicarbonate level of 8mmol/L, albumin of 2.9g/dl, alkaline phosphate 538 IU/L, AST 101 IU/L and

ALT of 64 IU/L. His INR and bilirubin were normal. An ABG showed a pH of 7.28, pCO2 of 21mmHg, and calculated bicarb of 9mmol/L. Serum lactic acid was measured at 18 mmol/L. CT scan was obtained showing numerous hypervascular liver lesions, and biopsy confirming melanoma reoccurrence. Nephrology was consulted to help with his metabolic acidosis. When examined the patient was noted to be resting comfortably with only mild tachypnea. Thiamine along with bicarbonate 1300mg three times a day was tried for the patient with no improvement in bicarbonate levels. The patient remained fairly asymptomatic and was discharged home. Four days post discharge the patient presented again to the hospital with increased dyspnea along and altered mental status. Serum bicarbonate was measured at less than 5mmol/L and lactate level obtained was 22mmol/L. An ABG showed a pH of 6.9, pCO2 8mmHg and calculated serum bicarbonate of 2mmol/L. It was decided a focus on comfort would be more appropriate than treatment and the patient ultimately passed away later during the day.

Results:

Conclusions: The patient's persistent lactic acidosis was initially fairly asymptomatic leading to only mild tachypnea and compensatory respiratory alkalosis. It was believed that the majority of his lactate generation was due to his melanoma using primary glycolytic pathways, the Warburg effect. Unfortunately, this is generally seen as a poor prognostic indicator, as was the case for our patient.

SA-PO1014

Thiamine Deficiency Leading to Severe Lactic Acidosis Jamil Ibrahim,[3] Daniel W. Ross,[2] Kenar D. Jhaveri,[1] Richard L. Barnett.[2] *[1]Hofstra Northwell School of Medicine- Northwell health system, Great neck, NY; [2]None, Great Neck, NY; [3]Northwell, Mineola, NY.*

Background: Sepsis and drug induced lactic acidosis are encountered commonly in clinical practice. Lactic acidosis is a rare side effect of thiamine deficiency. Here we will describe a confounding case of Type B lactic acidosis rapidly reversed by thiamine infusion.

Methods: An 88 year old Chinese woman with heart failure on furosemide, tricuspid regurgitation, hypertension, right hand nerve palsy, chronic anemia secondary to beta thalassemia intermedia presented with worsening shortness of breath. She was noted to have a poor diet that featured mainly porridge and polished white rice. Early in her admission she exhibited a lactic acid of 10.8 mmol/L without signs of infection or impending hemodynamic collapse; no complaints apart from shortness of breath. Her elevated lactic acid raised concerns for a major ischemic compromise; clinical stability and absent lab and imaging findings of any end organ damage suggested an alternate cause of her lactic acidosis. Her lactic acid rose to19 mmol/L two days after admission. She was started on an intravenous bicarbonate infusion in order to mitigate further worsening acidosis without success. Her anion gap increased to39 mmol/L, while serum bicarbonate declined to less than 10 mmol/L. Given her dietary history, diuretic use and ethnicity, a diagnosis of thiamine deficiency was made and empirically received 1 dose of thiamine 100 mg intravenously. Her lactic acid level plummeted within hours to 2.7 mmol/L her anion gap closed and serum bicarbonate increased to 32; this alkalosis likely resulted from the HCO3 infusion concurrent with rapid lactate metabolism.

Results:

Conclusions: Thiamine deficiency can lead to wet and dry beri beri, usually seen in alcoholics with/without poor nutrition, weight loss surgery and parenteral therapy if adequate thiamine is not provided. Studies have suggested that subclinical thiamine deficiency is common among hospitalized patients with heart failure, especially if they are treated with loop diuretics but lactic acidosis is uncommon. Nonetheless it should be considered in susceptible individuals such as our patient. The bicarbonate drip further accelerated the rise in lactic acid by creating a low intracellular [H+] environment that stimulates phosphofructokinase activity and hence glycolysis. The extremely rapid disposal of lactic acid consequent to thiamine mediated stimulation of pyruvate dehydrogenase was diagnostic.

SA-PO1015

Pseudo-Anion-Gap Metabolic Acidosis from Severe Hypertriglyceridemia Corrected by Plasma Exchange: A Case Series John T. Ludwig,[1] Charissa Marie R. Carag,[1] Venkata R. Behara,[2] Pravir V. Baxi,[1] Casey N. Gashti.[1] *[1]Rush University Medical Center, Chicago, IL; [2]NANI (Nephrology Associates of Northern Illinois), Mt. Prospect, IL.*

Background: A link between severe hypertriglyceridemia (H-TG) and falsely low or even unmeasurable serum bicarbonate ([HCO3]), known as pseudo-hypobicarbonatemia, has been reported. This is believed to be due to interference by serum triglycerides (TG) - typically >1000 mg/dL - when the commonly used enzymatic assay is utilized for [HCO3] measurement. When the [HCO3] is calculated using an ABG machine, the value is near normal. Chloride measurements are not affected by the TG level. This could lead to the misdiagnosis of a severe anion-gap metabolic acidosis, resulting in an extensive work-up that would typically include expensive toxicology screening.

Methods: We report a series of 4 pts with pseudo-hypobicarbonatemia associated with severe H-TG (Tab. 1). All TG values were >2000 mg/dl and each pt had lipemic serum. All pts had a measured serum [HCO3] of ≤ 6 mmol/L and an elevated anion gap (AG). The calculated [HCO3] from a simultaneous blood sample run using a blood gas machine was 15-27 mmol/L with a pH in the normal range. 3 of the 4 pts presented with acute pancreatitis from H-TG and received 1-3 membrane based therapeutic plasma exchange (TPE) treatments with immediate improvement in TG levels. The 4th pt had discontinuation of PEG-L-asparaginase, known to cause H-TG, and did not require TPE. In each case the serum [HCO3] normalized after lowering of H-TG with a simultaneous resolution of the elevated AG.

Results:

Conclusions: Pseudo-anion-gap metabolic acidosis is a laboratory phenomenon seen when severe H-TG interferes with the normal enzymatic measurement of the [HCO3]. The calculated [HCO3] is not affected when determined using a blood gas analysis machine. While this phenomenon has been previously described, this is the first report to demonstrate immediate resolution of the pseudo-anion-gap metabolic acidosis following aggressive lowering of the TG levels with TPE. Recognition of lipemic serum in the setting of an otherwise unexplained AG metabolic acidosis should prompt the clinician to get an ABG sample for true determination of the acid-base status. Doing so may avoid an extensive and expensive metabolic work-up.

Pt	TG[I]	TG[P]	HCO3[I]	HCO3[P]	AG[I]	AG[P]	HCO3[ABG]	# of TPE
1	4807	303	<5	24	18	8	19	2
2a	8000	341	6	27	19	9	15	3
2b*	5680	653	<5	28	21	12	21	N/A
3	2068	307	<5	24	37	12	27	1
4	2980	332	5	25	29	8	24	N/A

I = initial value, P=post TPE, ABG =arterial blood gas measurement

SA-PO1016

Total CO2 Assay Interference Induced by Hypertriglyceridemia Diego A. Beltran Melgarejo, Gautam B. Bhave, Anna M. Burgner. *Division of Nephrology, Vanderbilt University Medical Center, Nashville, TN.*

Background: Measurement of CO_2 is a key component of acid base assessment. Although modern laboratory instruments provide high accuracy and reliability, assays are still prone to error. We present a case where interference in CO_2 measurement lead to significant disparities between total CO_2, calculated CO_2, and clinical findings.

Methods: A 55-year-old female with type 1 diabetes mellitus and alcohol abuse, presented with 1 day of dyspnea, palpitations, vomiting and abdominal pain. She reported recent binge drinking, poor dietary intake and missing insulin doses. Physical exam revealed sinus tachycardia and no other abnormalities. Workup indicated acute liver failure, anuric acute kidney failure, and a high anion gap metabolic acidosis initially attributed to ketoacidosis. There was a discordance on labs with total CO_2 (TCO_2) measuring 13mmol/L and venous blood gases (VBG) showing a pH of 7.33, pCO_2 of 33 mmHg, and calculated HCO_3 ($cHCO_3$) 17mmol/L. On follow up labs, tCO_2 dropped to <5 mmol/L, while VBG continued to show pH>7.33, and cHCO3 >18mmol/L. Discrepancies amongst tCO_2, $cHCO_3$, and clinical findings suggested a falsely low tCO_2 result. There was no hemolysis or significant hyperbilirubinemia, which commonly interfere with the tCO_2 assay, however triglycerides (TG) were 1712mg/dL, and the serum sample was markedly lipemic on visual inspection. She was treated with normal saline, insulin drip, and continuous renal replacement therapy. The discrepancy between tCO_2 and $cHCO_2$ resolved as TG improved. Hepatic and renal failure resolved.

Results:

Conclusions: Measurement of tCO_2 can be achieved by electrode-based assay or as in this case by spectrophotometry. Lipemia might interfere with the latter, as large lipid particles like VLDL and chylomicrons absorb or disperse light, leading to erroneous results. Although manufacturers report minimal error with TG of 1000-2000mg/dL, this error is estimated using a lipid emulsion (Intralipid) that does not match the large size of TG particles. Mixing experiments by Wiencek et al, demonstrated a greater negative CO_2 error when estimates are based on TG dilutions instead of Intralipid testing. This case illustrates that accurate acid base assessment requires a careful clinical interpretation of tCO_2/$cHCO_3$ and patient's clinical condition.

SA-PO1017

A Case of Perioperative Euglycemic Ketoacidosis and Concomitant Non-Anion Gap Metabolic Acidosis and AKI Associated with Canagliflozin Manuel E. Gonzalez, Juan Carlos Q. Velez. *Department of Nephrology, Ochsner Clinic Foundation, New Orleans, LA.*

Background: Oral inhibitors of the renal sodium-glucose cotransporter SGLT2 ("-gliflozins") are now available for the management of type 2 diabetes mellitus. Reports of euglycemic ketoacidosis caused by these drugs have emerged. However, concomitant acute kidney injury (AKI) and non-anion gap (NAG) metabolic acidosis are not usually present in those cases. We report a case suggestive of euglycemic ketoacidosis due to the SGLT2 inhibitor canagliflozin that was confounded by concomitant AKI and NAG metabolic acidosis.

Methods: A 65 year-old Caucasian woman with type 2 diabetes mellitus, hypertension and obesity was evaluated for profound weakness and vomiting on post-operative day 1 after a laparoscopic sleeve gastrectomy indicated for weight loss. Her home medications included dulaglutide, metformin, and canaglifozin. Dulaglutide was stopped 1 week prior to the procedure, and metformin and canaglifozin were stopped 1 day prior her surgery. Upon evaluation, her blood pressure was 131/64 mmHg, her pulse was 94/min and her body mass index was 36 kg/m^2. Examination was remarkable for obesity and a mildly tender abdomen with a dressed abdominal incision. Serum studies revealed: sodium 135 mEq/L, chloride 113 mEq/L, total CO_2 < 5 mEq/L, potassium 4.8 mEq/L, glucose 128 mg/dL, urea nitrogen 12 mg/dL and a creatinine 1.0 mg/dL (up from a baseline of 0.6 mg/dL). The serum anion gap (AG) was 17 mEq/L. An arterial blood gas revealed a pH 7.1 and a pCO_2 20.8 mmHg. She had a normal lactate of 0.9 mmol/L but a positive

beta-hydroxybutyrate of 5.1 mmol/L. Urinalysis showed 2+ ketones. The delta AG / delta bicarbonate was 0.3, suggesting co-existence of AG and NAG metabolic acidosis, caused by ketoacidosis and AKI, respectively. She was treated with intravenous isotonic sodium bicarbonate solution, followed by normal saline, insulin infusion with dextrose drip until the AG normalized and her kidney function returned to baseline.

Results:

Conclusions: This case illustrates that SGLT2-induced euglycemic ketoacidosis with concomitant AKI can occur as a serious disorder in diabetics. The combination of fasting, volume depletion and deficiency of insulin appear to trigger this relatively novel syndrome. We call for caution in preoperative care of patients taking "-gliflozins".

SA-PO1018

Caffeine Overdose: Case Report Andrew Hipp, Keith E. Eidman. *Hennepin County Medical Center, Minneapolis, MN.*

Background: Caffeine is a ubiquitous stimulant in today's society. Massive caffeine ingestion, although rare, is associated with life threatening complications. This case involves a patient presenting after intentional caffeine overdose of approximately 20g(LD50 for patient is 6g). Previous case reports have demonstrated hemodialysis as an effective treatment. Dialysis treatment directed by hemodynamic parameters was used in this case and proved helpful in guiding repeat dialysis treatments as caffeine levels were not readily available.

Methods: The patient was brought in following an intentional overdose of caffeine pills. Patient presented with hypotension, tachycardia, hypokalemia, and depressed mental status. Patient was treated with IVF, sedation, intubation, and blood pressure support with phenylephrine. Hemodialysis was started in the setting of massive ingestion and ongoing hemodynamic instability. Patient underwent hemodialysis using a high flux dialyzer with improvement in both tachycardia and blood pressure. Patient required a second run of hemodialysis after decompensating after cessation of the first run and required placement back on phenylephrine. Following the completion of a second run, the patient remained hemodynamically stable and off vasopressor support. Caffeine levels prior to HD eventually returned at 187.5 mcg/ml. Post first HD run caffeine levels improved to 57 mcg/ml and subsequently to 6.0 mcg/ml after second run of HD.

Results:

Conclusions: Caffeine and it numerous metabolites including theophylline, theobromine, and paraxanthine can cause life threatening hemodynamic instability. The mechanism of caffeine and its metabolites actions are through adenosine antagonism, catecholamine release, and phosphodiesterase inhibition. Caffeine is a suitable target for removal with Vd of 0.6 L/kg, small molecular weight, and only 25-36% protein bound. This case demonstrates acute hemodialysis is indicated in massive caffeine ingestion and treatment can be directed by hemodynamic parameters.

SA-PO1019

Acute Hypocalcemia in Patients on Denosumab Therapy Following Transfusion Warda Zaman, Komal Patel. *Northwell Health Lenox Hill Hospital, New York, NY.*

Background: We present two patients on denosumab therapy with acute hypocalcemia following pRBC transfusion.

Methods: An 84-year old man with CKD III presented with fatigue 12 days after denosumab therapy to treat bone metastases from carcinoid tumor. Initial labs showed Ca 7.9mg/dL, albumin 2.5g/mL, Cr 1.57mg/dL, and eGFR 40mL/min. He received 1 unit pRBC and developed muscle cramps 2 hours post transfusion. Repeat blood work revealed Ca< 5.0mg/dL, ionized Ca 0.77mmol/L, albumin 2.5g/mL, Cr 1.46mg/dL, eGFR 40mL/min, 25-OH Vitamin D 4ng/mL, 1,25-di(OH) Vitamin D 41.6pg/mL and PTH 340pg/mL. He required calcium infusion for 4 days, and maintained his calcium level above 8.0 mg/dL with oral supplementation. A 77-year old man with CKD IV and metastatic prostate cancer who had received denosumab 4 weeks prior presented with a right pathologic femoral neck fracture. Labs revealed Ca 7.7mg/dL, albumin 2.7g/mL, Cr 2.57mg/dL, and eGFR 23mL/min. On hospital day 9, after a second pRBC transfusion, Ca level was < 5.0mg/dL from 6.1mg/dL, ionized Ca 0.83mmol/L, albumin 2.0g/mL, Cr 2.73mg/dL, eGFR 21mL/min, 25-OH Vitamin D 21.4ng/mL, 1,25-di(OH) Vitamin D 112pg/mL and PTH 1321pg/mL. He reported lethargy with perioral paresthesia without Chvostek sign or carpopedal spasm. He required calcium infusion for 24 hours, along with oral supplementation and subsequently maintained a calcium level of 8.3 mg/dL.

Results:

Conclusions: Denosumab, a monoclonal antibody to RANK ligand, inhibits osteoclast formation decreasing bone resorption and increasing bone mineral density. It is not metabolized or excreted renally. Hypocalcemia post-denosumab is reported in 5.5% to 20.8% of patients. It is known to cause a nadir in calcium 10 days after administration, with effects lasting up to twelve months. Renal insufficiency results in activated vitamin D deficiency and secondary hyperparathyroidism increasing risk of hypocalcemia with denosumab. Symptomatic hypocalcemia with citrated blood is rare unless citrate metabolism is impaired in hepatic or renal failure. Our case report demonstrates the need for providers to adhere to guidelines advising against blood transfusion with Hgb >7.0g/dl. Furthermore, providers should maintain a high degree of suspicion for hypocalcemia and closely monitor Vitamin D and calcium levels when using denosumab in CKD patients.

SA-PO1020

Acute Myeloid Leukemia Presenting as Nephrotic Syndrome Maryam K. Saeed. *University of Illinois- Urbana Champaign, Urbana, IL.*

Background: Nephrotic syndrome(NS) is characterized by heavy proteinuria, hypoalbuminemia and peripheral edema. Acute Myeloid Leukemia(AML) has been rarely reported in association with NS.

Methods: 73 year old white male presented with lower extremity edema and dyspnea for the last 3 weeks. He denied chest pain, palpitations, fevers, or recent immobilization. History was significant for non-insulin dependent type II diabetes mellitus with neuropathy without retinopathy and hypertension. On examination his blood pressure was 160/80mm Hg with + 2 pitting peripheral edema. Basic labs showed hemoglobin of 12.7g/dL, Creatinine 0.8 mg/dL, total serum protein 6.8mg/dL, albumin 3.6g/dL with 24 hour urine protein of 5.9 grams and no hematuria. Echocardiogram and renal ultrasound were unremarkable. Furosemide was initiated for suspected diabetic nephropathy. However, patient's edema significantly worsened with development of ascites. Repeat labs showed proteinuria(5.6g/24 hours)and hypoalbuminemia(2.9g/dL). Serum complement levels, hepatitis panel, antinuclear antibody levels were unremarkable. A renal biopsy was scheduled for possible secondary causes of NS.Labs prior to biopsy showed a decreased white cell count of 3.1 x10^3/uL, hemoglobin of 8.9 g/dl, MCV of 67.6 fL and normal platelet count. Peripheral smear revealed neutropenia with left shift and frequent blasts. The patient was referred for urgent bone marrow biopsy and flow cytometry with results consistent with AML.Azacitadine chemotherapy was subsequently started. Renal biopsy revealed features consistent with renal involvement by extramedullary myeloid neoplasm, diffuse glomerular mesangial sclerosis and changes suggestive of chronic thrombotic microangiopathy. Despite chemotherapy, the patient's condition worsened with development of healthcare associated pneumonia, refractory ascites and multiple hospital readmissions. Eventually the patient decided to opt for comfort care measures

Results:

Conclusions: Hematological malignancies associated with NS are mainly Hodgkin's and non-Hodgkin's lymphomas and chronic lymphocytic leukemia. The onset of NS in patients with AML is reported after development of leukemia, during chemotherapy or at presentation. In our patient NS preceded AML with evidence of renal extramedullary hematopoiesis, rarely described with myeloproliferative neoplasms.

SA-PO1021

A Rare Case of Renal Oncocytosis with Agent Orange Exposure Amit Reddy,[1] Mary T. Sessums,[1] John C. Henegan,[2] Varsha Manucha.[1] *[1]Pathology, University of Mississippi Medical Center, Jackson, MS; [2]Hematology/Oncology, University of Mississippi Medical Center, Jackson, MS.*

Background: During the Vietnam War, more than 3 million veterans were exposed to Agent Orange, an herbicide containing dioxin that has been linked to increased cancer risk. There is sufficient evidence for an association between Agent Orange and hematological disorders, but only a few cases have been reported in relation to renal neoplasms. Here we present a case of bilateral renal masses with right sided renal oncocytosis and Agent Orange exposure in a patient with chronic kidney disease (CKD).

Methods: A 68-year-old Caucasian male with hypertension, CKD, and previous Agent Orange exposure was noted to have an elevated serum creatinine of 1.9mg/dL and blood urea nitrogen of 36mg/dL which triggered further evaluation. He had no recent hematuria, flank pain, or weight loss. A renal ultrasound showed multiple renal masses, and magnetic resonance imaging confirmed these to be concerning for renal cell carcinoma with one mass in the upper pole of the right kidney measuring up to 3.3cm and a second mass in the interpolar region of the left kidney measuring 2.3cm. All nodules were completely confined to the kidney. Preoperative germline testing of a panel of genes in which variants are associated with hereditary renal carcinoma syndromes revealed no pathogenic mutations. Right partial nephrectomy was performed which noted multiple oncocytic nodules ranging in size from a microscopic collection of a few cells to large, grossly visible nodules. Immunostains were negative for AMACR and CK7 and positive for CAM5.2 and CD117, consistent with a diagnosis of renal oncocytosis.

Results:

Conclusions: Renal oncocytosis is an extremely rare disorder with multiple oncocytic nodules of the renal parenchyma and is associated with CKD and Birt-Hogg-Dube Syndrome. The incidence is about 4.3% of all solid renal masses. According to literature, there have been only 4 similar cases reported of oncocytosis with Agent Orange exposure but there has been no definitive link. The diagnosis of renal oncocytosis remains a challenge due to the difficulty in distinguishing between benign and malignant lesions with imaging. As with this case, partial nephrectomy allowed for a definitive diagnosis. Renal oncocytosis in this case could be related to CKD and any link to previous exposure to Agent Orange will require further follow-up of patients with this history to determine if it is a risk factor for renal oncocytosis.

SA-PO1022

A Report on Multifocal Bilateral Renal Oncocytomas Leading to Interstitial Nephritis Divyanshu Malhotra,[1] Randy L. Luciano.[2,1] *[1]Yale New Haven Hospital, New Haven, CT; [2]Yale University School of Medicine, New Haven, CT.*

Background: Renal oncocytomas are benign tumors originating from the intercalated cells of the collecting duct. They are rare, with an incidence of up to 7% of all renal

tumors. The majority of tumors are solitary, but up to 12% can be multifocal with 4-12% being bilateral. These are often found incidentally, but on occasion flank pain or hematuria are presenting signs. Less is known about the nature of multifocal bilateral oncocytomas and their renal complications. Here we present two patients with multifocal bilateral oncocytomas with associated interstitial nephritis.

Methods: The first patient is a 44 year old gentleman with no significant medical history who was found to have multifocal renal tumors on CT scan that was performed after the discovery of hematuria. Biopsy showed multiple oncocytomas with a surrounding dense interstitial infiltrate. Clinically the patient had a serum creatinine of 1.5 mg/dL with no underlying medications or co-morbid conditions that could be attributed to the interstitial inflammation. The second patient is a 72 year old gentleman with a history of treated prostate cancer and well controlled hypertension who had multifocal kidney lesions identified on CT scan when he was diagnosed with prostate cancer. Biopsy revealed a dense interstitial infiltrate in tissue adjacent and away from the encapsulated lesions. No medications or disease could explain the interstitial nephritis. Clinically his creatinine has increased steadily from 1.8 mg/dL to 2.7 mg/dL over the last five years.

Results: Renal oncocytomas are rare but potentially important tumors. Diagnosis through histology is important because they can appear similar to malignant renal tumors. Pathological examination reveals a well-circumscribed collection of oncocytes with a central scar, devoid of necrosis or vascular inflammation. Treatment usually consists of radical or partial nephrectomy versus observation, and prognosis is excellent. Both of these patients demonstrate the importance of diagnosing renal involvement in patients with multifocal oncocytomas. Since surgery is not possible for these multifocal and bilateral kidney lesions, it is necessary to monitor these patients closely with the possibility of medically treating the underlying inflammation if unexplained rises in creatinine ensue.

Conclusions:

Erythropoietin Producing Glioblastoma Multiforme in a Patient with ESRD Min Naing,[1] Farhanah Yousaf,[1] Andres A. Urrutia,[2] Volker H. Haase,[2] Alla Goldberg,[1] Bruce S. Spinowitz.[1] *[1]Nephrology, New York Presbyterian Queens, Flushing, NY; [2]Vanderbilt University Medical Center, Nashville, TN.*

Background: Elevated hemoglobin (Hgb) is rare in patients undergoing hemodialysis and may be associated with malignancy, polycythemia vera, nephroangiosclerosis, lung or liver disease or acquired cystic kidney disease. We report a rare case of elevated Hgb associated with glioblastoma multiforme (GBM).

Methods: A 66-year-old, white, non-Hispanic male with history of hypertension, diabetes mellitus type 2, dyslipidemia, secondary hyperparathyroidism on maintenance hemodialysis since March 2010 presented to our center in May 2015 with elevated Hgb. Physical exam was unremarkable. Patient's erythropoietin (EPO) level was elevated to 42.7 mIU/mL during 2014 but evaluation for erythrocytosis did not reveal any suspicious lesion on abdominal ultrasound. The EPO level continued to rise to 116 mIU/mL with Hgb 18 g/dL and JAK-2 V617F mutation analysis was negative by July 2015. An EPO producing tumor seemed likely but only splenomegaly was evident on CT abdomen and pelvis. On March 2016, transferrin saturation had fallen to 17% and ferritin was 60 ng/mL with a resultant Hgb drop (10 g/dL) and received 2 doses of 300 mg of IV iron sucrose which increased Hgb to 11.4 g/dL. Leukocytes and platelets remained in the normal range. In April 2016, patient was evaluated for depression and memory problems. All the tests were unremarkable except elevated thyroid stimulating hormone. CT head revealed a right frontal GBM which was resected and he underwent radiation therapy. Hgb fell and he received multiple blood transfusions while ESAs were contraindicated. Two months post resection, EPO level was 9.4 mIU/mL. He expired in Oct 2016 after withdrawing from hemodialysis. GBM tissue sample slides were analyzed using EPO mRNA fluorescent in situ hybridization which showed low levels of EPO mRNA throughout the GBM tissue sample except in necrotic areas.

Results:

Conclusions: This is the first case report of an EPO producing GBM. The expression of EPO mRNA in the GBM tissue and the temporal relationship of changes in EPO and Hgb levels with respect to the GBM resection strongly support GBM as the ectopic EPO production site.

SA-PO1024

Autoantibodies: Novel Biomarkers for Diagnosing Malignancy? Divyanshu Malhotra,[1] Maryam Gondal,[1] Randy L. Luciano.[2] *[1]Yale New Haven Hospital, New Haven, CT; [2]Yale University School of Medicine, New Haven, CT.*

Background: ANA and related autoantibodies can be detected with a variable frequency in patients with Lymphoma. However, a majority of these patients do not display features of any underlying autoimmune disease. The exact patho-physiological significance of these is not well defined at this time. Here we present a case of positive autoantibodies in a patient with T-cell Lymphoma and membranous nephropathy which initially posed a diagnostic dilemma.

Methods: 37 year old male with an unremarkable past medical history was admitted for fatigue, lethargy, anorexia and weight loss. He had been experiencing shortness of breath with exertion and also noted that his urine was foamy. He was taking naproxen infrequently for generalized pain. Physical exam was remarkable for significant peripheral edema. Labs revealed a BUN 48 mg/dl, Cr 3.2 mg/dl, phosphorus 5.8 mg/dl, Hgb 7.1g/dl, Platelet count 30000, Albumin 2.2 g/dl and Urine Pr/Cr 5 g/g. Urine analysis showed a mix of isomorphic and dysmorphic RBCs however no casts were noted. Autoimmune work up was positive for ANA, AntidsDNA, AntiSm, AntiSm/RNP and Anti SS-B. However he did not meet the criteria for SLE and did not have any clinical features consistent with other autoimmune conditions. Thus a further work up was planned. Renal US was remarkable for echogenic right and left kidney measuring 12.7 cm and 13.8 cm respectively. Renal Biopsy was consistent with membranous nephropathy with negative immunofluorescence. Bone Marrow biopsy was performed and was consistent with T-cell lymphoma and this prompted initiation of chemotherapy. Unfortunately, despite therapy his disease progressed with multi-organ involvement and patient was transitioned to hospice care.

Results:

Conclusions: A wide spectrum of renal lesions can be observed in patients with T-Cell Lymphoma including glomerulonephritis, acute kidney injury and parenchymal infiltration. This case is unique, as the autoimmune markers were not related to the glomerulonephritis but independently associated with the T-Cell Lymphoma. In small retrospective analyses it is interesting to note that these autoantibodies were generally not assocaited with underlying auto-immune conditions, were seen more commonly in men and did not appear to have any significant prognositc significance. Thus it is important to recognize this entity and look for underlying malignancies when the clinical features do not corelate.

SA-PO1025

Resistant Edema – Management of Chronic Systemic Capillary Leak Syndrome with IVIG Ryan Mullane, Eric D. Langewisch, Troy J. Plumb. *University of Nebraska Medical Center, Omaha, NE.*

Background: Systemic capillary leak syndrome (SCLS) is a rare, poorly understood disorder characterized by increased vascular permeability. It presents with intermittent acute episodes of profound capillary leak that may result in hypotension/shock. There are few reported cases of chronic SCLS, which is characterized by persistent refractory edema and pleural effusions. We present a case of chronic SCLS where ongoing treatment with intravenous immunoglobulin (IVIG) has resulted in a marked and sustained improvement in the signs and symptoms of the capillary leak syndrome.

Methods: A 54-year-old man presented with new onset lower extremity edema, which initially responded to oral diuretics. However, his edema later worsened with the development of upper extremity edema, bilateral pleural effusions and a total fluid weight gain of 20 kg which was refractory to diuretics. He required ultrafiltration for fluid removal in addition to recurrent thoracentesis for his pleural effusions. Evaluation revealed hypoalbuminemia and an IgG kappa monoclonal gammopathy, but bone marrow biopsy was normal. Cardiac, renal, hepatic and lymphatic evaluations failed to disclose an etiology for his edema. Initial therapy with theophylline was discontinued due to significant chest discomfort. Initiation of IVIG 1 g/kg every 4 weeks for a period of 4 months and then maintenance therapy every 6 weeks has resulted in a significant and persistent improvement over the past 18 months.

Results:

Conclusions: Systemic capillary leak syndrome presents with recurrent episodes of generalized edema, hypotension and hypoalbuminemia. Although the pathogenesis is unknown, IVIG decreases the occurrence of episodes in the acute form of SCLS. Few cases of the chronic form of SCLS are reported in the literature with prior treatments including theophylline, terbutaline and steroids. There have been no prior reports of IVIG therapy for chronic SCLS. Our patient had significant and durable improvement of refractory edema related to chronic systemic capillary leak syndrome with IVIG. This case demonstrates that IVIG may be an effective treatment modality for the chronic form of this disorder.

SA-PO982

Canagliflozin Associated Fanconi Syndrome Don H. Esprit,[1] Abhilash Koratala.[2] *[1]University of Florida, Gainesville, FL; [2]University of Florida, Gainesville, FL.*

Background: Sodium-glucose cotransporter-2 (SGLT2) inhibitors have gained popularity due to convenient, once-daily oral dosing and their association with weight loss, lower blood pressure, and a low risk of hypoglycemia as well as lower cardiovascular mortality as with empagliflozin. However, with the increasing use of these drugs, there have been increased reports of adverse effects as well. Herein, we present the case of a diabetic patient on canagliflozin who presented with EuDKA and found to have proximal renal tubular acidosis with Fanconi syndrome that was attributable to the drug. To the best of our knowledge, this is the second such case in the literature.

Methods: A 54-year-old Caucasian woman with a past medical history of type 2 diabetes mellitus, hypertension, coronary artery disease, and hyperlipidemia has originally presented with chest pain and found to have EuDKA. Her blood glucose was 175 mg/dL but had anion gap metabolic acidosis with a serum bicarbonate of 9 mmol/L (22-28) and elevated beta-hydroxybutyrate. Serum lactate was 0.65 mmol/L (0.3-1.5). Her medications consisted of canagliflozin 300 mg daily, metformin 500 mg twice daily, lisinopril 10 mg daily and atorvastatin 20 mg daily. She was treated with insulin until the anion gap closed and then was switched to oral medications. However, she was noted to have persistent non-anion gap metabolic acidosis and hypophosphatemia. Urinalysis was significant for glycosuria, which is expected with SGLT2 inhibitor use. Interestingly, she was found to have phosphaturia with a fractional excretion of phosphate of 23% (normal <5) with a serum phosphate of 1.8 mg/dL (2.7-4.5) and generalized aminoaciduria with prominent excretion of glycine suggesting impaired renal tubular function. On reviewing her old labs, she was found to have some degree of persistent non-anion gap metabolic acidosis for the past 2 years, which temporally correlates with canagliflozin therapy. We discontinued this medication in favor of home insulin therapy. Her renal function remained normal during this period.

Results:

Conclusions: While we do not have follow up data on whether the patient's laboratory abnormalities resolved after discontinuation of the drug, we recommend that clinicians be aware of the emerging side effects of SGLT2 inhibitors and closely monitor the metabolic profile of these patients.

SA-PO983

Severe Partial Fanconi Syndrome with Nephrogenic Diabetes Insipidus After Initiation of the Newer "Non-Nephrotoxic" Tenofovir Alafenamide Fumarate Connor Deal, Daniel C. Andreoli, Roger A. Rodby. *Rush University Medical Center, Chicago, IL.*

Background: Tenofovir disoproxil fumarate (TDF) is one of the more commonly used antiretroviral agents and is a well-established cause of renal tubular toxicity which may manifest as partial or complete Fanconi syndrome, AKI, CKD and rarely nephrogenic diabetes insipidus (NDI). Tenofovir Alafenamide Fumarate (TAF), a prodrug of tenofovir (FDA approved in 11/16), has a larger volume of distribution requiring a lower dose to achieve the same antiviral effect and thus has yet to demonstrate the nephrotoxicity associated with TDF. We describe a patient receiving TAF who developed severe hypokalemia (K), hypophosphatemia (PO4) leading to rhabdomyolysis, in addition to NDI, all of which resolved with cessation of the TAF.

Methods: A 35-year-old male with HIV presented with 2-days of proximal muscle weakness and tenderness. He had been started on Genvoya (elvitegravir, cobicistat, emtricitabine, TAF) 2-weeks prior. On presentation, his serum creatinine was normal at 0.8 mg/dL, PO4 < 0.7 mg/dL and K 2.0 mmol/L, with rhabdomyolysis (CPK 10,769 U/L). The serum HCO3 was normal and glycosuria was not present. He did not develop AKI. Initial urine studies showed K and PO4 wasting (see Table). The patient was polyuric with 24-hour urine of 6.1 L/d. A random urine osmolality was 179 mosm/kg with a serum Na of 147 mmol/L. 16 units of ADH were administered IV and a Uosm was 165 mosm/kg at 2 hours, confirming a diagnosis of partial NDI. The TAF was discontinued upon admission and after aggressive K and PO4 repletion, these values normalized and remained normal without further need for supplementation. His polyuria similarly resolved with a urine output of 1-2 L/d.

Results:

Conclusions: TAF is a newer form of tenofovir felt to have minimal nephrotoxicity. This patient developed both proximal and distal tubular defects following the initiation of TAF that were identical to that described with TDF. The timing of the presentation relative to starting TAF, and the complete resolution after TAF discontinuation suggests a direct causative effect.

Initial Blood and Urine tests

Serum PO4 (mg/dl)	<0.7
Fractional excretion of PO4 (%)	38
Serum K (mmol/l)	2.0
Fractional excretion of K (%)	8.2
Urine K/creatinine ratio (meq/g)	33

SA-PO984

A "Paint"ed Picture of RTA Amaleswari Pamarthy, Juan A. Medaura. *UMMC, Madison, MS.*

Background: Toluene is by far the most commonly inhaled volatile drug. It is used in various ubiquitous products such as paints, paint thinners, glues, adhesives and cleaning products. It is easily accessible and of low cost. It is hard to control or regulate as well. Acute toluene toxicity causes neurological changes as well as various metabolic alterations and almost all organs suffer from some form of alteration. Case reports from 1950's described it as "sudden sniffing death" which could be due to malignant ventricular arrhythmias. Hypokalemic paralysis and renal failure are other life-threatening complications. Neurological sequelae including memory and learning deficits can persists for years.

Methods: 44year old female presented with 1week history of nausea, vomiting and diarrhea. In ER, She was found to be drowsy and lethargic, got intubated for airway protection. She was afebrile with blood pressure of 152/73mm of hg. EKG showed ventricular bigeminy and prolonged QTc interval. Labs showed mild AKI, severe hypokalemia (<2mmol/L), severe non-anion gap metabolic acidosis(<7). Drug and volatile screen positive for benzodiazepines only. No serum osmolar gap noted. Etiology was not clear but initially was thought to be secondary to diarrhea. She was started on aggressive bicarbonate and potassium repletion. Positive urine anion gap and clinical picture suggested distal RTA. Further history was available from patient's family. Reportedly patient is addicted to inhalant paint and might have snuffed the paint in a trip a week ago. After 2 days she became more awake but could not move which was thought to be secondary to hypokalemic periodic paralysis. With all the supportive management patient recovered well without any focal deficits.

Results:

Conclusions: Inhalant abuse can result in a wide array of pathology on most of organ systems. Inhalant drugs are notoriously difficult to capture on laboratory testing. A detailed history is the key to diagnosis. Meticulous clinical assessment not to miss any underlying causes of RTA is critical. The most important role of laboratory testing is to assess the effects of inhalants on other organ systems which can be the clue to diagnosis. Studies indicate there is clearly overproduction of hippuric acid and overt reduction of excretion of net acid (NH4+) excretion in urine, hence checking them in urine might be of value.

SA-PO985

Ibuprofen Induced Renal Tubular Acidosis Muhammad Y. Jan,[3] Mirza M. Baig,[1] Tarek M. El-Achkar.[2] *[1]Nephrology, Indiana University, Indianapolis, IN; [2]Nephrology, Indiana University, Indianapolis, IN; [3]Internal Medicine, Indiana University School of Medicine, Indianapolis, IN.*

Background: Ibuprofen is a widely available over the counter analgesic. We report a rare but potentially fatal case of renal tubular acidosis (RTA) from ibuprofen overuse.

Methods: A 58 year old African American male with no past medical history presented to the emergency department with complaints of generalized upper and lower extremity weakness 2 weeks after undergoing dental extraction. This was associated with poor oral intake. He reported taking up to 60 pills of 200mg Ibuprofen daily for 10 days (up to 12 grams/day) for pain. He denied diarrhea or vomiting. Physical exam showed normal vital signs and generalized weakness in all extremities, with preserved reflexes and sensation. History was negative for autoimmune diseases and any other medication use. Lab results showed serum potassium of 1.8mmol/l (3.5-5.5), creatinine of 2.79mg/dl (0.6-1.1), bicarbonate of 10mmol/l (21-32), chloride of 110mmol/l (98-106), blood urea nitrogen of 69 mg/dl (7-18), phosphorus of 2.3mg/dl (2.5-4.9 mg/dl) and normal sodium level. Venous blood gas showed a pH of 7.10 (7.35-7.45) and pCO2 of 33 mm Hg (35-48). Urine pH was 6.0(5-8) with a positive urine anion gap. Serum alcohol, acetone, isopropyl alcohol, methanol, salicylate, acetaminophen levels and urine drug screen was negative. Thyroid stimulating hormone level and kidney ultrasound were normal. Given the severe non anion gap metabolic acidosis, he was diagnosed with distal renal tubular acidosis due to ibuprofen overuse, in the absence of other identifiable etiology. He was admitted to the intensive care unit for monitoring due to severe acidosis and wide QRS interval on electrocardiogram. He was managed with intravenous fluids and potassium repletion, followed by sodium bicarbonate infusion and oral citrate. His motor strength gradually improved over 4 days and he was discharged home, after correction of the metabolic acidosis and normalization of kidney function.

Results:

Conclusions: Ibuprofen is known to inhibit carbonic anhydrase enzyme in the renal proximal tubule as well as the collecting ducts and can cause proximal as well as distal RTA. Timely repletion of potassium prior to correction of acidosis is vital in preventing fatal arrhythmias. Ibuprofen toxicity should be considered in the differential diagnosis of patients who present with severe hypokalemia and metabolic acidosis.

SA-PO986

An Unusual Cause of Delirium: Ibuprofen Induced Renal Tubular Acidosis Roulan Abu hwij, Dima Jaradat, Aziz Bakhous. *cleveland clinic-akron general, Akron, OH.*

Background: Ibuprofen is one of the easily accessible over the counter (OTC) medication, general population perceive it as nonharmful. Few cases in the literature reported ibuprofen as a cause of distal renal tubular acidosis (dRTA) associated life-threatening hypokalemia. It is hypothesized that carbonic anhydrase (CA) inhibition may play a role in the pathogenesis of ibuprofen-induced dRTA.

Methods: Our 65-year-old female patient presented to the ER with altered mental status, she has a history of fibromyalgia, chronic pain syndrome and hypertension. laboratory workup showed K of 2.2, HCO3 9, BUN 18, Cr 0.69, AG 12, Mg 2. Urine studies showed K of 13, Na 63, CL 71, urinary anion gap 5, urine PH 6.5 and her VBG revealed PH of 7.179. Serologic studies including ANA, C3, C4, RF, anti-ccp and urine protein electrophoresis were all unremarkable. Patient was managed supportively with bicarbonate infusion and potassium replacement. We discontinued iboprofen. Her mental status improved gradually. Our patient was diagnosed with RTA type 1. Ibuprofen is the presumed underlying culprit as she had more than 6 months of daily use of ibuprofen 800 mg bid. After ibuprofen was stopped and with supportive management her symptoms as well as her labs improved. No other etiologies were identified including auto-immune diseases (Rheumatoid arthritis, Sjogren's syndrome, Multiple myeloma). No family history of dRTA was identified.

Results:

Conclusions: This case highlights the association between ibuprofen use and dRTA. We hope to raise awareness among the general population and physicians regarding the need for more strict NSAID use "an OTC drug".

SA-PO987

Simultaneous Renal Tubular Acidosis and Nephrogenic Diabetes Insipidus in a Patient with Sjogren's Syndrome Mohamad A. Hanouneh, Steven Menez, Jose M. Monroy-Trujillo. *Department of Medicine, Division of Nephrology, Johns Hopkins University, Baltimore, MD.*

Background: There are several renal manifestations of Sjogren's Disease. Among them are distal and proximal renal tubular acidosis, diabetes insipidus, tubulointerstitial nephritis. However, it is unusual to find multiple manifestations simultaneously.

Methods: 39 year old woman with medical history significant for anorexia nervosa (BMI 17 kg/m2) was transferred to psychiatric unit for management of eating disorder. She additionally had nausea, vomiting, polyuria and polydipsia. She complained of longstanding dry eyes and mouth. She described prolonged history of joint pain and

recurrent nephrolithiasis. She was only taking Sertraline 100 mg twice a day. Vitals were normal. Mucous membranes were significantly dry. She had significant digital clubbing. Cardiac, pulmonary, and neurological exams were normal. Urine output was 4-5 L/daily. Workup revealed non-anion gap metabolic acidosis with hypokalemia (serum sodium 138 mmol/L, serum potassium 3.0 mmol/L, sodium HCO3 20 mmol/L, serum chloride 108 mmol/L). Serum creatinine was 1.1 mg/dL which was stable over the prior year. Urine anion gap had a positive value. (Urine sodium 20 mmol/L, urine potassium 10 mmol/L, urine chloride 21 mmol/L) and urine osmolality 130 mosm/kg. CT abdomen showed bilateral nephrocalcinosis with no hydronephrosis. She was diagnosed with distal renal tubular acidosis. Regarding polyuria and polydipsia, diabetes insipidus was suspected given development of hypernatremia (her serum Na trended up to 145 mmol/L) and low urine osmolality (Urine Osmolality was 150 mosm/kg at that time). Patient received desmopressin with no significant change in urine volume and urine osmolality. Anti-nuclear antibodies (ANA) and Ro antibodies were strongly positive. Schirmer's test confirmed the finding of dry eyes. She was diagnosed with Sjogren's syndrome based on The American College of Rheumatology (ACR) criteria. Patient was treated symptomatically with eye drops, recommended to continue oral hydration driven by thirst and to have water available at all times. She was also started on hydroxychloroquine 200 mg PO daily. She did not tolerate potassium citrate given GI symptoms.

Results:

Conclusions: Distal RTA with nephrocalcinosis and nephrogenic DI are known renal manifestations of Sjogren 's syndrome. However, it is unusual to find both manifestations simultaneously.

SA-PO988

Sweet and Salty: A Rare Case of Concomitant Nephrogenic Diabetes Insipidus and Fanconi Syndrome Induced by Tenofovir Mario J. Robles-Franceschini,[3] Hashim K. Mohmand,[4] Lisa M. Sebastian,[3] Elena Chen,[2] Andrew Coppola.[1] *[1]Baylor Family Medicine Residency at Garland, Garland, TX; [2]Texas A&M College of Medicine, Plano, TX; [3]Nephrology Division, Methodist Dallas Medical Center, Dallas, TX; [4]Nephrology, Dallas Nephrology Associates, Garland, TX.*

Background: Tenofovir is widely used in combination with other antivirals for treatment of patients with HIV. It has been well reported to be nephrotoxic, but reports of hypernatremia are rare. This case is unusual in having concomitant presentation of Fanconi Syndrome and Nephrogenic Diabetes Insipidus.

Methods: A 21 year old female with history of cerebral palsy, seizures, and HIV was brought to ER with one week history of decreased oral intake, decreased responsiveness, and higher than usual urine output despite poor oral intake. Home medications included Divalproex, Baclofen, Tenofovir disoproxil combined with Elvitegravir/Cobicistat/Emtricitabine. Physical examination was remarkable for cachexia, hypotension, and tachycardia. Initial labs showed Na 162 mmol/L, K 2.0 mmol/L, CL 131 mmol/L, CO2 19 mmol/L, Phos 2.0 mg/dL, BUN 25 mg/dL, and Cr 1.4 mg/dL (baseline creatinine was 0.5 mg/dL). Hypernatremia did not correct after appropriate volume expansion and free water administration. She continued with significant polyuria (4L urine/d) and low urine osmolality (158 mOsm/kg), consistent with diabetes insipidus. She did not respond to conventional dosing of DDAVP therapy. Further testing revealed aminoaciduria, glycosuria with normoglycemia, hypophosphatemia with inappropriate phosphaturia, consistent with Fanconi Syndrome. Management consisted of discontinuation of Tenofovir, administration of free water through PEG tube, and bicarbonate, potassium, and phosphorus replacement. The patient's electrolytes normalized with treatment and was discharged.

Results:

Conclusions: The most common renal complications of Tenofovir are glycosuria and AKI. The simultaneous presentation of Nephrogenic Diabetes insipidus and Fanconi Syndrome is a rare complication of Tenofovir. It is important to recognize that Tenofovir nephrotoxicity is not limited to the proximal tubule, but that can also affect other segments of the nephron. Nephrologists should be suspicious of this potential complication in patients who take Tenofovir and present with hypernatremia.

SA-PO989

Double Trouble: Severe Hypernatremia Secondary to Central Diabetes Insipidus (DI) Complicated by Hypercalcemic Nephrogenic DI: A Case Report Waqas J. Siddiqui,[1] Muhammad abdullah Yousaf,[2] Zehra Tauqir,[2] Sandeep Aggarwal.[1] *[1]Drexel University College of Medicine, Levittown, PA; [2]Rawalpindi Medical University, LANSDALE, PA.*

Background: Patients with advanced malignancies often have electrolyte abnormalities. We present a case of patient with central DI secondary to metastatic pituitary invasion complicated by hypercalcemic nephrogenic DI.

Methods: 40 year old female with history of stage IV Breast Ca including skeletal and leptomeningeal metastasis with compression of optic chiasm and pituitary with central DI, baseline labs shown in table 1, was admitted with confusion. Patient's husband stated that she had been constantly thirsty, drinking "gallons" of water in the recent past and making a lot of urine. Pertinent vitals and physical exam showed: BP = 134/76 mmHg and heart rate = 130/minute, patient was confused, sunken eyes, flat neck veins, and tachycardia and reduced skin turgor. Patient was found to have severe hypercalcemia and profound hypernatremia (Electrolytes and urine output are summarized in table 1). Other relevant labs: PTH = 24 pg/mL, PTH-rp = 2.4 pmol/L and 25-OH Vitamin D = 25.9ng/mL. Patient received 5% dextrose for rehydration, one dose of Intravenous (IV) Pamidronate 90 mg, one dose of IV Desmopressin 2mcg and 4 days of subcutaneous Calcitonin 200 International Units Q12H was given. Initially Patient's urine output in the hospital was in the range of 350 – 400 mL/hour which responded well to one dose of DDAVP. In the subsequent days, patient's serum sodium and calcium normalized but she died because of the extensive malignancy.

Results:

Conclusions: Our case emphasizes the importance of identification of causes and complications of electrolyte abnormalities associated with metastatic cancers. These electrolyte abnormalities can be primary or paraneoplastic and should be actively pursued and treated in such cases.

Table 1: Urine and serum electrolyte and Urine output trends

Timeline/Trends	Serum Na meq/L	Serum Osmolality msom/kg	Urine Na mmol/L	Urine Osmolality msom/kg	Serum Ca mg/dL	Urine output ml/hour
Baseline - Prior to admission	151	334	20	115	8.8	N/A
At admission – Day 0	167	347	72	185	16.5	350 - 450
Day 1 (DDAVP + Calcitonin + Pamidtronate)	158	N/A	189	451	12.2	100 - 150
Day 2	158	N/A	N/A	N/A	11.5	50 - 150
Day 3	148	303	151	455	9.3	75 - 150

Na = Sodium; Ca = Calcium; N/A = Not available; DDAVP = Desmopressin; msom = milliosmoles; kg= Kilogram; mmol = millimoles; mg = milligrams; dL = deciliter; L = liters; mL = milliliters

SA-PO990

A Case of Hypophosphatemia Due to Ferric Carboxymaltose Induced Renal Phosphate Wasting Tramanh Phan, Scott E. Liebman. *University of Rochester Medical Center, Rochester, NY.*

Background: Hypophosphatemia due to renal phosphate wasting typically results from either hyperparathyroidism or as part of global proximal tubular dysfunction as in Fanconi syndrome. Isolated renal phosphate wasting is rare, but has been described with ferric carboxymaltose (FCM). Here we report a case of transient, but symptomatic hypophosphatemia due to renal phosphate wasting in the setting of FCM infusion.

Methods: A 26-year-old male with a past medical history of ulcerative colitis status post total colectomy and J pouch creation three years prior presented for evaluation of hypophosphatemia. He initially saw his primary care physician complaining of diffuse bone pain. Laboratory studies at that time showed a phosphorus level of 1.5 mg/dL. He did not note any gastrointestinal symptoms, and noted his ostomy output was unchanged from baseline. He did not have any prior history of hypophosphatemia except immediately post-operative following his colectomy. He was not taking any medications known to cause hypophosphatemia, but review of his past medical history showed that he had iron deficiency and had received FCM two days prior to symptom onset. His physical examination was benign and did not show any musculoskeletal abnormalities. Further work up revealed a fractional excretion of phosphate (FE_{PO4}) of 25.5%, normal calcium, parathyroid hormone and 25-OH vitamin D levels, and the absence of glucose in the urine indicating a primary, isolated renal phosphate wasting disorder, suspected due to receipt of FCM. FGF-23 levels were not obtained. He was started on an oral phosphate supplement with subsequent normalization of serum phosphorus and resolution of the bone pain within several days. His phosphorus remained normal and oral phosphate supplements were discontinued six weeks later. Two weeks thereafter, his phosphorus level was maintained off supplementation and his FE_{PO4} was 9.3%.

Results:

Conclusions: FCM is a convenient treatment option for iron deficiency as it only requires a single infusion. Clinicians should be aware of the association between FCM and hypophosphatemia, and consider this diagnosis in patients who present with symptoms consistent with hypophosphatemia after infusion.

SA-PO991

Refractory Hypokalemia Secondary to Intestinal Pseudo-Obstruction Vijaya Kumar Gorantla,[1] Geeta G. Gyamlani,[2] Barry M. Wall.[2] *[1]Nephrology, University of Tennessee Health Science Center, Memphis, TN; [2]Veterans Affairs Medical Center, Memphis, TN.*

Background: Intestinal pseudo-obstruction, a functional obstruction of the bowel seen in multiple medical and surgical conditions, is likely due to autonomic imbalance. Water and electrolytes can be sequestrated in dilated intestinal loops resulting in profuse watery diarrhea and hypokalemia. This is likely mediated by upregulation of BK channels in colonic mucosa, which are thought to be responsible for hypersecretion of potassium, which drives the osmotic diarrhea. Stool potassium concentrations are significantly elevated.

Methods: A 64-year old male with hypertension, GERD, muscular weakness and alcoholism was admitted for evaluation of hypotension and electrolyte abnormalities: serum potassium 1.4mEq/L, magnesium 1.3mg/dL and calcium 7.2mg/dL for which oral and intravenous replacement was initiated. Due to persistent hypokalemia (<2.5mEq/L) Nephrology was consulted. On initial examination, he was afebrile, normotensive, appeared thin built with soft, distended abdomen with hyperactive bowel sounds and poor muscle tone. Abdominal X-ray showed adynamic ileus. After evaluation, proton pump inhibitor intake and alcoholism were thought to be the cause and were discontinued and potassium replacement was continued. Renin (<0.15ng/ml/hr), aldosterone(<1ng/dL), random urine potassium (7 meq/L), creatinine, osmolality were measured to calculate fractional excretion of potassium (2%) and transtubular potassium gradient (TTKG) (<2) suggesting extrarenal potassium losses. He continued to have abdominal distention with intermittent profuse watery diarrhea. Infectious and GI workup, including colonic

mucosal biopsies were negative. He had recurrent admissions for abdominal distention, diarrhea and hypokalemia. Abdominal imaging continued to show dilated loops of small bowel and colon (>13cm). Stool electrolytes were measured as sodium (<20mEq/L) and potassium (162mEq/L). This pattern was consistent with intestinal pseudo-obstruction causing extrarenal potassium loss.

Results:

Conclusions: Clinicians should be aware of this unusual etiology for extrarenal potassium wasting and the need for aggressive potassium replacement until the pseudo obstruction resolves. Measurement of stool electrolytes are necessary to confirm the etiology of the refractory hypokalemia.

SA-PO992

Hypokalemia in Pregnancy: A Case of Maternal Bartter Syndrome Savannah Vogel,[1] Daniel Guerra Rodas,[2] Sana Waheed.[1] *[1]University of Wisconsin - Madison, Madison, WI; [2]University of Wisconsin Hospital and Clinics, Middleton, WI.*

Background: Bartter Syndrome (BS) type 3, a rare autosomal recessive renal tubular disorder caused by a mutation in the CIC-Kb chloride channel in the ascending loop of Henle, is characterized by a post-natal presentation of hypokalemia, metabolic alkalosis, hypomagnesemia and failure to thrive. Here, we report a case of the management of BS during pregnancy.

Methods: A 22-year-old G1P0 female presented to us at 19w0d gestation for management of BS diagnosed at 6 months of age. Prior to her pregnancy, she was managed with indomethacin 50mg QD, spironolactone 25mg BID and potassium chloride (KCl) 30mEq BID. Due to the risk of fetal complications, these medications were discontinued, amiloride was added at 10mg QD and KCl supplementation was increased. Potassium levels stabilized after an eight-week titration period up to 10mg BID amiloride and 400mEq QD potassium. Her potassium levels remained stable between 3.2-3.7 mEq/L for the remainder of the pregnancy. The patient delivered a healthy male infant with Apgar scores of 9 at 1 and 5 minutes by spontaneous vaginal delivery at 38w5d. Amiloride was discontinued at the start of labor and the patient was given potassium and magnesium supplementation throughout labor, delivery and her postpartum hospital stay. Following delivery, as patient was breastfeeding, indomethacin was restarted at 50 mg QD and potassium supplementation was titrated down to 30mEq BID. Postpartum potassium levels stabilized in the range of 3.4-3.6 mEq/L.

Results:

Conclusions: Patients with Bartter Syndrome often experience severe metabolic disturbances without treatment. NSAIDs, aldosterone antagonists and ACE inhibitors are considered the mainstay of treatment, however, these drugs have documented fetal side effects and thus cannot be safely used during pregnancy. Management of BS in pregnancy is further complicated by increased potassium needs due to increased volume of distribution. In our patient, we successfully used amiloride, a class B drug during pregnancy, along with increased KCl supplementation to maintain serum potassium levels. She was able to tolerate the high dose of KCl 400mEq QD without any complications. Due to concerns for its safety in breastfeeding, amiloride was discontinued at the initiation of labor and replaced with indomethacin and patient's post-partum potassium levels were again stabilized.

SA-PO993

Hypokalemic Periodic Paralysis Possibly Precipitated by Amphetamine Abuse Rashna Shetty,[4] Liang Wang,[1] Justin Hoskin,[5] Saisridhar Boddupalli,[2] Ibrahim Qaqish.[3] *[1]Barrow Neurological Institute, Phoenix, AZ; [2]Dignity Health, Scottsdale, AZ; [3]Mayo Clinic, Scottsdale, AZ; [4]ST. JOSEPH'S HOSPITAL AND MEDICAL CENTER, PHOENIX, AR; [5]Barrow Neurological Society, Phoenix, AZ.*

Background: We describe a rare case of acute hypokalemic paralysis associated with the abuse of methamphetamine.

Methods: A 28-year year old Caucasian male with a history of polysubstance abuse presented to the emergency department with a chief complaint of painless bilateral lower extremity paralysis that developed over several hours. He denies vomiting, diarrhea, diuretic use or previous similar episodes. He denied any trauma to the back or heavy carbohydrate diet preceding this event. Physical exam revealed normal vital signs and bilateral lower extremity muscle weakness; proximal greater than distal with hyporeflexia. Cranial nerves were intact. Initial serum potassium was 2.4mmol/L. Urine drug screen was positive for amphetamine and random urine potassium was 14 mmol/L. Serum magnesium and TSH were within normal limits. Electrocardiogram revealed no QT interval changes or U wave. Patient was started on careful supplementation with 30mEq of intravenous and 40 mEq of oral potassium chloride that increased the level to 4.9 mmol/L. This lead to slow but complete resolution of the paralysis causing the patient to be able to walk after six hours.

Results:

Conclusions: Hypokalemic periodic paralysis (HPP) is neuromuscular disorder characterized by episodes of painless muscle weakness. Most cases are hereditary from calcium channel mutations but acquired cases have been described. Usually there is an increased release of epinephrine or insulin causing potassium to shift into cells. Methamphetamine is an indirect sympathomimetic amine, although it lacks direct adrenergic stimulation, it inhibits presynaptic epinephrine and dopamine reuptake mediated adenosine triphosphate dependent (ATP) channels resulting and surge of both alpha and beta adrenergic effects. The main steps in the management include exclusion of other causes of hypokalemia, potassium replacement, close monitoring of the cardiac rhythm and serum potassium levels. While the mechanism of action of amphetamine explains the physiology of HPP, no cases have ever been reported of amphetamine induced HPP in literature.

SA-PO994

Unusual Case of Severe Hypokalemia, Metabolic Alkalosis, and Starvation Ketosis Nihar Jani, Iris J. Lee, Duncan B. Johnstone, Swati Rao. *Temple University School of Medicine, Philadelphia, PA.*

Background: Severe hypokalemia is a life threating emergency and requires prompt therapeutic and diagnostic intervention. Causes of inappropriate renal potassium (K) loss are traditionally divided into conditions based on concomitant acidosis or alkalosis. We present a case of severe hypokalemia with combined metabolic alkalosis and acidosis.

Methods: A 59 y/o African American male presented with 2 weeks of decreased oral intake due to severe food paranoia. He appeared malnourished and hypovolemic with BP 107/56mmHg. Laboratory data revealed K of 1.3 mEq/L, glucose of 134mg/dl, bicarbonate of 40 mEq/L, anion gap (AG) of 23, lactate 3.6mmol/l, arterial pH 7.56 and ketonuria. With aggressive K repletion (920 mEq oral and IV), K improved from 1.3 to 2.2mg/dl. Urine studies were consistent with renal K wasting: high urine K (27mEq/L), high TTKG (9.9) and high FeK (21%). Over the next few days, the patient increased his oral intake and starvation resolved along with normalization of patient's electrolyte derangements. Renal K handling normalized and the patient remained normokalemic with acid-base equilibrium.

Results:

Conclusions: In our case, identifying a unifying diagnosis of hypovolemia, renal K wasting with combined severe metabolic alkalosis and acidosis was challenging. Genetic (Bartter, Gittleman) and pathological (diuretic abuse) causes were considered given low blood pressure, K wasting and alkalosis. The AG acidosis however, remained unexplained and unaccounted for by the level of lactate. In our patient, a prolonged duration of starvation ketoacidosis addressed all metabolic findings. Starvation resulted in renal excretion of non-absorbable anions (ketones) along with increased obligatory loss of cations (such as K). Ensuing hypokalemia and hypovolemia caused and sustained a metabolic alkalosis, due to distal tubular exchange of K with hydrogen (H) via H-K ATPase and activation of H-ATPase. Normalization of severe electrolyte and acid-base disturbances as well as renal K handling after adequate nutrition, confirmed a transient reversible defect in renal K handling. Although ketone body production from starvation is commonly associated with metabolic acidosis, our case instead presented with alkalosis and alkalemia. We believe this is a rare presentation of severe hypokalemia and metabolic alkalosis due to starvation ketosis overwhelming renal tubular handling capacity.

SA-PO995

Watch What You Eat: An Unusual Cause of Hypercalcemia Muhannad Leghrouz, Abhilash Koratala, Jogiraju V. Tantravahi. *University of Florida, Gainesville, FL.*

Background: Primary hyperparathyroidism and malignancy are by far the most common causes of hypercalcemia, though the differential diagnosis is usually broad. Determining the etiology of hypercalcemia is the cornerstone of its management. Herein, we describe an interesting case of a patient who developed severe hypercalcemia as a result of "pica", which in turn was secondary to iron deficiency anemia.

Methods: A 66-year-old man with history of hypertension and diabetes mellitus type 2 has presented with fatigue, diarrhea, polyuria and hand tremors for 3 days. His vitals were stable. Laboratory values demonstrated acute kidney injury with a serum creatinine of 2.2 mg/dL (baseline ~1), hypercalcemia with serum calcium 14.8 mg/dL, and metabolic alkalosis with a bicarbonate level of 39 mmol/L. His hemoglobin was 10.7 g/dL. Patient denied taking any antacids, calcium or vitamin D supplements. His serum PTH was 15 pg/mL, PTH-related peptide and vitamin D level were not elevated. Protein electrophoresis was negative for paraproteinemia and age-appropriate cancer screening was apparently negative. He was found to be iron deficient with an iron saturation of 6% and on detailed questioning, he admitted to having an irresistible urge to eat small white stones from his backyard, which are found to be chalks, i.e., calcium carbonate [Figure 1]. This is the most likely cause for both his hypercalcemia and metabolic alkalosis. The patient was managed with counselling and further work up for his iron deficiency has been negative so far.

Results:

Conclusions: Pica is characterized by an appetite for substances that are largely non-nutritive, such as ice, paper, metal, paint, stones etc. It has been linked to iron deficiency and mental disorders of obsessive–compulsive spectrum. In our patient, pica has turned out to be the cause for hypercalcemia. Through this case report, we would like to emphasize the importance of "most inexpensive" investigation in the evaluation of hypercalcemia, i.e., "careful history taking".

SA-PO996

Hypercalcemia: Lung Nodules with a Pathological Fracture Are Not Always Indicative of Malignancy Omer Alrawi,[2] Ravi K. Thimmisetty,[2] Nehal Altaie,[1] Walid Ibrahim,[4] Yahya M. Osman Malik,[3] Nashat B. Imran.[2] *[1]Detroit medical center, Detroit, MI; [2]Wayne State University, Detroit, MI; [3]Wayne State University Medical School, Detroit, MI; [4]Wayne State University/ DMC, Dearborn, MI.*

Background: Hypercalcemia is a relatively common clinical problem. The initial goal of the laboratory evaluation is to differentiate parathyroid hormone (PTH)-mediated hypercalcemia from non-PTH mediated hypercalcemia. Although malignancy is the most common cause of non-PTH mediated hypercalcemia, other differentail should be considered specially in immunocompromised patients.

Methods: A 60-year old Asian female with past medical history inclusive for diabetes type 2, hypertension, chronic kidney disease stage 3, hepatitis B on treatment, myasthenia gravis on immunosuppressive treatment (prednisone, mycophenolate mofetil), and osteoporosis presented following a fall. Her x-ray showed a fracture of the left forearm and an incidental small left upper lobe lesion adjacent to the aorta. Chest CT scan confirmed the lesion and PET scan was suspicious for malignancy. Initial workup was remarkable for hypercalcemia at 11 mg/dl with inappropriate normal PTH (due to CKD 3). Left lobectomy with excision of 11 lymph nodes was done. Final report revealed giant cell granulomas and fungus consistent with cryptococcal infection. All lymph nodes were negative for malignancy and were sterile for anaerobic, aerobic, TB and other fungal culture. A serum cryptococcal antigen was positive at 1:4 titer. Brain imaging and CSF exam were negative for cryptococcal involvement. HIV testing was negative. Other workup showed High 1,25 Vitamin D at 148 pg/ml (normal range 15-75 pg/ml) with normal Vitamin D 25 at 42 ng/ml that is consistent with granulomatous process. She was started on fluconazole. Consequently, her calcium and cryptococcal antigen were normalized following 9 months of therapy.

Results:

Conclusions: This case demonstrates the importance of considering all differential diagnoses of non-PTH mediated hypercalcemia, which include granulomatous disorders, vitamin D intoxication, and malignancy. Before committing the patient to unnecessary procedures; it is imperative to have a tissue diagnosis to guide further surgical and medical management, especially in immunocompromised patients were infection is more common.

SA-PO997

The Great Masquerader: Persistent Hypercalcemia in a Multiple Myeloma Patient Kayla Shirley, Sean Verma, Claude Bassil. *University of South Florida, Tampa, FL.*

Background: Hypercalcemia is a commonly encountered electrolyte abnormality in multiple myeloma patients. We present a case of persistent hypercalcemia which was not fully explained by underlying multiple myeloma and did not respond to initial treatment, thus, alerting a concomitant disease process and new diagnosis.

Methods: A 60-year-old woman with lambda light chain multiple myeloma, CKD secondary to biopsy proven chronic tubular injury secondary to lambda light chain proximal tubulopathy, type 2 diabetes mellitus, and hypertension was found to have acute on chronic renal failure with creatinine of 3.5 mg/dl (baseline 2.8 mg/dl) and hypercalcemia with corrected calcium of 13.3 mg/dl on routine labs. The patient was previously treated with bortezomib, dexamethasone, and cyclophosphamide, followed by autologous hematopoietic stem cell transplant with appropriate response and was not currently receiving chemotherapy. Hypercalcemia was previously attributed to underlying multiple myeloma and tertiary hyperparathyroidism, however, responded incompletely to treatment with intravenous fluids and pamidronate. She underwent additional workup, with intact parathyroid hormone of 319.5 pg/ml, 25-hydroxy vitamin D of 10.8 ng/ml, and elevated 1, 25-dihydroxy vitamin D level of 109 pg/m. Parathyroid hormone related peptide was within normal limits. PET/CT revealed hypermetabolic supraclavicular, mediastinal, and hilar lymphadenopathy. Left supraclavicular lymph nodes were biopsied, revealing rare small lymphocytes, rare epithelioid cells and multinucleated giant cells, suggesting a granulomatous process. Angiotensin converting enzyme was 46 U/L. The patient was diagnosed with sarcoidosis and treated with prednisone with improvement in hypercalcemia and creatinine.

Results:

Conclusions: Hypercalcemia in patients with granulomatous disorders is driven primarily by elevated calcitriol concentrations, which serve to increase calcium absorption from the gut and resorption from bone. Treatment of hypercalcemia in this setting involves not only treating the underlying disease process, but reducing dietary calcium and vitamin D supplementation. While in multiple myeloma patients, hypercalcemia is likely related to underlying disease, the nephrologist should rule out less common etiologies in cases poorly responsive to traditional therapy.

SA-PO998

A Rare Case of De Novo Claudin 19 Mutation Nhi Tan, Aalia Akber, Sijie Zheng. *Kaiser Oakland Medical Center, OAKLAND, CA.*

Background: Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC) is an autosomal recessive disorder caused by mutations in the tight junction proteins claudins. Claudins play a key role in regulating paracellular transport of ions in the thick ascending loop of Henle. Mutations lead to decreased cell membrane permeability, limiting reabsorption of magnesium and calcium. FHHNC may present as nephrocalcinosis, vision defects, and renal failure in childhood. First described in 1972, more than 120 cases have been reported, though exact prevalence is unknown. Most cases are found within family clusters. We present a rare case of de novo claudin-19 mutation.

Methods: A 17-year-old Hispanic woman presented with 15 lb weight loss over 6 months, polyuria, and polydipsia. She had alwasy been a "picky eater" and shorter and thinner than her siblings. Past medical history noted macular dystrophy at age 3, and short stature less than fifth percentile and less than mid-parental height. Family history was unremarkable. Labs were notable for end stage renal disease with a creatinine of 7.3 mg/dl, secondary hyperparathyroidism, hyperphosphatemia of 6 mg/dl, hypocalcemia of 7.4 mg/dl, normocytic anemia of 8.9 g/dl, but surprisingly hypomagnesemia of 1.2 mg/dl and mild metabolic acidosis for the degree of renal failure. Ultrasound showed atrophic kidneys with nephrolithiasis. Peritoneal dialysis was initiated. Genetic testing revealed homozygous variant in CLDN 19 gene, NM_148960.2:c.59G>A(p.Gly20Asp). The variant p.Gly20Asp has been reported in heterozygous and homozygous individuals with FHHNC with ocular involvement and is the founder pathogenic variant in the Spanish and French population.

Results:

Conclusions: Treatment options are limited. Oral magnesium may be used to supplement tubular magnesium wasting. Amiloride can exert magnesium sparing effects. Thiazides increase calcium reabsorption in the distal tubule. None have significant effect and patients eventually progress to end stage renal disease. The only curative treatment is transplant, where calcium and magnesium excretion is normalized following transplant and there is no recurrence of the disease. In young patients who present with early ocular deficits, FHHNC should be evaluated. Given the limits of supportive care, and no recurrence of FHHNC with renal replacement, early transplant should be considered.

SA-PO999

12 Years of Intraperitoneal Magnesium Infusions for Gitelman Patient with Normal GFR Nasir Khan,[1] David Geller,[1,2] Margaret J. Bia.[1] *[1]Nephrology, Yale University School of Medicine, New Haven, CT; [2]Nephrology, West Haven VA Hospital, West Haven, CT.*

Background: Gitelman's Syndrome is an autosomal recessive salt-wasting renal tubular disorder characterized by hypokalemic metabolic alkalosis with hypomagnesemia that can be potentially life threatening. We report a case of Gitelman's Syndrome with use of peritoneal infusions in the setting of preserved renal function to manage these severe electrolyte complications.

Methods: A 57-year-old Caucasian female with longstanding history of muscle weakness and twitching, paresthesias and palpitations manifested at the time of her pregnancy at age 24 years when she was found to have severe hypomagnesemia and hypokalemia. She was presumptively diagnosed with Gitelman's Syndrome, a diagnosis confirmed genetically years later. She did not tolerate oral magnesium(Mg) replenishment due to severe gastrointestinal side effects. Intramuscular Mg replenishment was also attempted but this was complicated by recurrent boils at injection sites. She was diagnosed with idiopathic cardiomyopathy and heart block, both attributed to her electrolyte derangements, and a permanent pacemaker was placed. A Hickman catheter was placed to allow parenteral electrolyte repletion, but this led to multiple bouts of septicemia over a period of several years, caused by gram-positive, gram-negative and fungal infections. In addition she had several pacemaker lead changes, resorting to epicardial leads at times to avoid transvenous leads. Given her significant disease burden and electrolyte derangements, a peritoneal catheter was placed to attempt intraperitoneal(IP) infusion as a method to replenish Mg and potassium(K). Although she did not tolerate intraperitoneal K infusions (abdominal pain), she has now infused IP Mg for 12 years with relatively few complications and a significant improvement in her health and quality of life.

Results:

Conclusions: Gitelman's Syndrome is a hereditary cause of potentially severe hypokalemia and hypomagnesemia. Management of these electrolyte complications is challenging, and patients often suffer significant morbidity from both the electrolyte derangements and the efforts to control these derangements. We describe the successful use of IP infusions to manage a particularly challenging case of hypomagnesemia. We believe the unique characteristics of the peritoneal membrane make this modality an excellent option in patients in whom parenteral electrolyte repletion is considered necessary.

SA-PO1026

Furosemide Increases Green Fluorescent Protein-Arginine Vasopressin Expression in the Hypothalamus in Transgenic Rats Hiromichi Ueno,[1] Tetsu Miyamoto,[1] Kenichiro Bando,[2] Yutaka Otsuji,[2] Masahito Tamura,[1] Yoichi Ueta.[2] *[1]University of Occupational & Environmental Health, Kitakyushu, Japan; [2]University of Occupational and Environmental Health, Kitakyushu, Japan.*

Background: Furosemide is an essential medication for fluid overload by inhibiting sodium reabsorption in the Henle's loop, however, furosemide resistance is often observed in patients with kidney disease. Arginine vasopressin (AVP) is synthesized in the paraventricular nucleus (PVN) and the supraoptic nucleus (SON) of the hypothalamus, and increases water reabsorption in the collecting duct. Although previous studies have reported that furosemide activates the neurohumoral factors, AVP synthesis in the hypothalamus after peripheral administration of furosemide remains unclear.

Methods: Measurement of serum AVP levels is difficult because of its short half life (4-20 min). We therefore generated transgenic rats carrying a novel enhanced green fluorescent protein (eGFP)-AVP fusion gene. We examined AVP expression in the hypothalamus by observing fluorescence after intraperitoneal administration of furosemide in transgenic rats. We also investigated AVP gene expression using in situ hybridization histochemistry. Neuronal activity in the hypothalamus was examined by immunohistochemistry for Fos.

Results: After peripheral administration of furosemide in the transgenic rats, the fluorescence intensities in the SON and the magnocellular divisions of PVN (mPVN) were significantly increased. eGFP expressions in the SON and the mPVN were accompanied by Fos expression. Furthermore, AVP hnRNA levels in the SON and the mPVN were significantly increased after administration of furosemide.

Conclusions: We observed increased neuronal activity and AVP expression in the hypothalamus after peripheral administration of furosemide in eGFP-AVP transgenic rats. These results might account for one of the cause of furosemide resistance.

SA-PO1027

Fludrocortisone-Induced Production of Erythropoietin (Epo) in Mouse Kidney Nephron Yukiko Yasuoka,[2] Tomomi Oshima,[2] Yuichi Sato,[2] Hiroshi Nonoguchi,[3] Katsumasa Kawahara.[1] *[1]Dept of Physiol, Kitasato Univ School of Med, Sagamihara, Japan; [2]Kitasato University, Sagamihara, Japan; [3]Kitasato University Medical Center, Kitamoto, Japan.*

Background: Under normal conditions, Epo mRNA expression was small but clearly detected in kidney tubules, such as proximal convoluted tubule (PCT), medullary thick ascending limb (MTAL), distal convoluted tubule (DCT) and collecting ducts (CDs). The expression in the peritubular cells was observed only in hypoxic condition (7% O2, 4 hr). (Nagai, Yasuoka, et al, 2014). We investigated the effect of fludrocortisone (an aldosterone receptor agonist) on Epo mRNA in the mouse kidney.

Methods: Fludrocortisone of 2.5 mg/100 g BW was once applied to mice (C57BL/6J, male, 10 weeks) at time 0. Then, Epo, hypoxia-inducible factor 2α (HIF2α) and prolylhydroxylase 2 (PHD2) mRNAs expressions were evaluated at 2, 4, 6 and 72 hr using tyramide-ISH technique.

Results: After the injection, Epo mRNA expression was slightly increased in MTAL, and strongly increased in CCD and outer medullary CD (OMCD). However, it was never detected in the peritubular interstitial cells. The HIF2α mRNA was increased in glomerulus, PCT, TAL, DCT, CCD and OMCD as well as the peritubular cells of both kidney cortex and medulla. The PHD2 mRNA expression was also increased in PCT, TAL, DCT, CCD and OMCD. Epo, HIF2α and PHD2 mRNA expressions were increased in parallel at 4 hr after injection, and decreased to the original level at 72 hr.

Conclusions: Epo mRNA expression is increased only at renal tubule cells by stimulation of fludrocortisone. The regulation of the Epo expression by fludrocortisone is different from that by hypoxic stimulation.

SA-PO1028

Endoplasmic Reticulum Stress Induces Aminoaciduria Moeko Koga, Ayaka Kato, Hiroko Sonoda, Sayaka Oshikawa, Masahiro Ikeda. *Department of Veterinary Pharmacology, University of Miyazaki, Miyazaki, Japan.*

Background: Endoplasmic reticulum (ER) stress is caused by accumulation of misfolded proteins in the ER. ER stress is known to activate intracellular signaling pathway, named unfolded protein response (UPR). UPR has been reported to be involved in kidney disease, including acute kidney injury and diabetic nephropathy. However, the effect of ER stress on the renal physiological function is largely unknown. The purpose of this study is to clarify the effect of ER stress on the function, focusing on renal handling of amino acids.

Methods: Tunicamycin (TM), a ER stress inducer, was administered to rats by subrenal capsule injection. Urine samples were collected at 18-24 hours after injection. The composition of urinary amino acids was investigated by HPLC. Total RNA was extracted from the kidney 24 hours after administration.

Results: Real-time PCR and microarray analyses showed that GRP78 (known to be a marker for activation of the UPR) mRNA level dramatically increased in the treatment group. Urinary amino acid analysis showed that TM increased excretion of threonine, serine, glutamine, glycine, and alanine. Gene expression analyses showed that the mRNA levels of glutamine transporter (Slc38a3) and glycine transporters (Slc6a18 and Slc6a20) were significantly decreased in the TM group. Microarray analysis also showed the decrease in 7 genes out of 12 known causal genes for Fanconi syndrome.

Conclusions: These results suggest that ER stress lowers the expression levels of glutamine and glycine transporter genes, resulting in aminoaciduria. Also, it is considered that ER stress is a common mechanism of pathogenesis of aminoaciduria in Fanconi syndrome.

SA-PO1029

Bioimpedance Vector Analysis (BIA) in Patients with Systemic AL Amyloidosis Tamer Rezk,[2,3] Andrew Davenport,[1] Christianne Guillotte,[3] Helen J. Lachmann,[3] Ashutosh Wechalekar,[3] Philip N. Hawkins,[3] Julian D. Gillmore.[3] *[1]Royal Free Hospital, London, United Kingdom; [2]Center for Nephrology, UCL Division of Medicine, London, United Kingdom; [3]National Amyloidosis Centre, London, United Kingdom.*

Background: Systemic AL amyloidosis is a progressive and fatal disease affecting the heart and kidneys in 50% and 70% of patients respectively. Fluid retention and sarcopenia from heart failure may be exacerbated by systemic chemotherapy(Sattianayagam. 2013) and influence management and prognosis. BIA has been validated in patients with CKD and cardiovascular disease(Davenport. 2012). We hypothesize that BIA is a superior method of detecting fluid retention and sarcopenia among patients with systemic AL amyloidosis than absolute change in weight.

Methods: All newly diagnosed patients with systemic AL amyloidosis attending the UK National Amyloidosis Centre from April 2016 to April 2017 who were enrolled into the ALCHEMY prospective observational study underwent body composition assessment via BIA using InBody 770 at baseline (n=193) and first follow up (n=58) in conjunction with routine clinical, biochemical and scintigraphy assessments.

Results: Median age was 68yr, M:F ratio 1:1. Median serum creatinine 98μmol/L, eGFR 62ml/min and NT-proBNP 2389ng/L. At baseline; median ECW/TBW ratio was 0.411 (normal range 0.36-0.39); 183/193 (95%) patients had ECW/TBW ratio above the normal range. SMM/h^2 revealed severe sarcopenia in 0 (0%), moderate sarcopenia in 33 (17%) and normal muscle mass in 159 patients (87%) respectively (NHANES III). There was a correlation between baseline plasma NT-proBNP and ECW/TBW ratio (Pearson correlation 0.337 $p<0.001$). Follow up BIA revealed median weight loss of 3kg (4%), ECW/TBW ratio increase of 0.008 (2%) and SMM loss of 1kg (2%). Follow up SMM/h^2 revealed severe sarcopenia in 1 (2%), moderate sarcopenia in 14 (24%) and normal muscle mass in 43 (74%) patients respectively. Again, there was a correlation between percentage change in ECW/TBW ratio and percentage change in Log NT-proBNP at 6 months (Pearson correlation 0.4673, $p<0.008$).

Conclusions: BIA is a non-invasive method of assessing fluid excess and sarcopenia in patients with systemic AL amyloidosis at baseline and follow up. Significant fluid retention and sarcopenia were present in 93% and 17% at baseline and both worsened during or shortly after systemic chemotherapy. Since sarcopenia is increasingly recognised to be an independent risk factor for treatment intolerance, BIA may help minimise treatment toxicity in systemic AL amyloidosis.

SA-PO1030

The Role of Desmopressin in the Management of Severe Hypovolemic Hyponatremia Frank Ward,[1] David M. Naimark.[2] *[1]Nephrology, Sunnybrook Health Science Centre, Toronto, ON, Canada; [2]Sunnybrook Health Science Centre, Toronto, ON, Canada.*

Background: The role of desmopressin (DDAVP) to prevent or treat rapid serum sodium concentration ([Na]s) correction during hyponatremia management remains unclear. The study aim was to assess DDAVP use during the first 48-hours of severe, hypovolemic hyponatremia management. The primary study hypothesis was that the use of DDAVP would slow the rate of [Na]s correction compared to those not receiving DDAVP.

Methods: A retrospective, observational study was conducted in a single, tertiary centre of all patients managed for severe, hypovolemic hyponatremia over a 12-month period. Inclusion criteria were [Na]s <125mmol/l at referral, serum osmolality <275mOsm/kg, urine sodium <30mmol/l and urine osmolality >100mOsm/kg. Patients with signs of extra-cellular fluid compartment overload were excluded. The primary outcome measure was $[Na]_s$ correction during the first 48-hours, compared between patients who did or did not receive DDAVP using linear regression.

Results: Twenty-eight patients were identified, with baseline mean [Na]s of 112.7±6.6mmol/l vs 117±4.3mmol/l ($p=0.06$) in those who received (n=16) and did not receive DDAVP (n=12), respectively. The DDAVP group had a more rapid [Na]s correction on the first day compared to those who did not receive DDAVP, 7.7±3.8mmol/l/day vs 5.1±2.0mmol/l/day ($p=0.04$). On the second day, there was a similar rate of [Na]s correction for those receiving DDAVP and those who did not, 1.3±4.3mmol/l/day vs 2.6±3.2mmol/l/day ($p=0.39$). Overall, there was no difference in [Na]s correction after 48-hours between those who received DDAVP and those who did not, 121.7±7.5mmol/l vs 124.8±5.7mmol/l ($p=0.24$). Patients who had experienced an over-correction were successfully treated with DDAVP (n=5), so that no patient had an ongoing over-correction by 48-hours. The final [Na]s for patients who received a single dose of DDAVP (n=7) was similar to those who received multiple doses (n=9), 123.8±5.8mmol/l vs 120±8.5mmol/l, $p=0.32$.

Conclusions: DDAVP appears safe and effective in the management of severe, hypovolemic hyponatremia, associated with similar [Na]s correction to those who did not receive DDAVP after 48-hours, despite an initial more rapid correction. A single dose of DDAVP may be as effective as multiple doses. A randomized trial should examine what benefit DDAVP confers in addition to standard care in the management of severe, hypovolemic hyponatremia.

SA-PO1031

Neonatal Syndrome of Inappropriate Antidiuretic Hormone Secretion (SIADH) Associated with Hypothalamic Malformation in a Patient with Chromosome 1q21.1 Deletion Syndrome Bakri Alzarka,[1] Rachel L. Usala,[2] Sun-Young Ahn.[1] *[1]Children's National Medical Center, Washington, DC; [2]MedStar Georgetown University Hospital, Washington DC, DC.*

Background: Chromosome 1q21.1 deletion syndrome (OMIM 612474) is associated with a wide range of clinical abnormalities including mental retardation, microcephaly, autism, cardiac abnormalities, and cataracts. SIADH, caused by impaired water excretion, can develop from various conditions including tumors, central nervous system disorders, medications, pulmonary disease, hypothyroidism, and glucocorticoid deficiency. To our knowledge, it has not yet been reported in association with chromosome 1q21.1 deletion syndrome.

Methods: A 6 week-old, former 34-week gestational age, female was noted to have hyponatremia (serum sodium 128 mmol/L) shortly after birth. Clinical evaluation showed a low serum osmolality, relatively high urine osmolality and urine sodium, and a significantly elevated plasma arginine vasopressin (AVP) level (32.7 pg/ml, normal 1-11). With the absence of any clinical evidence of volume depletion or any other cause of hyponatremia including renal, thyroid or adrenal dysfunction, these findings were consistent with a diagnosis of SIADH. Her exam also showed microcephaly and situs inversus with dextrocardia. Microarray results were consistent with chromosome 1q21.1 deletion syndrome. Her brain MRI revealed multiple anomalies, including posterior/inferior hypothalamic malformation with hypoplastic mammillary bodies and a markedly diminutive posterior pituitary hyperintensity on T1-weighted images, which may reflect abnormal release of AVP from the posterior pituitary gland. The patient had a partial response to fluid restriction, furosemide, and sodium supplementation. However, tolvaptan initiation resulted in effective normalization of the patient's serum sodium level.

Results:

Conclusions: We report an unusual case of congenital SIADH associated with hypothalamic malformation in a neonate with chromosome 1q21.1 deletion syndrome. Our findings suggest that congenital hypothalamic/pituitary malformations should be considered as a cause of SIADH in patients with phenotypic findings consistent with chromosome 1q21.1 deletion syndrome. In addition, tolvaptan may provide an effective therapeutic option for infants with SIADH.

SA-PO1032

Gene Expression Changes in Vasopressin-Sensitive mpkCCD Cells after CRISPR/Cas9-Deletion of cAMP-Dependent Protein Kinase (PKA) Hyun Jun Jung, Kiyoshi Isobe, Chin-Rang Yang, Maurice B. Burg, Viswanathan Raghuram, Mark A. Knepper. *NHLBI/NIH, Bethesda, MD.*

Background: Vasopressin regulates collecting duct water permeability in part through stimulation of transcription of the aquaporin-2 gene, *Aqp2*. Vasopressin signaling occurs via several mediators including β-arrestin, Epac (RapGEF3/4), and cAMP-dependent protein kinase (PKA).

Methods: To address the role of PKA in gene expression in the renal collecting duct, we used genome editing (CRISPR-Cas9) to ablate expression of both PKA catalytic subunits in mouse mpkCCD cells. We carried out transcriptomics (RNA-Seq) and quantitative proteomics (SILAC-based quantitative LC-MS/MS) of in three pairs of PKA-KO vs. control clones. Deletion was confirmed using newly developed isoform-specific PKA antibodies. Cells were grown on permeable supports in the presence of 0.1 nM dDAVP.

Results: The PKA-KO cells were viable and maintained polarity. In RNA-Seq, only 68 out of 10,190 transcripts showed significant abundance decreases based on dual criteria (FDR-corrected $P < 0.05$ and $\log_2$(PKA-KO/Control) < -1). These included several transcripts previously found to be upregulated by vasopressin (Aqp2, Adh1, Akr1b3, Bcat1, Cyfip2, Gsdmc2, Gsdmc4, Gsta4, Pde4b, Tmem45b and Tmprss4). Quantitative proteomics confirmed the deletion of both PKA isoforms, showed that AQP2 protein was undetectable in the PKA-KO cells (confirmed by immunoblotting), and showed decreases in protein abundances of Tmprss4, Baiap2l2, Prom1, C3, Upk1a and Muc4, in parallel with mRNA changes. When either PKA catalytic subunit was transfected into the PKA-KO cells, AQP2 protein expression was rescued (immunofluorescence microscopy and immunoblotting).

Conclusions: We conclude that transcription of the *Aqp2* gene requires PKA. PKA-dependent gene transcription is highly selective, involving less than 1% of expressed genes in collecting duct cells.

Comparative Analysis of Vasopressin V1a Receptor Distribution in Rodent and Human Kidneys Torsten Giesecke,[1] Taka-aki Koshimizu,[4] Katsumasa Kawahara,[3] Nina Himmerkus,[2] Julian Isermann,[2] Markus Bleich,[2] Alina Smorodchenko,[1] Sebastian Bachmann,[1] Kerim Mutig.[1] *[1]Charité Universitätsmedizin Berlin, Berlin, Germany; [2]Christian Albrechts Universität Kiel, Kiel, Germany; [3]Dept of Physiol, Kitasato Univ School of Med, Sagamihara, Japan; [4]Jichi Medical University, Shimostuke, Tochigi, Japan.*

Background: Selective antagonists of V1a vasopressin receptor (V1aR) have been discussed as an emerging therapeutic strategy for retardation of chronic kidney disorders. Therefore, detailed knowledge of renal V1aR distribution is fundamental. This work provides comparative analysis of segmental and cellular localization of the receptor in mouse, rat, and human kidney supported by functional studies.

Methods: Immunofluorescence and high-resolution immunocytochemistry using own antibody to V1aR were performed for localization studies. Functional experiments with a V1aR agonist (AO-4-67) were conducted in vivo cultured cells and isolated, perfused renal tubules.

Results: Incubation of mouse kidney sections with the anti-V1aR antibody produced basolateral signal in macula densa cells and in type-A intercalated cells of connecting tubules and collecting ducts, whereas type-B intercalated cells showed punctate perinuclear and apical V1aR signal. In the rat and human kidneys, both types of intercalated cells exhibited chiefly diffused intracellular or apical V1aR signal patterns, whereas macula densa cells did not show any significant V1aR immunoreactivity. Administration of AO-4-67 to vasopressin-deficient Brattleboro rats for 4h induced luminal trafficking of V-ATPase in type-A intercalated cells suggesting increased proton secretion. Accordingly, treatment of isolated mouse collecting ducts with vasopressin or AO-4-67 decreased the luminal pH. Cultured mouse macula densa cells responded to the agonist with rise of intracellular calcium, which verified the V1aR presence in this cell type in mice.

Conclusions: In summary, these results suggest that activation of V1aR modulates function of intercalated cells across the studied species, whereas effects in macula densa cells may be restricted to the mouse species.

SA-PO1034

Quantification of Single and Multi-Site AQP2 Phosphorylation Naofumi Yui, Shinichi Uchida. *Tokyo Medical and Dental University, Sagamihara-shi, Kanagawa-ken, Japan.*

Background: Vasopressin regulates AQP2 phosphorylation at several serine residues. However, the amounts of the singly and multiply phosphorylated forms in the whole AQP2 population are unclear.

Methods: In this study, we developed an immunoprecipitation-based quantification of AQP2 phosphorylation. MDCK cells expressing FLAG-tagged human-AQP2 were grown to confluence, lysed, and precipitated with an anti-pS261 antibody, and then blotted and probed with anti-pS256, anti-pS261, and anti-FLAG-M2 antibodies. The signal intensity of the precipitated pS261-positive AQP2 (IP-pS261; consisting of pS261-single form and pS256-pS261-double form) was normalized to the whole pS261 signal in the lysate (IP-pS261/whole-pS261), and the ratio was used as the control. The ratios of the IP-pS261 signal intensity to the whole pS256 signal intensity (IP-pS261/whole-pS256), and to the whole AQP2 signal intensity (IP-pS261/whole-AQP2) were compared with the control ratio. pS256-positive AQP2 was analyzed in the same way.

Results: pS261-positive AQP2 constituted 21% of the whole AQP2 population under basal condition, this declined to 10% after FK (20 μM, 60 min) treatment. pS256-positive AQP2 constituted 48% of the whole AQP2 population under basal condition, this was at 51% after FK treatment. In the pS256-positive AQP2 population, pS261-positive AQP2 (pS256-pS261-double form) constituted a major part of the pS256-positive AQP2 population at 59% under basal condition, this declined to 27% in the population after FK treatment. IP-pS256/whole-pS256 did not differ significantly from IP-pS256/whole-pS261 with or without FK treatment.

Conclusions: Ser-256 is most highly phosphorylated in the cell; pS256-positive AQP2 constantly constitutes around 50% of the whole AQP2 population with or without FK treatment. Most pS261-positive AQP2 is the pS256-pS261 doubly phosphorylated form. This double phospho-form constitutes about a half population in the pS256-positive AQP2, and decreased by 50% after FK treatment in the population. To the contrary, the pS261-single form may constitute a minor component. This study suggests that relative quantification of pS261 signal may be a good biomarker of vasopressin action on pS256-positive AQP2, and will contribute to develop inspective assays of renal vasopressin action in animal and human samples.

SA-PO1035

A Transcriptional Network Controlling Epithelial Barrier Function in the Collecting Duct Is Necessary to Maintain Renal Medullary Osmolality Christian Hinze,[5,2] Janett Ruffert,[2,3] Katharina Walentin,[2] Kerim Mutig,[4] Sebastian Bachmann,[4] Michael Schumann,[6] Nina Himmerkus,[1] Markus Bleich,[1] Kai M. Schmidt-Ott.[5,2] *[1]Institute of Physiology, CAU, Kiel, Germany; [2]Max Delbrueck Center for Molecular Medicine, Berlin, Germany; [3]Urological Research Laboratory, Charité-Universitätsmedizin, Berlin, Germany; [4]Anatomy, Charité, Berlin, Germany; [5]Nephrology, Charité, Berlin, Germany; [6]Gastroenterology, Charité, Berlin, Germany.*

Background: Osmolytes are accumulated in the renal medulla generating a gradient between the hypertonic interstitial medullary tissue and the urine to facilitate urinary concentration. The transcription factor grainyhead-like 2 (GRHL2) is highly expressed in renal collecting ducts. We previously showed that mice with collecting duct-specific GRHL2 deficiency show a decreased urine concentrating ability and a predisposition for prerenal acute kidney injury. We also demonstrated a loss of barrier function in GRHL2-deficient collecting ducts, as shown by a reduced transepithelial resistance in freshly isolated collecting ducts from the inner stripe of the outer medulla. However, the functional consequences of the epithelial barrier loss remained unclear.

Methods: We generated collecting duct-specific GRHL2 knockout mice (Hoxb7/Cre; $Grhl2^{flox/-}$, further referred to as $GRHL2^{CD-/-}$) and measured tissue osmolalities in the cortex, the inner stripe of the outer medulla (ISOM) and the inner medulla (IM) in control and $GRHL2^{CD-/-}$ mice. We used inner medullary collecting duct (IMCD-3) cells with a

CRISPR/Cas9-induced Grhl2 knockout and wildtype control cells for functional analyses. GRHL2 target genes were identified by microarray gene expression analyses from control and GRHL2$^{CD-/-}$ kidneys and by Grhl2 chromatin immunoprecipitation followed by next generation sequencing (ChIP-seq) from wildtype kidneys.

Results: Our data show a significantly decreased tissue osmolality in ISOM and IM of GRHL2$^{CD-/-}$ kidneys compared to control kidneys. GRHL2 knockout IMCD-3 cells when compared with wildtype cells showed a significantly reduced transepithelial resistance and an increased paracellular flux of sodium and chloride. Integration of microarray and ChIP-seq data indicated that Grhl2 target genes were involved in tight junction assembly.

Conclusions: These data functionally link collecting duct epithelial barrier function with urinary concentrating ability for the first time. We identify a transcriptional network regulated by the transcription factor GRHL2, which is necessary to maintain tight epithelial barriers across the collecting duct epithelium, thereby preventing leakage of sodium and chloride into the urine and preserving a high medullary osmolarity.

SA-PO1036

SLC26A6 Mediates Enteric Oxalate Secretion in CKD Laura I. Neumeier,[1,3] Robert B. Thomson,[3] Kai-Uwe Eckardt,[2] Peter S. Aronson,[3] Felix Knauf.[2,3] *[1]Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Germany; [2]University Hospital Charite Berlin, Berlin, Germany; [3]Yale University School of Medicine, New Haven, CT.*

Background: A state of oxalate equilibrium is maintained in patients with healthy kidney function. However, as GFR declines plasma oxalate levels start to rise. Upregulation of oxalate secretion in the colon of rats with CKD has been described in the past, yet the molecular identification of the oxalate transporter(s) involved has yet to be defined. Hence, we examined whether oxalate transporter SLC26A6 contributes to the extrarenal clearance of oxalate via the gut in CKD.

Methods: CKD was induced by injecting age- and gender-matched 129S6 (wild-type) and Slc26a6$^{-/-}$ mice with aristolochic acid. Renal function was monitored by changes in plasma creatinine sampled retro-orbitally. Intestinal SLC26A6 was assessed by qPCR and western blot analysis. Mice were maintained on an oxalate-free diet and plasma and fecal oxalate levels were measured enzymatically using an oxalate oxidase assay.

Results: SLC26A6 mRNA and protein expression were greatly increased in colon of mice with CKD. However, expression levels of glucose (SGLT-1) and amino acid transporters (CAT-1), other representative intestinal transport processes, did not differ in colon of CKD mice. In line with these findings, fecal oxalate excretion was increased in mice with CKD. In contrast, fecal oxalate excretion was reduced and plasma oxalate levels significantly increased in Slc26a6$^{-/-}$ mice as compared with wild-type mice.

Conclusions: In summary, we demonstrate that SLC26A6-mediated enteric oxalate secretion is critical in decreasing the body burden of oxalate in CKD.

Quantification of Urinary Extracellular Vesicles Charles J. Blijdorp, Thomas Hartjes, Martin E. Van royen, Robert Zietse, Ewout J. Hoorn. *Erasmus Medical Center, Rotterdam, Netherlands.*

Background: Urinary extracellular vesicles (uEVs) have emerged as a powerful non-invasive tool to study renal epithelial transport in humans. However, the optimal method to quantify and normalize uEVs remains unclear, especially for spot urines.

Methods: Four healthy subjects were subjected to overnight thirsting (10 pm-noon) followed by water loading (20 ml/kg in 30 min). Spot urines were collected during thirsting (T1-2) and after water loading (WL1-4, noon-7 pm). Subsequently, 4 uEV quantification techniques were compared: (1) nanoparticle tracking analysis (NTA), (2) uEV isolation by ultracentrifugation followed by immunoblotting of CD9, CD63, CD81, ALIX, and TSG101, (3) a time-resolved fluorescence immunoassay (TRFIA) that captures CD9+ uEVs, and (4) EVQuant, a novel technique which counts individual fluorescently labeled EVs after immobilization in a matrix. A Bland-Altman analysis was used to compare methods using NTA as reference.

Results: As expected, urine osmolality was near-maximal during thirsting, decreased after water loading and then increased again (Figure). The results of the 4 uEV quantification methods showed similar dynamics as urine osmolality suggesting that uEV number changes in proportion to urinary concentration (Figure). Of interest, EVQuant identified 2.4 ± 0.6 times more uEVs than NTA. Using NTA as reference, the Bland-Altman analysis showed that EVQuant had the lowest bias (% difference 6 ± 27) followed by TRFIA (10 ± 21). Of the uEV-markers, CD9 agreed best with NTA (-12 ± 34). uEV number correlated strongly with urine creatinine (Figure) and osmolality (r^2 for both 0.9, P<0.0001).

Conclusions: uEV number is proportional to urinary concentration and both urine creatinine and osmolality can be used to normalize spot urines for uEV number. EVQuant is a promising alternative to NTA and appears more sensitive for uEV detection. These uEV quantification methods can be used to analyze if changes in a uEV protein of interest are the result of more protein per uEV or the excretion of more uEVs containing this protein.

WNK4 Deletion Inhibits Adipogenesis In Vitro and In Vivo Daiei Takahashi,[4,6] Takayasu Mori,[4] Eisei Sohara,[4] Miyako Tanaka,[2] Yuichi Inoue,[5] Naohiro Nomura,[4] Motoko Chiga,[1] Moko Zeniya,[4] Takayoshi Suganami,[2] Tatemitsu Rai,[3] Shinichi Uchida.[4] *[1]Department of Nephrology, Graduate School of Medical and Dental Sciences, Tokyo Medical and Dental University, Bunkyo-ku, Tokyo, Japan; [2]Nagoya University, Nagoya, Japan; [3]TOKYO MEDICAL & DENTAL UNIV, TOKYO, Japan; [4]Tokyo Medical and Dental University, Tokyo, Japan; [5]Tokyo medical and dental university, Tokyo, Japan; [6]Internal medicine, Tokyo Metropolitan Ohtsuka Hospital, Tokyo, Japan.*

Background: The *with-no-lysine kinase (WNK) 1 and WNK4* genes are responsible for pseudohypoaldosteronism type II (PHAII), a hereditary hypertensive disease. We have demonstrated the importance of the WNK4–OSR1/SPAK–NCC signaling cascade in the kidney for blood pressure regulation, however, the extrarenal roles of WNK4 is not clear. We previously presented WNK4 is induced in the early phase of 3T3-L1 adipocyte differentiation and is expressed in mouse mature adipose tissues. In this study, we evaluated *WNK4*'s contribution to the adipogenesis *in vitro* and *in vivo*.

Methods: We used mouse primary preadipocytes, 3T3-L1 fibroblasts, and human mesenchymal stem cells (hMSC-AT) to elucidate potential roles of WNK4 in adipose tissue. The functions of WNK4 in these cells was examined by siRNA specific to WNK4 (si-WNK4). We also generated WNK4 knock-down 3T3-L1 cell lines using TALEN. We fed WNK4$^{-/-}$ mice a high-fat diet and examined their metabolic functions.

Results: In mouse primary preadipocytes, WNK4 was predominantly expressed in the mature adipocyte, and WNK4 in the stromal vascular fraction was induced by the differentiation stimuli. WNK4 expression preceded the expression of key transcriptional factors PPARγ and C/EBPα. Si-WNK4-transfected 3T3-L1 cells and hMSC-AT cells showed reduced expression of PPARγ and C/EBPα and decreased lipid accumulation. WNK4 knocked-down 3T3-L1 cells also showed reduced PPARγ expression. In the WNK4$^{-/-}$ mice, PPARγ and C/EBPα expression were decreased in adipose tissues, and the mice exhibited partial resistance to high-fat diet-induced adiposity.

Conclusions: WNK4 is a key molecule of adipocyte differentiation and is involved in diet-induced adiposity. Thus, WNK4 would be a novel target molecule for the treatment of metabolic syndrome.

SA-PO1039

Decreased Protein Expression of KLHL3 Is Involved in the Pathogenesis of PHAII Caused by CUL3 Mutation In Vivo Sayaka Yoshida, Yuya Araki, Takayasu Mori, Emi Sasaki, Yuri Kasagi, Kiyoshi Isobe, Koichiro Susa, Yuichi Inoue, Tatemitsu Rai, Shinichi Uchida, Eisei Sohara. *Department of Nephrology, Tokyo Medical and Dental University, Bunkyo-ku, Japan.*

Background: Pseudohypoaldosteronism type II (PHAII) is a hereditary hypertensive disease. PHAII is caused by mutations in four genes: WNK1, WNK4, KLHL3 and Cullin3 (Cul3). Recently it was revealed that Cul3-KLHL3 E3 ligase complex ubiquitinate WNK1 and WNK4, leading to their degradation, and that one of the common pathogenesis of PHAII is the defective degradation of WNKs by Cul3-KLHL3 E3 ligase complex. PHAII-causing Cul3 mutations result in the skipping of exon 9, leading to a CUL3 protein with a 57-amino acid deletion(Δ403-459). However, the pathogenesis of PHAII caused by CUL3Δ403–459 *in vivo* is still unclear.

Methods: We generated and analyzed CUL3$^{WT/Δ403-459}$ PHAII model mice.

Results: CUL3 $^{WT / Δ 403-459}$ mice were successfully generated, and they exhibited hyperkalemia, metabolic acidosis and hypertension, indicating that they are good mouse model of PHAII. Protein levels of WNK kinases were increased, resulting in increased phosphorylation of OSR1, SPAK, and NCC, the downstream components of the WNK signal. In CUL3$^{WT/Δ403-459}$ mice, the abundance of KLHL3 protein was decreased in kidney and brain. On the other hand, the protein levels of the other KLHL family proteins, KLHL2 and Keap1, which also form ubiquitin ligase complexes with CUL3, were comparable between CUL3$^{WT/WT}$ and CUL3$^{WT/Δ403–459}$.

Conclusions: In CUL3 $^{WT / Δ 403-459}$ mice, expression levels of KLHL3 were decreased. Considering that heterogygous knockout of CUL3 expression alone in mice which we

published previously was not sufficient to develop PHAII, the decreased protein expression of KLHL3 observed in CUL3$^{WT/\Delta 403-459}$ mice could be involved in the mechanism of PHAII caused by the CUL3 mutation *in vivo*. As KLHL2 and Keap1 were not decreased in CUL3 $^{WT/\Delta 403-459}$mice, it might be a specific phenomenon in KLHL3.

SA-PO1040

KS-WNK1: An Aldosterone-Induced Inhibitor of ENaC? Maria Chavez-Canales,[1] Peng Wu,[2] Shaohu Sheng,[1] Jingxin Chen,[3] Bettina Serbin,[1] Nikita Radionov,[1] Christelle Soukaseum,[1] WenHui Wang,[2] Thomas R. Kleyman,[3] Juliette Hadchouel.[1] *[1]INSERM, Paris, France; [2]New York Medical College, Valhalla, NY; [3]University of Pittsburgh, Pittsburgh, PA.*

Background: Mutations in the gene encoding the serine threonine kinase WNK1 [With No lysine (K)] result in an increased expression of the catalytic isoform, thus causing Familial Hyperkalemic Hypertension, a rare form of human hypertension. Another isoform, KS-WNK1, is also produced from the *WNK1* gene. Devoid of kinase activity, it is expressed specifically in the distal nephron. *In vitro* data suggest that KS-WNK1 inhibits the activity of other WNK kinases. We previously showed that the inactivation of KS-WNK1 in mice leads to an increased expression of the Na-Cl cotransporter NCC, which could result from an increased activity of WNK1 and/or WNK4. However, aldosterone secretion is decreased in *KS-WNK1*$^{-/-}$ mice while renin is not, suggesting that potassium balance is impaired, which could also explain the increased NCC expression.

Methods: KS-WNK1 is expressed in the distal convoluted tubule but also in the connecting tubule (CNT) and cortical collecting duct (CCD). In order to characterize its role in potassium balance independently from the DCT, we generated a mouse model of KS-WNK1 inactivation specifically in the CNT-CCD (*WNK1*$^{AQP2/AQP2}$ mice).

Results: As in *KS-WNK1*$^{-/-}$ mice, the secretion of aldosterone, but not renin, is decreased in *WNK1*$^{AQP2/AQP2}$ mice. An increase in aldosterone, by chronic infusion or potassium load, as well as a sodium load provoke a significant decrease in plasma potassium in *WNK1*$^{AQP2/AQP2}$ mice, suggesting that the activity of the Na channel ENaC is increased. Using patch-clamp on isolated tubules, we confirmed that ENaC activity is increased in the CNT of *WNK1*$^{AQP2/AQP2}$ mice. Accordingly, overexpression of KS-WNK1 in *Xenopus laevis* oocytes decreases the activity of the sodium channel.

Conclusions: Taken together, these data suggest that KS-WNK1 is an inhibitor of ENaC in a Nedd4-2 independent manner. Since the expression of KS-WNK1 is induced by aldosterone infusion or potassium load, KS-WNK1 could therefore be an aldosterone-induced inhibitor of ENaC.

Funding: NIDDK Support, Government Support - Non-U.S.

SA-PO1041

Depletion of Kidney-Specific WNK1 (KS-WNK1) Abolishes the Effect of High Dietary K Intake (HK) on ROMK Channel in the Distal Convoluted Tubule (DCT) WenHui Wang,[2] Peng Wu,[2] Xiao-Tong Su,[2] Andrew Terker,[3] Zhongxiuzi Gao,[2] David H. Ellison,[4] Juliette Hadchouel,[1] Jacques Teulon.[5] *[1]INSERM, Paris, France; [2]New York Medical College, Valhalla, NY; [3]OHSU, Portland, OR; [4]Oregon Health & Science University, Portland, OR; [5]University Pierre et Marie Curie-UPMC, Paris, France.*

Background: Previous studies have shown that with-no-lysine kinases (WNK) regulate ROMK (Kir1.1) channel, a K secretory channel expressed in the apical membrane of aldosterone-sensitive distal nephron (ASDN). While WNK4 and full-length WNK1 (L-WNK1) inhibit ROMK cannel activity by facilitating endocytosis, KS-WNK has been shown to inhibit L-WNK1 thereby stimulating ROMK.

Methods: Since KS-WNK1 is mainly expressed in the DCT, we now performed the whole-cell patch-clamp recording to measure TPNQ (ROMK inhibitor)-sensitive K currents in the isolated split-open DCT of WT and WNK4 knockout (KO) or KS-WNK1 KO mice.

Results: TPNQ-sensitive K currents in DCT2 of KS-WNK1 KO (450±40 pA) and WNK4 KO mice (370±50 pA) were significantly smaller than that of WT mice (1060±120 pA). Moreover, WNK4 KO mice were hypokalemic (3.2±0.05 mM) while KS-WNK1 KO mice had normal plasma K level (4.5±0.3 mM). Thus, it is possible that diminished ROMK cannel activity in WNK4 KO mice may be the result of hypokalemia. HK intake (7 days) significantly increased K currents in DCT2 to 1600±80 pA (WT) and to 1090±40 pA (WNK4 KO), suggesting that lack of WNK4 did not compromise the effect of HK intake on ROMK in DCT2. In contrast, HK intake fails to stimulate ROMK channels in DCT of KS-WNK1 KO mice because TPNQ-sensitive K currents were not significantly increased (540±30 pA) in DCT2 of KS-WNK1 KO mice. However, plasma K level in KS-WNK1 KO mice on HK was even lower (3.9±0.1 mM) than that of WT mice (4.4±0.1 mM), suggesting that defective regulation of ROMK by HK in DCT2 did not decrease net renal K excretion in KS-WNK1 KO mice. This notion is supported by the observation that HK intake actually stimulates TPNQ-sensitive K currents in the CCD from 1090±90 pA to 2400±140 pA in KS-WNK1 KO mice.

Conclusions: In summary, ROMK cannel activity is decreased in DCT2 of WNK4 KO and KS-WNK1 KO mice. However, only the depletion of KS-WNK1 but not WNK4 abolished the stimulatory effect of HK intake on ROMK in DCT2. However, HK intake is still able to activate ROMK in the CCD of KS-WNK1 KO mice. We conclude that KS-WNK1 plays a role in mediating the stimulatory effect of HK intake on ROMK in the DCT2 but not in the CCD.

SA-PO1042

WNK4 Acts on Thick Ascending Limbs In Vivo as Well as Distal Convoluted Tubules Andrew Terker,[3] Kayla J. Erspamer,[4] Lauren N. Miller,[5] Mohammed Z. Ferdaus,[4] WenHui Wang,[2] Xiao-Tong Su,[2] Ryan J. Cornelius,[5] James A. McCormick,[4] Gerardo Gamba,[1] Chao-Ling Yang,[5] David H. Ellison.[4] *[1]Instituto Nacional de Ciencias Medicas y Nutricion Salvador Zubiran, Tlalpan, Mexico City, Mexico; [2]New York Medical College, Valhalla, NY; [3]OHSU, Portland, OR; [4]Oregon Health & Science University, Portland, OR; [5]Oregon Health and Science University, Portland, OR.*

Background: WNK4 mutations increase thiazide-sensitive NaCl cotransporter (NCC) activity in the distal convoluted tubule (DCT) and cause familial hyperkalemic hypertension (FHHt). Conversely, WNK4 knockout (KO) in mice leads to a 'Gitelman-like' phenotype', similar to loss of NCC function. Even though the WNK/SPAK-OxSR1 pathway can modulate the Na-K-2Cl cotransporter (NKCC2) in vitro, effects of WNK4 KO on NKCC2 were not noted in mice. Yet WNK4 knockout mice are not hypocalciuric, a cardinal feature of NCC dysfunction, suggesting a mixed phenotype. To test this, we revisited the phenotypes of WNK4 KO and WNK4 activation (WNK4Q562E) in mice.

Methods: Plasma and urine electrolyte concentrations from WNK4 KO and WNK4Q562E mice were determined. Western blots determined protein abundance. Modified diets were reported previously. NKCC2 and NCC activity were assessed with furosemide (25mg/kg IP) and hydrochlorothiazide (25mg/kg IP).

Results: As reported previously, plasma potassium and chloride were significantly lower in WNK4 KO mice than in controls, but urine calcium excretion was normal. A high salt/high K^+ diet increased urine calcium in control mice, compared with high salt/normal K^+, but not in WNK4 KO (interaction p=0.0183). WNK4 KO mice exhibited low total and phosphorylated NCC, compared with controls, as expected, but also exhibited low phosphorylated NKCC2 (total NKCC2 was normal). In contrast, WNK4Q562E mice had more phosphorylated NKCC2 than controls. The response to furosemide, an index of NKCC2 function, was similar in WNK4 KO and control, but we reasoned that this may have reflected compensatory NCC activation in controls. When compensatory DCT transport was inhibited with thiazide, however, the response to furosemide was significantly lower in WNK4 KO mice than in controls, consistent with reduced NKCC2 activity.

Conclusions: While WNK4 clearly has predominant effects on NCC, it also modulates NKCC2 in vivo. Thus, although WNK4 deficiency has been suggested to cause a mild 'Gitelman-like phenotype', it much more closely mimics Bartter syndrome type III, with a mixed thick ascending limb and DCT phenotype. WNK4-mediated FHHt likely also involves activation of both NCC and NKCC2, accounting for variable reports of furosemide action in some cases.

Differential Regulation of L-WNK1 and KS-WNK1 by the Ubiquitin Ligases Nedd4-2 and Kelch-CUL3 Complex Mauricio Ostrosky-Frid,[1,3] Eduardo R. Argaiz,[1] Fabiola Gallardo,[1] Maria Chavez-Canales,[4] Norma H. Vázquez,[4] David H. Ellison,[2] Gerardo Gamba.[1,4] *[1]Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, Tlalpan, Mexico City, Mexico; [2]Oregon Health & Science University, Portland, OR; [3]Programa de Estudios Combinados en Medicina, UNAM, Mexico City, Mexico; [4]Instituto de Investigaciones Biomédicas, UNAM, Mexico City, Mexico.*

Background: It has been suggested that the full-length form of WNK1 kinase (L-WNK1) is a target for ubiquitylation by the Nedd4-2 and the Kelch-Cul3 ubiquitin ligases. The major transcript of WNK1 gene in the renal tissue is KS-WNK1, the truncated kidney-specific isoform that is almost exclusively expressed in the distal convoluted tubule, where its transcript is 80 times more abundant than L-WNK1. The higher transcript expression could be due to a different sensibility to the ubiquitin-induced degradation. The effect of ubiquitin ligases in the KS-WNK1 variant, however, is not known.

Methods: The effect of Nedd4-2 and Kelch3-CUL3 complex upon L-WNK1 and KS-WNK1 was assessed by western blot and immunoprecipitation (IP) two days after microinjection of *Xenopus* oocytes with Myc-tagged KS-WNK1-Δ11 and/or L-WNK1-Δ11 cRNA, in the absence or presence of Flag-tagged Nedd4-2 or Flag-tagged-Kelch3 cRNA. The NCC activity was measured by functional expression in the oocytes using tracer $^{22}Na^+$ uptake. We used the variants lacking the exon 11 (Δ11) because this is the most abundant form in the kidney. Immunoprecipitation between WNK1 variants and Nedd4-2 or Kelch3 was corroborated using a c-myc precipitation kit.

Results: We observed that KS-WNK1-Δ11, was completely degraded by Kelch-CUL3 complex (N=10). In contrast, only about 20% of the L-WNK1-Δ11 was degraded in the presence of Kelch3. The IP confirmed that the Kelch-CUL3 complex is co-precipitated with KS-WNK1, but not with L-WNK1-Δ11 (N=3). Functionally, the positive effect of KS-WNK1-Δ11, but not that of L-WNK1-Δ11, on NCC was prevented by the coinjection with Kelch3 (n=3). Interestingly, the effect of Nedd4-2 was the opposite. Nedd4-2 induced degradation of L-WNK-Δ11 and reduced its effect on NCC, while it had no effect on KS-WNK1-Δ11. Using the same expression system, we observed that WNK4 was also highly sensitive to Kelch3.

Conclusions: Although KS-WNK1 and L-WNK1 exhibit the same interaction site for ubiquitin ligases, KS-WNK1-Δ11 is sensitive to Kelch3, but not to Nedd4-2, while L-WNK1-Δ11 is sensitive to Nedd4-2, but not to Kelch3. Given the differential expression of KS-WNK1 and L-WNK1 along the distal nephron, modulation of these

kinases abundance by Nedd4-2 and Kelch3 could have an implication in the fine tune modulation of ion transport.

SA-PO1044

Role of WNK Aggregate Formation in Activating Na-Cl Cotransport Catherina A. Cuevas,[3] Lauren N. Miller,[4] Kerim Mutig,[1] Sebastian Bachmann,[2] Chao-Ling Yang,[4] David H. Ellison.[3] *[1]Charite-Universitaetsmedizin Berlin, Berlin, Germany; [2]Charité Universitätsmedizin Berlin, Berlin, Germany; [3]Oregon Health & Science University, Portland, OR; [4]Oregon Health and Science University, Portland, OR.*

Background: Activation of the thiazide-sensitive Na-Cl cotransporter (NCC) is essential to retain K^+ in response to dietary K^+ restriction and hypokalemia. Formation of WNK4/SPAK-OSR1 aggregates in distal convoluted tubule (DCT) cells is a common event that occurs when dietary K^+ is low and NCC activity is high. While these aggegates bring together key signaling proteins required to activate NCC, it has not been clear whether WNK4 aggregate formation facilitates NCC activation or whether these represent stress features, or even autophagosomes.

Methods: Here, we fed C57/BL6 mice normal (NK, 0.8% K^+) or potassium-deficient (LK, 0% K^+) diets for 12 to 72 hours. Some mice were switched to high potssium diet (HK, 5%). Plasma electrolytes were determined with iSTAT. Protein aggregates containing WNK4, SPAK and ATG5 (autophagy marker) was assessed by light and electron microscopy.

Results: Plasma [K^+] decreased with LK (3.3±0.3 vs 4.0±0.1 mmol/l); The abundance of phospho-NCC (T53) reached a maximum after only 12h of LK, with a striking increase in phospho SPAK-Ser373/OSR1-Ser325 at the apical membrane of DCT1 segments (identified with parvalbumin). Increased phospho NCC abundance at this time also correlated with appearance of phospho SPAK-Ser373/OSR1-Ser325 containing aggregates, but these aggregates did not contain WNK4, which appeared unaffected. WNK4 and ATG5, however, were clearly associated with aggregates in DCT seegments after 24h of LK diet and increased in a time-dependent fashion. By electron microscopy, the aggregates were not surrounded by membranes typical of autophagosomes. Potassium replenishment protocol (LK diet for 2 days followed by 2 additional days in HK) increased plasma [K^+] (5.2± 0.1 mmol/l), as expected, and reduced phospho-NCC protein abundance. WNK4, SPAK and ATG5 aggregates were no longer detected in the DCT after this brief K^+ replenishment. Basolateral K^+ channels (Kir4.1) mediate [K^+] sensing in DCT. In LK Kir4.1 KO mice, only occasional cells retaining Kir4.1 developed WNK4 aggregates.

Conclusions: WNK4-ATG5 aggregates are atypical, membraneless, dynamic structures that form after NCC is activated in response to LK, which require sensing through Kir4.1. WNK4 aggregate formation thus is not required for early NCC activation by LK, but these structures also are not typical autophagosomes.

Generation and Analysis of KLHL2 Knockout Mice Yuri Kasagi,[1] Daiei Takahashi,[1] Tomomi Aida,[2,3] Hidenori Nishida,[1] Naohiro Nomura,[1] Moko Zeniya,[1] Takayasu Mori,[1] Emi Sasaki,[1] Fumiaki Ando,[1] Tatemitsu Rai,[1] Shinichi Uchida,[1] Eisei Sohara.[1] *[1]Department of Nephrology, Tokyo Medical and Dental University, Bunkyo-ku, Japan; [2]Laboratory of Molecular Neuroscience, Medical Research Institute (MRI), Tokyo Medical and Dental University, Bunkyo-ku, Japan; [3]Laboratory of Recombinant Animals, MRI, Tokyo Medical and Dental University, Chiyoda-ku, Japan.*

Background: Mutations in the with-no-lysine kinase 1 (*WNK1*), *WNK4,* Kelch-like 3 (*KLHL3*), and Cullin3 (*CUL3*) genes were identified as being responsible for hereditary hypertensive disease pseudohypoaldosteronism type II (PHAII). KLHL3/CUL3 ubiquitin ligase complex regulates degradation of WNK kinases via their degradtion. In PHAII, the loss of interaction between KLHL3 and WNK4 increases levels of WNKs because of impaired ubiquitination, leading to abnormal over-activation of the WNK-OSR1/SPAK-NCC cascade in the kidney's distal convoluted tubules (DCT). KLHL2 is highly homologous to KLHL3, especially in kelch-repeat domain (WNK-binding domain). We previously reported KLHL2 ubiquitinated and degraded WNKs *in vitro*. However, the physiological role of KLHL2 *in vivo* is still unclear.

Methods: We generated KLHL2$^{-/-}$ mice using CRISPR/cas9 system and evaluated the phenotype.

Results: KLHL2 expressed abundantly in the brain, stomach, and kidneys. However, we found that the expression of WNK4 was increased only in the KLHL2$^{-/-}$ mice kidneys. KLHL2$^{-/-}$ mice did not exhibit increased phosphorylation of the OSR1/SPAK-NCC cascade in the kidneys and PHAII-like phenotype. KLHL2 was predominantly expressed in the kidney medulla compared with the cortex. Accordingly, medullary WNK4 protein levels were significantly increased in the kidneys of KLHL2$^{-/-}$ mice.

Conclusions: KLHL2 is indeed a physiological regulator of WNK4 *in vivo*; however, WNK protein levels in KLHL2-expressing tissues may not be solely governed by KLHL2, except in kidney medulla.

SA-PO1046

The Sensibility of WNK3 and WNK4 for Intracellular Chloride Concentration and Cell Volume Is Opposite Diego L. Carrillo Perez,[1] Karla Leyva-Rios,[3] Adriana P. Mercado,[2] Elisa Hernandez Mercado,[2] Erika Moreno,[1] Norma H. Vázquez,[4] Diana Pacheco-Alvarez,[3] Gerardo Gamba.[1,4] *[1]Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, Tlalpan, Mexico City, Mexico; [2]Instituto Nacional de Cardiología Ignacio Chávez, Mexico City, Mexico; [3]Universidad Panamericana, Mexico City, Mexico; [4]Instituto de Investigaciones Biomédicas, UNAM, Mexico City, Mexico.*

Background: The activity of the electroneutral chloride cotransporters (CCCs) such as the Na-K-2Cl and the K-Cl cotransporters is modulated by intracellular chloride concentration $[Cl^-]_i$ and cell volume. Depletion of $[Cl^-]_i$ and cell shrinkage induce phosphorylation of CCCs, while increase of $[Cl^-]_i$ and cell swelling induces dephosphorylation. However, cell shrinkage increases $[Cl^-]_i$ and cell swelling decreases $[Cl^-]_i$. It is known that the effect of $[Cl^-]_i$ towards CCCs is traduced by the WNK1 or WNK4 kinases. Thus, the effect of cell volume towards CCCs must be traduced by a different kinase. Because WNK3 bypasses the tonicity requirements for regulation of the CCCs (PNAS 2005 and 2006), we tested the hypothesis that WNK3 is sensitive to cell volume, rather than to the $[Cl^-]_i$.

Methods: Xenopus oocytes were microinjected with N(K)CCs or KCCs cRNA alone or together with WNK3 wild type or mutants in which catalytic activity and/or the chloride binding site has been eliminated (WNK3-DA; WNK3 L295/297F; WNK3-DA-LLFF). The effect of $[Cl^-]_i$ or extracellular tonicity on WNKs was assessed. WNKs phosphorylation at the activating serine of the T-loop with specific antibodies was analyzed as a surrogate of WNKs activity.

Results: Depletion of $[Cl^-]_i$ increases the activity of WNK1 and WNK4 and thus increases the NCC activity, while it had not effect on the WNK3 and its effect towards NCC. In contrast to what we previously observed for WNK1 and WNK4, elimination of the chloride-binding site in WNK3 had no effect on the activity of the kinase. WNK3, but not WNK4, phosphorylation was sensitive to changes in cell volume. Compared to isotonic condition, WNK3 phosphorylation significantly diminished or increased by 50% in hypotonic or hypertonic conditions, respectively. The phosphorylation of WNK4 was not affected by similar changes in tonicity.

Conclusions: Our data show that WNK3 is not sensitive to changes of the $[Cl^-]_i$, but is modulated by changes in cell volume in the expected direction according to the effect of WNK3 wild type and the catalytically inactive WNK3 on the CCCs. We propose that WNK3 is a volume sensitive kinase modulating the effect of cell volume changes in CCCs.

Cushing's Syndrome Increases Renal Sodium Transporters in Urinary Extracellular Vesicles Dominique M. Bovee, Mahdi Salih, Alexander H. Danser, Robert Zietse, Richard Feelders, Ewout J. Hoorn. *Erasmus Medical Center, Rotterdam, Netherlands.*

Background: Increased renal sodium (Na^+) reabsorption contributes to hypertension in Cushing's syndrome (CS). Renal Na^+ transporters can be analyzed non-invasively in urinary extracellular vesicles (uEVs). The aim of this study was to analyze renal Na^+ transporters in uEVs of patients with newly diagnosed CS.

Methods: uEVs were isolated by ultracentrifugation and analyzed by immunoblotting in 10 CS patients and 7 age-matched healthy subjects. The majority had an ACTH-producing pituitary adenoma (n=8). In 3 CS patients uEVs were analyzed before and after treatment (unilateral adrenalectomy or ketoconazole). uEVs were isolated without interfering medication (renin-angiotensin system inhibitors or diuretics).

Results: The 10 patients with CS were hypertensive (144 ± 14 / 92 ± 17 mmHg) and had a 2-fold higher abundance of the Na^+/H^+exchanger type 3 (NHE3) in uEVs compared to healthy controls ($p<0.05$). CS patients were subsequently divided in those with a suppressed and non-suppressed renin-angiotensin-aldosterone system (RAAS, n=5/group). CS patients with suppressed vs. non-suppressed RAAS had similar blood pressure but significantly lower serum K^+ (3.9 ± 0.2 vs. 4.4 ± 0.3 mmol/l, p=0.04). Furthermore, only those with suppressed RAAS had 3- to 4-fold higher phosphorylated Na^+-K^+-Cl^-cotransporter type 2 (pNKCC2) and higher total and phosphorylated Na^+-Cl^- cotransporter (NCC) in uEVs. Serum K^+ but not urinary free cortisol correlated with pNKCC2, pNCC, and NCC in uEVs (r = -0.9, -0.8, and -0.7, respectively; $p<0.05$ for all). In the 3 CS patients with uEV-analysis before and after treatment, pNKCC2, pNCC, and NCC abundances normalized after treatment in parallel with serum K^+. No changes were observed in other uEV proteins of interest, including prostasin (a regulator of the epithelial sodium channel), Rac1 (which reflects mineralocorticoid activity), and aquaporin-2.

Conclusions: CS increases renal Na^+ transporter abundance in uEVs especially in patients with suppressed RAAS. In addition to a mineralocorticoid effect of excess glucocorticoids, low serum K^+ may also contribute to increased renal Na^+ reabsorption and hypertension in CS. Our findings recapitulate previously characterized effects of glucocorticoids on NHE3, NKCC2, and NCC in experimental animals and of mineralocorticoids in patients with primary aldosteronism.

High K Intake Modulates Thiazide Sensitive Na-Cl Cotransporter Mediated Na and K Transport: Effects of Gender and Angiotensin II Type 1a (AT1a) Receptor Jing Li,[1] Shuhua Xu,[1] Claire J. Wang,[1] Haiyan Hu,[1] Alan M. Weinstein,[2] Lawrence G. Palmer,[2] Tong Wang.[1] *[1]Yale University, New Haven, CT; [2]Weill Medical College of Cornell, New York, NY.*

Background: The thiazide-sensitive Na-Cl cotransporter (NCC) plays a key role in controlling NaCl absorption in the distal tubule, and also modulates salt and fluid delivery to downstream portions of the nephron, thus regulating K secretion. Previously we reported that higher NCC expression correlates with activity in female WT, and that gender-specific differences were absent in AT1a receptor knockout (KO) mice. We have now studied the gender difference in response to high K intake in WT and AT1a receptor KO animals.

Methods: Renal clearance experiments were performed on male WT and KO mice treated with normal and high K (5% KCl, 7 days) diets. Urine volume (UV), glomerular filtration rate (GFR), absolute (ENa, EK) and fractional (FENa, FEK) Na and K excretion were measured and compared at peak changes after a bolus iv injection of hydrochlorothiazide (HCTZ; 30mg/kg). Total NCC (tNCC) and Na/H-exchanger isoform 3 (NHE3) expressions in the kidney were examined by Western blotting.

Results: In WT mice, HK reduced tNCC abundance by 70% in females and by 60% in males. In KO mice HK produced more reduction of tNCC in male (60%) than female (33%). Functional measurements showed that in WT, K loading diminished HCTZ-dependent FENa by 53% in females and 42% in males. FENa was not reduced by high-K diet in KO mice. High-K intake significantly increased HCTZ-induced kaliuresis (EK) by 129% in WT male, but reduced EK in WT female (68%), KO male (51%) and KO female (55%). NHE3 expression was significantly reduced with high-K diet in all groups. There was no hyperkalemia in any group.

Conclusions: These results suggest that i) NCC activity decreases in response to a high-K diet, in part through decreased protein expression; ii) these responses depend on gender as well as on the presence of the AT1a receptor; iii) Proximal tubule function is also regulated by chronic high-K intake.

Signaling through the Angiotensin-II Type 2 Receptor (AT2R) Suppresses AT1R-Induced SGK1 Phosphorylation and NHE3 Activity Vikram Suri,[2] David Pearce.[1] *[1]University of California San Francisco, San Francisco, CA; [2]University of California- San Francisco, San Francisco, CA.*

Background: Activation of the Angiotensin Type 1 Receptor (AT1R) by Angiotensin-II has been shown to enhance proximal tubular sodium reabsorption via induction of NHE3, as well as distal sodium reabsorption via ENAC. Evidence from the literature supports a role for SGK1 as a critical signaling intermediate in the activation of both transporter systems. The Angiotensin Type 2 Receptor (AT2R) is a well-described receptor that has been shown to exert beneficial effects on blood pressure and natriuresis, and these effects are hypothesized to occur through antagonism of AT1R. In this study, we hypothesized that AT2R suppresses Angiotensin-II-mediated induction of SGK1 activation by AT1R.

Methods: HEK293 cells were transfected with constructs expressing AT1R, AT2R, or both, and stimulated with Angiotensin-II. In order to correlate suppression of SGK1 phosphorylation with transporter activity, we measured the Na-dependent recovery from an acid load, as a marker of NHE3 activity (using Bafilomycin A1 and 1uM EIPA to inhibit the v-H^+-ATPase and NHE1, respectively). MDCK-2 cells were transfected with constructs expressing AT1R, AT2R, or both, loaded with the pH-sensitive dye BCECF-AM, stimulated with Angiotensin-II, and subjected to an acute acid load. Cytosolic pH was measured using ratiometric fluorescence measurements and calibration with Nigericin clamp.

Results: In these experiments, AT2R consistently suppressed AT1R-mediated SGK1 phosphorylation (at S422) by approximately 50% at 30 minutes (as measured by immunoblot). In addition, our data suggests that this suppression may occur through delayed kinetics of SGK1 phosphorylation. In response to an acute acid load, MDCK-2 cells that co-express AT1R and AT2R showed diminished/delayed recovery from an acid load (dpHi/dt), as compared to cells that express either AT1R or AT2R alone.

Conclusions: We conclude from these data that co-expression and activation of AT2R suppresses AT1R-mediated SGK1 phosphorylation and downstream NHE3 activation, and these effects may underlie the observed natriuretic effect of AT2R agonists.

SA-PO1050

Probenecid Downregulates Pendrin and Enhances Hydrochlorothiazide–Induced Diuresis Sharon L. Barone,[1,2] Jie Xu,[1] Kamyar A. Zahedi,[1,2] Marybeth Brooks,[1] Manoocher Soleimani.[1,2] *[1]University of Cincinnati, Cincinnati, OH; [2]Research Services, Veterans Administration, Cincinnati, OH.*

Background: The inactivation or inhibition of NCC or pendrin does not cause any overt salt wasting under baseline conditions. However, double deletion or inactivation of NCC and pendrin causes severe salt wasting in rodents, indicating an important role for pendrin in compensatory salt absorption in the setting of NCC inhibition. Probenecid is a uricosuric agent that inhibits the organic anion transporters (OAT) in the proximal tubule and is used in the treatment of hyperuricemia and gout. In addition, probenecid inhibits the ATP transporter Pannexin 1 in the proximal tubule (PT) and the collecting duct, downregulates pendrin in mammary gland cells and possesses a positive ionotropic effect in the heart. We hypothesized that pretreatment with probenecid will downregulate pendrin, and consequently enhances hydrochlorothiazide (HCTZ) diuresis.

Methods: Male Sprague Dawley rats were treated with probenecid i.p. at 250 or 100 mg/kg/day for 6 days and then received HCTZ daily for 4 days while being maintained on probenecid. Balance studies were performed and expression levels of pendrin and AQP-2 in the kidney were estimated using double immunofluorescence labeling.

Results: Urine output increased from 9.8 at baseline to 15.9 ml/24 hrs after 10 days of Probenecid at 250 mg/kg ($p<0.02$, n=5). Treatment with HCTZ alone for 4 days caused a mild diuresis, with urine output increasing to 13.8 ml/24 hrs ($p>0.05$, vs. baseline, n=5). However, rats pretreated with Probenecid for 6 days exhibited a profound diuresis when HCTZ was added for 4 additional days, with urine output increasing to 42.9 ml/day, a more than 300% increase vs. rats treated with either Probenecid or HCTZ ($p<0.003$ vs. both groups, n = 5). In the absence of pretreatment with Probenecid, the diuresis caused by concurrent Probencid plus HCTZ treatment was similar to HCTZ alone ($p>0.05$). Immunofluorescent labeling and/or Western hybridization studies demonstrated a significant reduction in the expression of pendrin and AQP2 in the kidney cortical collecting duct/cortex of probenecid treated rats.

Conclusions: Probenecid pretreatment downregulates pendrin and AQP2 and robustly enhances diuresis by HCTZ-mediated NCC inhibition in the distal nephron. We propose that Probenecid followed by HCTZ is a strong diuretic regimen for fluid overloaded states and also prevents the hyperuricemia that is caused by HCTZ.

Furosemide Is a Potassium-Sparing Diuretic in Mice on a Low Sodium High Potassium Diet Bangchen Wang, Donghai Wen, Jun Wang-France, Steven C. Sansom. *University of Nebraska Medical Center, Omaha, NE.*

Background: Because of its cardio-protective benefits, a low Na, high K diet (LNaHK) is often warranted in conjunction with diuretics for hypertensive patients. However, it is necessary to understand the renal handling of such diets in order to choose the best diuretic. As previously shown by our lab, furosemide, a K-wasting diuretic, decreased renal K clearance (CL_K) in mice on LNaHK by inhibiting the net K^+ secretion in the thick ascending limb (TAL). Given that furosemide acidifies the urine by increasing acid secretion from TAL and that distal K^+ secretion is affected by urine pH, we hypothesized that furosemide reduces distal K^+ secretion via the large conductance, Ca-activated K channel (BK).

Methods: Wild-type (WT) and BK-β4 knockout mice (KO) were kept on LNaHK (0.01% Na, 5% K) for 7 days. After intraperitoneal injections of vehicle, furosemide (furo; 15 mg/kg), amiloride (amil; 5 mg/kg), or amil + furo, mice were placed into metabolic cages to collect urine for 12 hours. Another group of WT were kept on LNaHK for 7 days and placed into metabolic cages to collect urine for 24 hours with access to either regular water or alkaline furosemide water (0.1 mg/mL, pH 8.8). The mice were then sacrificed and the [K^+] and pH were measured from blood and urine samples. Fluorescence immunohistochemistry (FIHC) was performed on paraffin-embedded kidney sections stained for BK-α.

Results: In WT, the furo group exhibited lower urine pH and lower CL_K than vehicle. In KO, the furo group exhibited a lower urine pH but a similar CL_K compared to vehicle. The amil + furo group had a lower CL_K than the amil group of both WT and KO. There is a positive linear association between CL_K and urine pH in WT but not BK-β4 KO on LNaHK. FIHC showed that BK-α was localized in the apical membrane of connecting tubule cells (CNT) in WT vehicle group. However, BK-α was localized in the cytoplasm of CNT in the WT furo group and both groups of KO. Urine pH and CL_K were not different between WT on LNaHK with regular water and alkaline furosemide water.

Conclusions: These results suggest that in mice on LNaHK, in addition to suppressing net K^+ secretion in TAL, furosemide inhibits BK-αβ4-mediated K^+ secretion in the distal nephron by acidifying the urine. These actions together make furosemide a K-sparing diuretic in the setting of LNaHK.

RNA-Seq Reveals the Transcriptome Changes of Mouse Collecting Duct Cells in Response to Urinary Flow and Primary Cilia Sensing Sami G. Mohammed,[1] Francisco J. Arjona,[1] Zeineb Z. Bakey,[2] Wynand Alkema,[4] Sacha Van hijum,[4] Miriam Schmidts,[3,2] René J. Bindels,[1] Joost Hoenderop.[1] *[1]Physiology, Radboud University Medical Center, Nijmegen, Netherlands; [2]Human Genetics, Radboud University Medical Center, Nijmegen, Netherlands; [3]University College London (UCL), London, United Kingdom; [4]Centre for Molecular and Biomolecular Informatics, Radboud University Medical Center, Nijmegen, Netherlands.*

Background: External cues such as mechanical forces generated by fluid flow play a crucial role in renal physiology. Studies have shown that renal tubular cells respond to mechanical stimuli generated by urinary flow, to regulate the activity and abundance of electrolyte transporters including ion channels. The aim of this study is to reveal the transcriptome changes of tubular epithelia in response to fluid flow and determine the role of primary cilia in this process.

Methods: IMCD3 (inner-medullary collecting duct) cells without cilia were generated using CRISPR/Cas9 technology. Cells were seeded onto μ-slide ibidi chambers and subjected to either static or physiologically relevant fluid flow (~0.7 dyne/cm^2) for 3 h at 37 ^{0}C. RNA was isolated and prepared for RNA-seq by next generation sequencer.

Differentially expressed genes with fluid flow between ciliated and unciliated cells were identified by applying statistical models and validated by RT-qPCR.

Results: The absence of cilia in two independent knockout IMCD3 cell lines (*Ift140* KO or *Dync2h1* KO) and the presence of cilia in one control cell line was confirmed by immunocytochemistry for the cilia marker ARL13b. RNA-seq analysis of ciliated cells subjected to fluid flow showed upregulation of 1379 genes and repression of 1294 genes compared to static control cells (adjusted $p < 0.05$). Several known flow-sensitive genes, such as *Ptgs2* and *Ccl2* were significantly upregulated with fluid flow. Interestingly, fluid flow sensing by primary cilia triggers a transcriptomic response of only 54 genes including genes linked to the regulation of the activity of the epithelial Na^+ channel ENaC, the activity of aquaporins, tight junction permeability, iron transport, phosphate transport, and bicarbonate handling.

Conclusions: Fluid flow elicits a transcriptomic response in the collecting duct of the kidney. The role of primary cilia in this response is restricted to 54 genes, of which 16 are involved in the primary function of the collecting duct, namely ion (principally Na^+) and water (re)absorption.

A Truncation Mutant Targets Wild-Type NKCC1 to the Apical Membrane of Epithelia Rainelli Koumangoye,[2] Salma Omer,[1] Eric J. Delpire.[3] *[1]Anesthesiology, Vanderbilt University Medical Center, Nashville, TN; [2]Anesthesiology, Vanderbilt University Medical Center, Nashville, TN; [3]Anesthesiology, Vanderbilt University Medical Center, Nashville, TN.*

Background: We recently reported the case of a 13-year old patient with complete gastrointestinal and bladder shut-downs; thyroid-, parathyroid-, and pancreatic-insufficiencies; and orthostatic intolerance. The patient carries a *de novo* mutation in SLC12A2, the gene encoding the Na-K-2Cl cotransporter-1 or NKCC1. The 11 bp deletion resulted in a *non-functional* transporter with a shorter cytosolic COOH-terminal tail. Presence of the mutant transporter was shown to increase the amount of dimer, indicating the possibility that the mutant transporter exerts dominant-negative effects on wild-type transporter. No dominant-negative effects were observed in *Xenopus laevis* oocytes.

Methods: In this study, we used fluorescent-tagged wild-type and mutant NKCC1 transporter cDNAs transfected in HEK293 and MDCK cells to examine cell membrane trafficking. HEK293 cells were grown on glass coverslips, whereas MDCK cells were grown on glass coverslips, permeabilized support, and matrigel.

Results: Cells transfected with mutant NKCC1 showed rounding and disruption of well-organized honeycomb-like structures. The overall NKCC1 signal was markedly reduced, indicating that the mutant transporter significantly affected expression of the wild-type transporter. In polarized MDCK cells, most of the mutant transporter signal was observed on the apical membrane. The mutant transporter also affected the formation of MDCK cysts in 3-D cultures, as we observed the presence of multiple lumens per cyst. To test whether mutant NKCC1 affected the trafficking of the wild-type cotransporter, co-transfection experiments with tdTomato- and EGFP-tagged transporters were performed. We demonstrated that the mutant transporter caused trafficking of wild-type cotransporter to the apical membrane. The NKCC1 mutant transporter, however, did not affect the overall polarity of the cells, as the alpha subunit of the Na^+/K^+-ATPase was still observed on the basolateral membrane.

Conclusions: Our data demonstrate that expression of a truncated Na-K-2Cl cotransporter in epithelia causes targeting of the wild-type cotransporters to the wrong membrane and also affects proper lumen formation in MDCK cysts. These observations may explain the multisystem dysfunction that is observed in the patient.

Cathepsin B Mediated ENaC Activation in Nephrotic Syndrome Alexey Larionov,[1] Abdel A. Alli,[2] Geraldine Mollet,[3] Franziska Theilig.[1] *[1]University of Fribourg, Fribourg, Switzerland; [2]University of FL, Gainesville, FL; [3]Inserm U1163, Paris, France.*

Background: Patients with nephrotic syndrome (NS) often present symptoms of volume retention, such as edema formation or hypertension. The primary dysregulation was localized to the renal cortical collecting duct and involves an inappropriate activation of the epithelial sodium channel, ENaC. Plasma proteases passing the leaky glomerular filter were made responsible; however clinical observations demonstrate volume retention before the onset of proteinuria.

Methods: To elucidate its relationship and the underlying mechanisms, inducible podocyte-specific^{Cre}; Nphs2$^{fl/fl}$ developing FSGS with NS was used.

Results: Analysis of renal functional parameters from NS mice revealed sodium retention between day 4 – 7, hypertension and proteinuria starting at day 10 and 12 after FSGS induction. Morphological and biochemical analysis of NS mice kidneys demonstrated at 5 and 9 days increased full-length α- and γENaC expression and proteolytical cleavage of αENaC, and at 17 days increased full-length ENaC and cleaved subunit expression. Aldosterone and vasopressin levels remained unaltered. Urine analysis from NS mice revealed proteolytic activity starting at day 2 after FSGS induction which increased over the time. Urine from day 2 – 9 of NS mice was separated by HPLC and proteases of proteolytic fractions were identified by mass spectrometry. From the identified proteases cathepsin B cleaved αENaC and cathepsin D and legumain cleaved γENaC and all of them resulted in increased ENaC activity.

Conclusions: We identified cathepsin B induced proteolytical activation of αENaC as a new mechanism of volume retention in NS early in FSGS development. Cathepsin D and legumain are new γENaC cleaving proteases; their role needs to be further clarified.

A High Salt Diet Suppressed CXCL9 and CXCL10 in Proximal Tubules through the IFNγ-JAK1-STAT1 Signaling Pathway Yohei Arai,[1] Daiei Takahashi,[1] Kenichi Asano,[3] Masato Tanaka,[3] Mayumi Oda,[2] Shigeru B. Ko,[2] Minoru S. Ko,[2] Shintaro Mandai,[1] Naohiro Nomura,[1] Tatemitsu Rai,[1] Shinichi Uchida,[1] Eisei Sohara.[1] *[1]Department of Nephrology, Graduate School of Medicine, Tokyo Medical and Dental University, Bunkyo-ku, Japan; [2]Department of Systems Medicine, Keio University School of Medicine, Shinjuku-ku, Japan; [3]Laboratory of Immune regulation, School of Life Science, Tokyo University of Pharmacy and Life Sciences, Hachioji-shi, Japan.*

Background: The mechanisms of immunosuppression by salt remain unknown, despite the existence of many clinical evidences indicating that salt loading protects proximal tubules from injury. Therefore, we investigated the mechanisms of immunosuppression by salt in proximal tubules *in vitro* and *in vivo*.

Methods: We focused on cytokine-related gene expression profiles suppressed in kidneys of mice fed a high salt diet using microarray analysis and quantitative RT-PCR. We investigated the mechanism of these cytokine suppressions by salt using a cultured line of human proximal tubular epithelial cells (HK2) *in vitro*. Then, we confirmed this mechanism could apply equally to kidneys of mice fed a high salt diet *in vivo*.

Results: We found that IFNγ inducible chemokine ligands, CXCL9 and CXCL10, and a specific receptor, CXCR3, were suppressed in kidneys of mice fed a high salt diet using microarray analysis and quantitative RT-PCR. Then, we revealed that a high salt concentration suppressed these CXCLs induced by IFNγ in HK2 cells using ELISA. We demonstrated that a high salt concentration decreased IFNGR1 expression in the basolateral membrane of HK2 cells using biotinylation assay, leading to decreased phosphorylation of activation sites of JAK1 and STAT1, activators of CXCLs. JAK inhibitor canceled the effect of a high salt concentration on STAT1 and CXCLs, indicating that the JAK1-STAT1 signaling pathway is essential for this mechanism. Furthermore, we confirmed that the induction of CXCL9 and CXCL10 by IFNγ was suppressed in kidneys of mice fed a high salt diet using immunoblotting. Moreover, the phosphorylation of JAK1 was decreased in kidneys of mice fed a high salt diet.

Conclusions: A high salt diet suppresses the IFNγ-JAK1-STAT1 signaling pathway and the induction of chemokines in proximal tubules in vivo. This finding may explain how salt ameliorates certain kinds of proximal tubular injury and offer a new insight into the linkage between salt and immunity.

Characterization of Kidney-Specific, C-Terminally Truncated Forms of WNK4 Kinase Adrian R. Murillo-de-Ozores,[3,4] Silvana Bazua-Valenti,[3,1] Alejandro Rodriguez-Gama,[3,1] Karla Leyva-Rios,[3] Norma H. Vázquez,[3,1] Chao-Ling Yang,[2] Johannes Loffing,[5] David H. Ellison,[2] Gerardo Gamba,[3,1] Maria Castañeda-Bueno.[3,4] *[1]Instituto de Investigaciones Biomedicas, UNAM, CDMX, Mexico; [2]Oregon Health & Science University, Portland, OR; [3]Molecular Physiology Unit, INCMNSZ, CDMX, Mexico; [4]Facultad de Medicina, UNAM, CDMX, Mexico; [5]Institute of Anatomy, UZH, Zurich, Switzerland.*

Background: The kinase WNK4 is an important regulator of renal salt handling. Mutations in this gene cause Familial Hyperkalemic Hypertension, mainly due to overactivation of the renal NaCl cotransporter, NCC. In addition to the full-length WNK4, we have observed shorter forms of this kinase in kidney lysates.

Methods: Western Blot, LC-MS/MS, immunoprecipitation, site-directed mutagenesis, transfection in HEK293 cells, and *in vitro* proteolytic assays were performed to characterize the short forms of WNK4.

Results: In Western blot assays, using WNK4$^{-/-}$ mice as control and two different N-terminal WNK4 antibodies, we observed lower bands (between 130 and 95 kDa) corresponding to WNK4 fragments in renal lysates of WNK4$^{+/+}$ mice. These bands were not observed in other tissue lysates. LC-MS/MS confirmed that these bands correspond to WNK4 fragments that lack a C-terminal segment. One of these WNK4 forms may be produced by proteolytic cleavage, as we found that recombinant WNK4 is cleaved when incubated with kidney lysate. This process was prevented by a Zn^{2+} chelator. In HEK293 cells, we observed that truncation of WNK4's C-terminus at several positions increases kinase's activity towards SPAK, unless the truncated segment is large enough to include the SPAK binding site. This gain of function is caused by the loss of a protein phosphatase 1 (PP1) binding site. Cotransfection of PP1 causes dephosphorylation of WNK4, while this effect is abrogated in the WNK4-PP1 binding site mutant. Biochemical evidence suggests that the WNK4 short forms detected *in vivo* may lack the SPAK binding site and thus may not behave as constitutively active kinases.

Conclusions: We show the identification of short, C-terminally truncated, and kidney-specific WNK4 forms, at least one of which may be product of proteolysis. Moreover, this work allowed us to identify a *bona fide* PP1 binding site in the C-terminal region of WNK4 that modulates its activity towards SPAK-NCC.

Functional Human Epithelial Na+ Channel Variants in the Extracellular Beta-Ball Domain Shaohu Sheng, Jingxin Chen, Thomas R. Kleyman. *Medicine, University of Pittsburgh, Pittsburgh, PA.*

Background: Epithelial Na^+ channels (ENaC) have a key role in the regulation of extracellular fluid volume, extracellular K^+ concentration and blood pressure. Recent human genome sequencing has revealed a large number of ENaC variants. However, the functional consequences of the vast majority of human ENaC variants are unknown. In this study, we investigated several non-synonymous ENaC variants located at a beta strand within a core beta-ball structure of the extracellular domain for their functional roles.

Methods: Point mutations corresponding to the selected variants were introduced into human alpha ENaC cDNA by site-directed mutagenesis. Wild type (WT) and mutant alpha subunits, together with WT beta and gamma subunits of human ENaC were expressed in *Xenopus* oocytes by cRNA injections. Channel activities were examined by two-electrode voltage clamp. Channel densities in plasma membranes were examined by a luminescence assay using a FLAG epitope tag inserted into the extracellular domain of beta subunit. Na^+ self-inhibition was determined by measuring the decrease in current from the peak to the steady state elicited by a rapid increase in extracellular Na^+ concentration from 1 to 110 mM at -100 mV.

Results: We examined three ENaC variants located at the beta strand 7, one of the five beta-ball strands at the extracellular domain core. Oocytes expressing the R350W ENaCs showed two-fold greater amiloride-sensitive currents than cells expressing WT channels ($p < 0.001$). The variation did not significantly alter channel surface expression. The mutant channels showed a diminished Na^+ self-inhibition, which correlates to an increased open probability. The V351A mutant had a reduced current (55% of WT, $p < 0.001$), whereas G355R showed an increased current (1.6-fold of WT, $p < 0.01$).

Conclusions: R350W and G355R are gain-of-function ENaC variants, and V351A is a loss-of-function variant. R350W is an ENaC gating modifier via suppressing Na^+ self-inhibition. Our results suggest that the core beta strand containing these variants and residing at a subunit interface has an important role in the regulation of ENaC gating.

The Different Modulations of NCC by ERK 1 and ERK 2 Signaling Pathway Xiuyan Feng,[1] Shan Chen,[1] Jia Xiao,[1] Xinxin Chen,[1] Hui Cai.[1,2] *[1]Emory University School of Medicine, Atlanta, GA; [2]Nephrology, Atlanta VA Medical Center, Decatur, GA.*

Background: In our previous studies we found that ERK 1/2 knock-down increased NCC expression in cell experiments. Staub group previously reported that total NCC abundance was siginificantly decreased in the nephron-specific *Nedd4L* knockout (KO) mice. ERK1 and ERK2 are presumed to be functionally redundant given their 84% sequence homology, shared upstream activators, and similar substrate specificity. Our preliminary data indicated that ERK 1 and ERK 2 have different roles in NCC modulation *in vivo*. However, the relationship between ERK 1/2 and Nedd4-2 as well as the effects of unique ERK 1 and ERK 2 on NCC remain not entirely clear. In this study, we investigated the different roles of ERK 1 and ERK 2 in NCC modulation in cells and in both ERK1 KO mice and Pax8+cre+ERK2$^{flox/flox}$ mice.

Methods: Cell culture, western blot analysis, siRNA knock-down experiments, ERK 1 global KO and Pax8+cre+ERK2$^{flox/flox}$ mice were used in this study.

Results: Firstly, we knocked down ERK1 or ERK2 expression separately in Cos-7 cells cotransfected with NCC. We found that ERK1 knock down increased NCC expression while ERK 2 knock down decreased NCC expression. To further explored the different roles of ERK 1 and ERK 2 on NCC. We generated the inducible nephron-specific ERK 2 KO (ERK 2 KO) mice by feeding Pax8+cre+ERK2$^{flox/flox}$ mice with doxycycline 1g/L for 14 days. Western blot results showed that the NCC expression in ERK1 global KO mice increased by 27.7%, whereas in ERK 2 KO mice NCC decreased to 62.1% compared to those in WT mice. We also found that total Nedd4-2, phospho-S448-Nedd4-2 and phospho-S328-Nedd4-2 were decreased to 50.4%, 52.5% and 76.8% respectively in ERK1 KO mice, while they were increased by 1.46, 1.5 and 3.11 folds in ERK 2 KO mice. We further tested the effects of low salt diet (LSD) on NCC abundance in ERK 2 KO mice fed with LSD for 14 days. We found that NCC abundance decreased to 68.8% while 14-3-3 gamma expression increased by 2.07 folds and total NEDD4-2 increased by 2.47 folds compared with that in WT mice.

Conclusions: All data suggested that ERK 1 and ERK 2 signalings have different role in regulationg NCC likely through modulating Nedd4-2 and 14-3-3 gamma. However, the interactions among MAPK- ERK1/2 signaling pathway, Nedd4-2 and 14-3-3 gamma need to be further investigated in the future studies.

A Novel Molecule, Gephyrin, Functionally Associates with ClC-5 Chloride Channel in Response to Metabolic Acidosis in the Mouse Kidney Miyuki Ogawa,[1] Hisato Sakamoto,[3] Makoto Itakura.[2] *[1]Nephrology, Kitasato University, SAGAMIHARA, Japan; [2]Biochemistry, Kitasato University, SAGAMIHARA, Japan; [3]Nephrology, Graduate School of Medical Science, Kitasato University, SAKAMIHARA, Japan.*

Background: ClC-5 channel is co-localized with the V-ATPase in subapical endosomes of renal proximal tubule (PT) and α-intercalated cells. ClC-5 may play a crucial role in regulating both endocytosis and sorting of the acid transporters. However the regulatory molecule associated with ClC-5 has not been elucidated. This study aimed to identify the associated molecule and to examine its physiological roles in the regulation of intracellular sorting of ClC-5 in response to metabolic acidosis.

Methods: Following to immunoisolation of ClC-5-bearing vesicles using the magnetic beads coated with originally generated specific antibody (Ab), we identified specific binding molecules using the analysis by LC-MS and immunoprecipitation assays. To examine the physiological role of the molecule, we prepared the fractions enriched for plasma membrane (P1) and endosomal membrane (P2) using differential centrifugation under conditions with or without NH_4Cl-induced acidosis. The protein abundances of transporters and associated molecule were assessed by Western blot. The co-localization of CLC-5 and associated proteins were also imaged using confocal microscopy.

Results: We identified gephyrin as a specific associated molecule with ClC-5 by LC-MS. Immunohistochemistry showed the predominant expression of gephyrin and its co-localized with ClC-5 in the apical membrane of PT compared with that of distal tubule. In addition, gephyrin was co-immunoprecipitated with specific Ab against ClC-5 using crude homogenates of mouse kidney. Mice given NH_4Cl in drinking water developed metabolic acidosis within 2 days of acid intake. ClC-5 protein abundance was relatively decreased in P1 and increased in P2 after 6 days of acid loading. In contrast the protein abundances of gephyrin were increased by 230% in P1 and 120% in P2 under the same condition of acid loading.

Conclusions: ClC-5 might be functionally anchored by gephyrin in the apical membrane of PT. Furthermore, gephyrin may implicate in the self-assemble into a scaffold to reconstruct and strengthen plasticity following to the sorting of ClC-5 from plasma membrane to intracellular vesicles after acid loading.

Low Chloride Increased NCC Expression through Modulating Both ERK1/2 and SPAK Signaling Pathways Jia Xiao,[1] Xiuyan Feng,[1] Xinxin Chen,[1] Shan Chen,[1] Hui Cai.[1,2] *[1]Emory University School of Medicine, Atlanta, GA; [2]Nephrology, Atlanta VA Medical Center, Decatur, GA.*

Background: Previous studies have showed that low chloride concentration activates NCC activity via WNK-SPAK signaling pathway. We also found that ERK1/2 signal pathway plays an important role in regulating NCC. We previously showed that ERK 1/2 phosphorylation increased in SPAK KO mice, suggesting that SPAK signaling affects ERK 1/2 signaling pathway. Therefore, we investigated whether low chloride concentration affects NCC expression through modulating interaction between ERK1/2 and SPAK signaling pathways.

Methods: Cell culture, transfection, siRNA knock-down, and western blot analysis were used in this study.

Results: We first treated the Cos-7 Cells transfected with NCC with different low chloride concentrations (chloride concentrations decreased from 142 to 7 mEq/L) for 12 hours. The western blot analysis showed that NCC protein expression increased with the decrease in chloride ion concentration in a dose-dependent manner while ERK1/2 phosphorylation decreased and S373-SPAK phosphorylation increased. To further confirm the role of MAPK-EKR1/2 signaling pathway in modulating NCC in response to low chloride concentration, we knocked down the ERK1/2 expression in Cos-7 cells using ERK1/2 siRNA and treated the cells with the low chloride solution. The western blot analysis showed that the basal NCC expression increased in the ERK1/2 siRNA knocked down group compared with the control group transfected with the scramble siRNA as expected. However, NCC expressions further increased with lowering chloride concentration while ERK 1/2 phosphorylation was also further decreased. We also found that SPAK phosphorylation increased with the ERK1/2 siRNA knocked down. To investigated the interation role of SPAK signal pathway with ERK 1/2 signaling, we knocked down SPAK expression in Cos-7 cells using SPAK siRNA and treated the cells with some chloride solutions. We found that the increase in NCC expression was partially reversed by SPAK Knocked down while the ERK1/2 phosphorylation increased.

Conclusions: These data suggested that both MAPK-ERK1/2 and SPAK signaling pathways are involved in the regulation of NCC in response to low chloride stimulation.

SA-PO1061

High Cholesterol Diet (HCD) Downregulates BK Channels in the Rabbit Cortical Collecting Duct (CCD) Rolando Carrisoza-Gaytan,[1] Daniel A. Flores,[2] Lisa M. Satlin.[1] *[1]Icahn School of Medicine at Mount Sinai, New York, NY; [2]Mount Sinai School Of Medicine, New York, NY.*

Background: The apical BK channel in the CCD mediates flow-induced K secretion (FIKS) and adaptation to K loading. Preliminary results had shown that 4-5 wks HCD increases plasma membrane cholesterol content in the CCD, blunts flow-stimulated but not basal net Na absorption (JNa), and inhibits FIKS (~37%) in rabbit CCDs. As studies in endothelial cells and osteoblasts identify genomic effects of a HCD (Physiol Genomics, 2012; Acta Pharm Sinica, 2011), we speculated that a HCD may reduce abundance of BK channels in the CCD.

Methods: NZW rabbits were randomized after weaning to receive either a standard (Base Diet; BD) or a cholesterol enriched diet (HCD; 0.3%) for 4-5 wks, at which time the animals were sacrificed. Kidneys were removed and CCDs microdissected for (i) microperfusion to measure JNa and net K secretion (JK), (ii) quantitative PCR to assess abundance of mRNA encoding Slo1 and (iii) immunoperfusion with anti-BKα Ab to examine plasma membrane expression.

Results: In 6 HCD CCDs, JNa increased from 13.3±6.6 to 30.1±8.5 pmol/min.mm (P≤0.01) in response to an increase in flow rate from 1 to 5 nl/min.mm; this flow-stimulated increase in JNa was less than observed in BD (25.9±4.3 to 73.3±7.0; n= 4; P≤0.01). In the same 6 HCD CCDs, a 5-fold increase in flow rate increased JK from -4.9±1.3 to -11.5±2.2 pmol/min.mm (P≤0.04), transport rates half those observed in BD (-11.3±4.0 to -21.2±1.6; n= 4; P≤0.03). Slo1 mRNA expression in HCD CCDs (n=6 samples; 10-20 mm total tubular length/sample) tended to be less than in BD CCDs (n=3 samples; 13-25 mm/sample; p=0.07). The relative apical/whole-cell expression of BKα was less in HCD principal (Δ=27±0.7%) and intercalated (Δ=24±1.0 %) cells than in BD cells (n=4 rabbits per diet; P≤0.001).

Conclusions: Our results suggest that HCD downregulates the transcription and apical expression of BKα and thus inhibits FIKS in the rabbit CCD. Whether HCD also reduces expression of other channels necessary for K secretion, including ENaC, ROMK and Ca2+ channels, remains to be explored.

SA-PO1062

14-3-3 γ Inhibits BK Activity by Enhancing Its Degradation through a Lysosomal Pathway via an ERK1/2 Signaling-Dependent Mechanism Shan Chen,[1] Xiuyan Feng,[1] Jia Xiao,[1] Xinxin Chen,[1] Hui Cai.[1,2] *[1]Emory University School of Medicine, Atlanta, GA; [2]Nephrology, Atlanta VA Medical Center, Decatur, GA.*

Background: 14-3-3 γ belongs to a family of multifunction regulatory proteins that mainly bind to phosphorylated Ser/Thr residues in the target proteins. Our previous data showed that 14-3-3 γ inhibits Big K (BK) channel activity and its protein expression through altering ERK1/2 signaling pathway. Thus, we hypothesized that 14-3-3 γ inhibits BK protein expression by altering BK protein degradation via ERK1/2 signaling.

Methods: Cell culture, transfection, western blot analysis, immunoprecipitation, and WT mice were used in this study.

Results: To determine the inhbitory effects of 14-3-3 on BK channel expression, we first did transfection experiments in Cos-7 cells. We found that overexpression of 14-3-3 γ significantly decreased BK protein expression, and knockdown of 14-3-3 γ expression obviously increased BK protein expression. To confirm that 14-3-3 γ modulates BK protein expression through an ERK1/2 signaling pathway, we performed ERK1/2 inhibition experiments. Cos-7 cells were cotransfected with Flag-14-3-3 γ and myc-BK for 48 hours with or without ERK1/2 inhibitior U0126 treatment. We found that inhibition of ERK1/2 phosphorylation abolished 14-3-3 γ-mediated inhibitory effects of BK protein expression. To explore whether overexpression of 14-3-3γ decreased BK protein expression through a lysosomal degradation pathway, we determined the effects of lysosomal inhibitor, bafilomycin A1 (Baf A1) on BK protein expression in Cos-7 cells. We found that Baf A1 treatments reversed the inhibitory effects of 14-3-3 γ on BK protein expression. We further investigated whether 14-3-3 γ involved in BK protein ubiquitination in HEK 293 stably expressing BK cells transiently transfected with 14-3-3 γ plasmid. We found that overexpression of 14-3-3 γ increased BK protein ubiquitination while increasing ERK 1/2 phosphorylation.

Conclusions: These data suggested that 14-3-3 γ inhibits BK protein expression by increasing BK ubiquitination, leading to enhanced BK degradation through a lysosomal pathway via an ERK1/2 signaling-dependent mechanism.

SA-PO1063

Differential Sodium Ion Distribution in Muscle and Skin and Its Relationship to Hydration Status in Advanced CKD Nicos Mitsides,[1] Damien J. Mchugh,[2] Jane Alderdice,[1] Agnieszka Swiecicka,[2] Paul E. Brenchley,[1] Geoff J. Parker,[2] Sandip Mitra.[1] *[1]Central Manchester University Hospitals NHS Foundation Trust, Manchester, United Kingdom; [2]The University of Manchester, Manchester, United Kingdom.*

Background: Body sodium (Na) excess is an important determinant of cardiovascular risk in chronic kidney disease(CKD). Its effect is mediated, predominantly, through extracellular fluid (ECW) expansion. Although ECW is assumed to be a homogenous isotonic compartment, the relative proportions of water & Na ions in different tissue is unclear in CKD. We aim to quantify Na concentration in muscle(M) and subcutaneous(SC) tissue in relation to hydration states in advanced CKD.

Methods: Na ionic concentration was measured using a 3T MRI scanner & a dual-tuned $^{1}H/^{23}Na$ coil. The lower leg of 8 healthy controls(HC) & 20 CKD stage 5 patients(eGFR<15 ml/min, not on dialysis) was imaged & the M & SC Na concentration derived using saline calibration phantoms. Overhydration index(OH), ECW, intracellular(ICW) & total body water(TBW) was assessed using multifrequency bioimpedance spectroscopy(BIS). Blood Pressure(BP) was assessed by 24hr ambulatory monitoring & Na balance calculated using 3 day food diary & 24 hr urine Na measurements.

Results: The HC & CKD cohorts were similar in age(HC: 50±14.3yr;CKD 53±9.3yr;p=0.60) & sex(50% male) but the CKD cohort had significantly higher comorbidity (Charlson Index:HC 1.0 v CKD 3.0;p<0.01). The MR derived M Na concentrations were not different between the 2 groups (CKD 24.9±5.5mmol/L;HC 23.1±2.7mmo/L,p=0.38). However, CKD participants had higher SC Na concentration than HC(CKD 25.8±10.2mmol/L;HC 19.5±5.0mmol/L,p=0.04). M Na was strongly correlated to BIS measured ECW volume(ECW/TBW:r=0.502,p=0.01). Higher M Na was also associated with increased ECW/ICW ratio(r=0.533,p<0.01) & higher systolic BP(r=0.449,p=0.02). Both M & SC Na correlated with OH(M: r=0.536,p< 0.01;SC:r=0.452,p=0.02). Baseline Na intake was 94.9±32.3mmol/24hr for CKD & 113.1±46.9mmol/24hr for HC(p=0.23) while urine Na excretion was 109.5±41.7 & 171.3±170.5 mmol/24hr respectively(p=0.98).

Conclusions: The distribution of Na ions appears to be heterogenous in body tissues. In M, Na appears to be accompanied by water (osmotically active) & closely linked to ECW expansion. On the other hand, the higher SC Na concentration seen in CKD is dissociated from ECW content & BP, implying an alternative pathophysiology, unrelated to volume homoeostasis, & possibly linked to CKD & higher comorbidity.

Reduced Secretion of PTH and Hypocalcemia in Systemic Heterozygous ATP2B1 Null Mice Yosuke Ehara,[1] Nobuhito Hirawa,[2] Akira Fujiwara,[2] Kouichi Tamura.[1] *[1]Yokohama City University Graduate School of Medicine, Yokohama-shi, Kanagawa, Japan; [2]Yokohama City University Medical Center, Yokohama, Japan.*

Background: We reported the association between high blood pressure and ATP2B1 gene in Japanese population through Millennium Genome Project. ATP2B1 is a gene encoding plasma membrane calcium ATPase 1 (PMCA1), which is known to be expressed throughout the body. PMCA1 plays a role of discharging Ca ions from the inside of the cell to the outside of the cell, and strictly adjusts the intracellular Ca concentration. In subsequent studies we reported that systemic heterozygous ATP2B1 deficient mice exhibited hypertension and reduced eNOS activity, NO production was involved. In addition, it was confirmed that the mouse exhibited hypocalcemia. Therefore, in order to investigate the mechanism of hypocalcemia, we studied bone, small intestine, kidney and parathyroid gland, which are important organs related to Ca metabolism.

Methods: Blood test, urinalysis, bone formation, bone resorption marker, bone density, bone tissue, and the expression levels of Ca regulatory protein in the small intestine in the Systemic heterozygous ATP2B1 deficient mice ($ATP2B1^{+/-}$) and the control mice ($ATP2B1^{+/+}$) were compared.

Results: In the $ATP2B1^{+/-}$ mice, bone mineral density ($ATP2B1^{+/-}$ versus $ATP2B1^{+/+}$: 689.0 ± 12.9 versus 645.2 ±9.2 ; P<0.05), bone mass and urinary calcium excretion (0.769 ± 0.117 versus 0.330 ± 0.082 ; P<0.05) were increased, serum intact PTH (153.6 ± 41.0 versus 324.4 ± 41.4 ; P<0.05) and ATP2B1 expression of intestine (0.56 ± 0.092 versus 1.00 ± 0.117 ; P<0.05) were decreased, compared with control mice. In the intestine, no significant change was observed in the expression levels of various Ca regulatory proteins other than ATP2B1.

Conclusions: Systemic heterozygous ATP2B1 deficient mice exhibited hypocalcemia, and increased bone density and decreased PTH secretion. ATP2B1 might play important roles in bone metabolism.

SA-PO1065

ApoL1 Confers pH-Switchable Ion Permeability to Phospholipid Vesicles John C. Edwards. *St. Louis University, Saint Louis, MO.*

Background: Variants in ApoL1 confer risk of certain chronic kidney diseases. ApoL1 is thought to function as an ion channel but reports vary substantially. We sought to characterize ApoL1 ion permease activity with the hope that it may provide insight into ApoL1-associated kidney disease.

Methods: Recombinant His-tagged ApoL1 was purified by Ni-affinity and gel filtration. Ion permeability was assessed using vesicle-based, voltage dependent Cl and K efflux assays using ion selective electrodes. ApoL1 membrane association was measured by mixing protein with lipid, Na_2CO_3 extraction to remove peripherally-associated protein, and isolation of the remaining integral membrane protein by floating the vesicles through a sucrose cushion.

Results: Addition of Apol1 to vesicles yields robust Cl selective permeability. The activity is dependent on pH at which protein and membranes interact, with a sharp drop above pH 6.0. K permeability is minimal at any pH when protein and vesicles are mixed and assayed at the same pH. However, K permeability is detected when protein and vesicles are allowed to interact at low pH and then shifted to neutral pH for efflux assay. K permeability is greatest if protein and vesicles are mixed at pH 5.5-6.0 and then assayed at pH 7.5. pH switch not only activates the K permeability but also partially inactivates the Cl permeability. Both Cl and K permease activities are linearly dependent on mass of protein, and are dependent on lipid composition, requiring the presence of negatively charged phospholipids. The K permeability requires the presence of Ca ion. Membrane association assays demonstrate pH-sensitive membrane insertion which occurs at low pH, requires the presence of negatively charged phospholipids, and is stable when pH is shifted back to neutral after insertion takes place.

Conclusions: ApoL1 inserts into vesicles at low pH and confers Cl-selective permeability if pH remains low, or switches to K-selective permeability if the pH is neutralized. The data suggest a model in which ApoL1 in the acidic and low Ca environment of the endocytic pathway could insert into membranes and confer Cl selective permeability, and if subsequently targetted to the plasma membrane where it would be exposed to neutral pH and Ca, switch to K permeability. This model might account for the variety of ApoL1 effects that have been reported in both trypanosomes and cultured mammalian cells.

SA-PO1066

MRI Spatial and Temporal Characterization of Acute and Chronic Hypotonic Brain Edema Marta Tejedor,[2] Giovanna Martín,[3] Ángel Nava,[3] Clara Usón,[3] Javier Soto,[3] Alberto Tejedor jorge.[1] *[1]Fundación para la Investigación Biomédica del Hospital General Universitario Gregorio Marañón, Madrid, Spain; [2]Hospital Infanta Elena, Valdemoro, Madrid, Spain; [3]Universidad Complutense de Madrid, Madrid, Spain.*

Background: Hypotonic brain edema has not been studied in depth with imaging techniques such as MRI. **Aims:** to assess spatial and temporal responses within different areas of the brain to hypotonicity, and differences between acute and chronic hyponatremia.

Methods: Chronic hyponatremia was induced in Wistar rats by intraperitoneal (ip) injection of desmopressin (0.4 ug/kg/d), hyposodic liquid diet and free access to water for 7 days (G1). A group of control normonatremic animals was fed with pellet based diet (G2). Brain edema was studied with MRI at baseline and after ip injection of either 10% of body weight in water (both G1 and G2) or 2 mL of NaCl3% for every 100 grams of body weight (G1) over 120 minutes. ADC (apparent diffusion coefficient) assessed the degree of brain edema in different regions of interest: cortex, hypothalamus, nervous fibers, extra-pyramidal system.

Results: Baseline [Na] were 147±7mmol/L (G2) and 136±7mmol/L (G1); after acute water load: 112±5mmol/L and 119±5mmol/L respectively. Baseline ADC values were lower in G1, indicating relevant brain edema. After acute water load, a further drop in the ADC levels was observed in both groups. A transient period of cellular defense where water was actively pumped outside the cells was observed, being more efficient in G1, becoming the ADC levels similar in both groups at 60 min, but worsening again at 90 and 120 min. Lateral hypothalamus was the first region to become edematous, followed by the cortex, and then, at different time points, by the extra-pyramidal system and myelinated fibers. Response to edema appeared with different time delays from the maximum degree of edema, but it seemed to follow a structural order: hypothalamus, cortex, extra-pyramidal system and fibers. Treatment of G1 with hypertonic saline (NaCl3%) induced a correction of the edema that was three times faster than the spontaneous one. Sodium concentrations went from 136±7mmol/L to 140±7mmol/L.

Conclusions: Brain response to hypotonicity is not homogeneous, and edema develops at different time points in different regions. The time course of the response to that edema is not homogeneous either. The different speed in the response to brain edema in adjacent areas suggests that damage leading to central pontine myelinolysis could be earlier than observed in clinical practice.

SA-PO1067

MT-3995, a Novel Non-Steroidal Mineralocorticoid Receptor Antagonist, Has Pharmacological Profiles Differentiated from Eplerenone and Spironolactone Kohei Kikkawa,[2] Naritoshi Shirata,[2] Misae Takakuwa,[2] Akito Nishi,[2] Taku Iguchi,[2] Hitomi Munakata,[2] Tomoko Ikeda,[3] Naomi Koyama,[2] Hidetoshi Shimizu,[2] Yoshinori Watanabe,[2] Masashi Nishio,[2] Makoto Katoh.[1] *[1]Medical Science, Mitsubishi Tanabe Pharma Corporation, Tokyo, Japan; [2]Innovative Medical Science, Mitsubishi Tanabe Pharma Corporation, Toda, Japan; [3]Discovery Technology, Mitsubishi Tanabe Pharma Corporation, Toda, Japan.*

Background: MR antagonists such as eplerenone (Epl) and spironolactone (Spi) improve outcomes in patients with heart failure. However, their use is limited because of steroid-related adverse effects and hyperkalemia risk. MT-3995 is a novel non-steroidal MR antagonist, and the clinical studies are ongoing in patients with diabetic nephropathy (P2b). This study was planned to clarify the pharmacological profiles of MT-3995, comparing with Epl and Spi.

Methods: MR selectivity was evaluated in steroid receptor binding assays. The effect on transcriptional activity was evaluated in cultured CHO cells expressing "Gain-of-function" type mutant MR (S810L). The organ protective effect was evaluated by histopathological finding in salt-loaded SHR/NDmcr-cp, measuring blood pressure via radiotelemetry, 24-hr urinary albumin excretion, mRNA levels in the kidney, and plasma drug concentrations.

Results: MT-3995 had a highly selective MR antagonistic activity with Ki value of 104 nmol/L (Epl: 84.9 nmol/L). MT-3995 (10,000 nmol/L) had almost no binding affinities for other steroid receptors (GR, PR, AR, ER). Spi and Epl enhanced the transcriptional activity in the mutant MR at therapeutic concentrations. While, MT-3995 (10,000 nmol/L or less) had no effect in the mutant MR. Chronic oral MT-3995 (1, 3, 10 mg/kg, for 4 weeks) prevented the progression of cardiorenal damage with a mild anti-hypertensive effect and suppression of pro-inflammatory and pro-fibrosis mRNA levels in the kidney (osteopontin, MCP-1, TGFb1, Col type1). The renal protective effect at 1mg/kg MT-3995 was equivalent to that of 100mg/kg Epl. The pharmacokinetic data indicated that the renal protective effect of MT-3995 was associated with the long-acting MR blockade around the Ki value all day.

Conclusions: MT-3995 is a highly specific MR antagonist, suggesting no risk of steroid-related adverse effects. MT-3995 has renal protective effect with a long-acting MR blockade around the Ki value, indicating that the avoidance of redundant Cmax elevation would be a strategy to minimize hyperkalemia risk in DN patients.

Mineralocorticoids Modulate the Expression of the Beta-3 Subunit of the Na +, K + - ATPase in the Renal Collecting Duct Macarena Rojas,[3] Pablo A. Leon,[1] Victor M. Barrientos,[3] Rodrigo Alzamora,[2] Luis F. Michea.[3] *[1]Universidad de Chile, Santiago, Chile; [2]University of Chile, Santiago, Chile; [3]Millennium Institute on Immunology and Immunotherapy, ICBM, Facultad de Medicina Universidad de Chile, Santiago, Chile.*

Background: Renal sodium reabsorption depends on the activity of the Na^+,K^+-ATPase (NKA) a/b heterodimer. Four a (a_{1-4}) and three b subunit isoforms (b_{1-3}) had been described. It is accepted that renal tubule cells express a_1/b_1. Aldosterone stimulates NKA se activity and may modulate a_1/b_1 expression. However, some studies suggested the presence of β3 in the kidney. We hypothesized that the β_3 isoform of the NKA is expressed by tubular cells of the distal nephron and is modulated by mineralocorticoids.

Methods: We studied kidney from rats (male SD) and mice (male C57BL/6). β_3 mRNA distribution was determined by qRT-PCR and *in situ* hybridization (ISH). We compared the abundance of renal β_3 mRNA to the abundance in other tissues known to express β_3 mRNA (testis, lung, liver). β_3 protein was analyzed by western blot. In addition, convoluted proximal tubules (CPT), cortical collecting ducts (CCD) and inner medullary collecting ducts (IMCD) were isolated for qRT-PCR studies. The MR-dependence of β_3 expression was studied in adrenalectomized (ADX) rodents with or without MR replacement therapy (DOCA; 7.6 mg/100 g b.w.; 5 days). We also tested the effect of the pharmacological MR blockade (Sprinololactone, SPIRO, 25 mg/kg/day)

Results: Kidney tissue express β_3 mRNA, with higher relative abundance in medulla (12.2±0.2- vs. 1.0±0.2 in cortex; n=3, $p<0.05$). ISH studies showed the preferential expression of β_3 mRNA in collecting duct principal cells of cortex and medulla. IMCD presented 4-fold higher abundance of β_3 mRNA as compared to CPT (n=4, $p<0.05$). ADX rodents showed increased β_3 mRNA and protein abundance by 3-fold and 2-fold respectively (n=4, $p<0.05$). The increase of β_3 was prevented by DOCA. SPIRO increased medullary β_3 mRNA (4-fold) and protein (2-fold, n=4, $p<0.05$). No changes in the abundance of β_1 (cortical/medullar) β_3 (cortical) were detected after ADX or Spiro.

Conclusions: We show that the β_3 isoform of the Na^+,K^+-ATPase is mainly expressed in collecting duct principal cells of renal under the modulation of mineralocorticoids. FONDECYT 1130550, FONDECYT 1171869, FONDECYT 1151423; IMII P09-016-F

A Dual COX2-sEH Inhibitor Prevents Sorafenib-Induced Renal Injury John D. Imig,[1] Abdul Hye Khan,[1] Sung hee Wang,[2] Bruce Hammock.[2] *[1]Medical College of Wisconsin, Milwaukee, WI; [2]UC Davis, Davis, CA.*

Background: Anti-cancer drugs, vascular endothelial growth factor receptor tyrosine kinase inhibitors (VEGFRi) can cause hypertension and severe glomerular injury that compromises their effective and safe use. Glomerular cells generate arachidonic acid metabolites with actions that can cause glomerular injury. Therefore, we hypothesized that a novel dual cyclooxygenase-2 and soluble epoxide hydrolase (COX-2/sEH) inhibitor, PTUPB, would decrease deleterious arachidonic acid metabolites, lower blood pressure, and prevent glomerular injury caused by the VEGFRi, sorafenib.

Methods: Sprague-Dawley male rats were administered sorafenib (20 mg/kg/d p.o.) alone or in combination with PTUPB (10 mg/kg/d i.p.) for 4 weeks. Blood pressure was measured weekly and urine and renal tissues were collected from rats after the treatment period.

Results: Sorafenib administration increased blood pressure and this elevated blood pressure reached a plateau by day 14. PTUPB treatment slowed the progression of hypertension (control = 126 ± 7 mmHg; sorafenib = 162 ± 5 mmHg; sorafenib & PTUPB = 148 ± 4 mmHg, $P<0.05$). Sorafenib-induced renal injury was significantly reduced by PTUPB treatment. Albumin to creatinine ratio in sorafenib rats was significantly elevated compared to controls (sorafenib = 18.4 ± 3.5 μg/mg; control = 1.2 ± 0.3 μg/mg). PTUPB treatment decreased albuminuria by 70% (sorafenib & PTUPB = 6.3 ± 0.7 μg/mg, $P<0.05$). Kidney histological analysis determined that glomerular injury as well as medullary fibrosis and tubular cast formation were decreased in rats administered sorafenib and treated with PTUPB.

Conclusions: In conclusion, PTUPB slows the progression of hypertension and significantly decreases glomerular and renal injury in rats administered the VEGFRi, sorafenib. These findings indicate that a novel dual COX-2/sEH inhibitor, PTUPB combats the detrimental side effects of hypertension and severe glomerular injury that compromises the effective and safe use of anti-cancer VEGFRi therapies.

Chronic ASA Administration Exacerbates Renal Damage in Hypertensive Rats Chris R. Kennedy,[1] Jean-Francois Thibodeau,[1,3] Chet E. Holterman,[2] Anthony Carter,[1] Greg O. Cron,[4] Rafael Glikstein.[5] *[1]Kidney Research Centre, Ottawa, ON, Canada; [2]Ottawa Hospital Research Institute, Ottawa, ON, Canada; [3]ProMetic BioSciences Inc., Laval, QC, Canada; [4]The Ottawa Hospital, Ottawa, ON, Canada; [5]The ottawa Hospital, U of Ottawa, Ottawa, ON, Canada.*

Background: Nonsteroidal anti-inflammatory drugs (NSAIDs, e.g. (Aspirin (ASA), ibuprofen, naproxen) inhibit cyclooxygenases whose eicosanoid products buffer renal vasoconstriction in hypertension (HTN) but are contraindicated in hypertensive

individuals as they increase risk for renal injury via decreased renal blood flow and GFR. However, there is little *in vivo* evidence of this phenomenon. We showed that in mice with HTN, vascular-specific deletion of the EP4 receptor (mimicking some of the downstream effects of NSAIDs) significantly reduced renal perfusion and exacerbated injury. The present study was undertaken to test the hypothesis that hypertensive renal injury would be more severe with chronic ASA administration.

Methods: Male Sprague-Dawley rats (n=5 per group) were implanted with Model 2002 Alzet osmotic minipumps loaded with vehicle or Angiotensin II (AngII) to deliver a dose of 400 ng/kg/min for 4 weeks. ASA was administered concurrently via drinking water (0.067 mg/ml) to yield a dose of 10mg/kg/day. Renal function was assessed by plasma creatinine using HPLC. Renal histology was assessed on Masson trichrome and PAS-stained kidney sections. At 0, 2, and 4 weeks, dynamic contrast-enhanced (DCE) MRI was performed using a 7T GE/Agilent MR901 and data analyzed with a two compartment filtration model (PMI, S. Sourbron) to estimate renal blood volume.

Results: After 4 weeks of AngII infusion, rats given daily ASA had significantly decreased bodyweight and appeared dehydrated. Surprisingly, despite comparable ASA dosing, this combination was associated with a 60% survival rate compared to 100% in all other groups. AngII/ASA decreased renal function vs all other groups as indicated by a doubling of plasma creatinine. Renal hypertrophy was similar in both AngII-treated groups. AngII treatment alone led to modest tubulointerstitial injury, characterized by increased tubulointerstitial fibrosis, tubular flattening/dilation and proteinaceous casts. However, the combination of ASA and AngII significantly increased the severity of tubular and glomerular injury, while DCE-MRI revealed profound loss of renal blood volume (P<0.006 vs all other groups).

Conclusions: The combination of AngII-mediated hypertension and chronic ASA intake accelerates renal function decline and injury.

Paternal Factors Contribute to Development of Superimposed Preeclampsia in the Stroke-Prone Spontaneously Hypertensive Rat (SHRSP)

Jorge E. Toblli,[1] Gabriela Barrientos.[2] [1]*Laboratory of Experimental Medicine Hospital Aleman, Buenos Aires, Argentina;* [2]*Laboratory of Experimental Medicine, Hospital Alemán, Buenos Aires, Argentina.*

Background: We have recently demonstrated that the SHRSP strain represents a spontaneous model of superimposed PE, characterized by defective trophoblast-dependent arterial remodeling and placental insufficiency. In the present study we have evaluated the contribution of paternal genotype to the placental pathology associated with the development of superimposed PE in this model.

Methods: A paternal effect model was established by mating normotensive Wistar Kyoto females to SHRSP males (WKYxSHRSP), and compared with control (WKYxWKY) and preeclamptic (SHRSPxSHRSP) pregnancies. Maternal blood pressure (BP) was determined pre-mating and on the morning of gestation day (GD)1, 7, 9, 13, 17 and 19. On the selected dates, 24 h urine and blood samples were collected. Animals were euthanized and implantation sites isolated for morphological analyses. Fetal and placental weights were recorded on GD18 and GD20

Results: Pregnancies sired by SHRSP males displayed decreased numbers of implantation units versus control (WKYxWKY) pregnancies (Fig. 1A). Maternal SBP rose suddenly in WKYxSHRSP pregnancies, peaking on GD9 and returning to pre-pregnancy levels at term (GD19, Fig 1B). WKYxSHRSP dams displayed a significant increase in proteinuria on GD14 (Fig 1C) versus controls, consistent with glomerular damage. Pregnancies sired by SHRSP males showed signs of placental insufficiency and fetal growth restriction (FGR) on GD18 and 20 (Fig. 1D). At mid pregnancy (GD14), morphological alterations were evident in the placenta, including an expansion of the labyrinth layer and thickened walls of the uterine spiral arteries.

Conclusions: Hypertension as a paternal factor influences the kinetics of maternal blood pressure during pregnancy and compromised fetal growth, as a result of placental dysfunction. Identification of placental factors contributed by the paternal genotype may improve the understanding of disease mechanisms in hypertensive disorders of pregnancy.

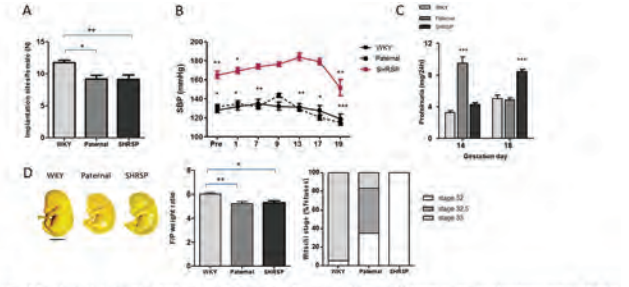

Figure 1. Hypertension as a paternal factor influences maternal physiology and compromises fetal growth A) Females pregnant from hypertensive males (WKYxSHRSP matings, Paternal model) showed an impaired fertility, as noted by decreased number of implantation sites respect to controls (WKY matings). **B)** Analysis of systolic blood pressures (SBP) registered by the tail-cuff method in the different mating models. WKYxSHRSP dams showed a sudden, significant increase in SBP (>140 mmHg, systolic hypertension) on GD9 compared to controls **C)** Urinary protein levels (mg/24 h) in the different models. **D)** Placental dysfunction and fetal growth restriction in WKYxSHRSP pregnancies. Left panel: Representative examples of GD18 fetuses recovered from the different models. Scale bar: 5 mm. Fetuses sired by SHRSP males showed signs of FGR (i.e., reduced length) and placental insufficiency (e.g.: significant reduction of F:P ratios, middle panel) on GD20. FGR in WKYxSHRSP matings was also evident as a maturation delay according to the Witschi Scale for fetal development (i.e.: open eyelids and divergence of the anterior fingers, features consistent with a Witschi stage 32, left). In all panels, *p<0.05, ** p< 0.01 and *** p<0.001 assessed by two-way ANOVA.

SA-PO1072

Preeclamptic Pregnancy Exacerbates Renal Injury in Dahl Salt Sensitive (S) Rats

Hannah Rice, Michael R. Garrett, Jennifer M. Sasser. *University of Mississippi Medical Center, Jackson, MS.*

Background: Preeclampsia results in increased susceptibility to stroke, heart attack, hypertension, and chronic kidney disease postpartum. Despite increased cardiorenal disease risk, recommendations for prevention in these patients have not been established due to a lack of evidence for the mechanisms responsible for disease progression or evaluation of optimal therapeutic regimens. The purpose of this study was to test the hypothesis that preeclampsia accelerates the progression of chronic kidney disease and is associated with changes in the nitric oxide (NO):endothelin-1 (ET-1) balance.

Methods: Dahl S rats on a 0.3% salt diet (previously characterized model of superimposed preeclampsia) who experienced 2 pregnancies (12 and 17 weeks of age) and virgin littermate controls were aged to 6 months. Rats were implanted with telemetry transmitters (DSI), mean arterial pressure (MAP) was recorded, and rats were placed in metabolic cages for 24 hour urine collection prior to tissue harvest.

Results: Prior pregnancy did not result in a further increase in MAP at 6 months in the already hypertensive Dahl S females (virgin:185±6.9 mm Hg, prior pregnancy:184.6±6.6 mm Hg, n=8-10). Despite similar BP, rats who experienced prior preeclamptic pregnancy had greater renal injury compared to virgin littermates. Urinary excretion of protein (96±20 vs 195±45 mg/day), nephrin (0.6±0.4 vs 3.1±1.2 µg/day), and podocalyxin (4.9±1.0 vs 21.0±7.6 µg/day) was higher compared to littermate controls (p<0.05, Bradford assay, Exocell ELISA). These measures of renal injury were corroborated by histological examination as kidneys from rats that experienced preeclampsia demonstrated greater glomerular sclerosis (2.9±0.3) compared to virgin littermates (2.5±0.3, p=0.05). Analysis of urine from Dahl S rats following 2 consecutive pregnancies indicated decreased NO bioavailability (13.0±5.0 vs 5.2±1.6 µmol/day, Cayman Chemical NOx Assay) and increased renal production of ET-1 (4.6±1.5 vs 11.9±3.5 pg/day, with no change in plasma levels of ET-1, R&D Systems Quantiglo ELISA) suggesting that there may be an imbalance in the NO and ET-1 systems following preeclamptic pregnancy.

Conclusions: These data support the hypothesis that alterations in the NO/ET-1 balance in the kidney could link the maternal syndrome of preeclampsia to the increased postpartum risk of cardiovascular and renal disease.

SA-PO1073

Impairment of Key Sphingolipid Metabolism Enzymes in Placenta and Kidneys of Reduced Uterine Perfusion Mouse Model

Suttira Intapad. *Pharmacology Department, Tulane University School of Medicine, New Orleans, LA.*

Background: Preeclampsia (PE), is a pregnancy disorder characterized in the early gestation by placental ischemia, hypertension, and proteinuria. These complications may lead to the development of chronic kidney disease. Bioactive sphingolipids ceramide and sphingosine-1-phosphate (S1P) function as key regulators of cellular homeostasis such as angiogenesis, inflammation and endothelial permeability. Ceramide and S1P levels are altered in preeclamptic women, and sphingolipid pathway has been reported to involve in renal injury. Ceramidase hydrolyzes ceramide to produce sphingosine. Sphingosine can then be phosphorylated by sphingosine kinase (Sphk) 1 and 2 to form S1P. In the present study, we tested the hypothesis that placental ischemia alters the acid ceramidase 1 (ASAH1), Sphk1 and Sphk2 enzymes expression in placenta and kidneys of reduced uterine perfusion (RUP) mouse model.

Methods: C57bl/6J mice underwent sham or RUP surgeries at day 13 of gestation. Mice were instrumented with a carotid arterial catheter for measurement of mean arterial pressure (MAP) at E18 in the conscious state. Placenta and kidneys were harvested after MAP measurement and subjected to western blot analysis.

Results: MAP was significantly elevated in RUP (N=8) versus sham (N=5) (122±2 vs. 105±3 mmHg, $P<0.01$; respectively). ASAH1 were significantly($P<0.01$) lower in the kidneys (50%) and placenta (40%) of RUP (N=4) compared to sham (N=4). Sphk 1 and Sphk 2 were significantly decreased in the placenta of RUP compared to sham (30 % decrease in Sphk1 and 55 % decrease in Sphk2). However, Sphk1 and sphk2 were significantly increased in kidneys of RUP (N=4) compared to sham (N=4) (100 % increase in Sphk1 and 75 % increase in Sphk2).

Conclusions: Taken together, this study suggests the reduced uterine perfusion in mice alters keys sphingolipid metabolism enzymes in placenta and kidneys and may play an important role in the pathogenesis of PE.

SA-PO1074

Uncoupled Endothelial Nitric Oxide Synthase (eNOS) in the Kidney Correlates with Increased Blood Pressure (BP) in Insulin-Infused Mice

Carolyn M. Ecelbarger,[1] Ashley Alunan,[2] Hwal Lee,[1] Maurice Fluitt,[1] Swasti Tiwari,[3] Lijun Li.[1] [1]*Georgetown University, Washington, DC;* [2]*Willamette University, Salem, OR;* [3]*SGPGIMS, Lucknow, India.*

Background: Insulin stimulates NO production in the kidney via activation of eNOS which may lower BP; however, whether and how insulin resistance alters this relationship is unclear.

Methods: We tested whether insulin infusion into insulin-sensitive (C57Bl/6, "C57") versus insulin-resistant (TALLYHO, "TH") mice resulted in differential BP responses and renal eNOS regulation. Male mice (4-6 months old) were infused with insulin (50 U/

kg●bw/d) by osmotic minipump for 14 days (some mice were maintained as untreated). One-half of the infused mice in each strain were switched from a normal NaCl diet (NSD, 1%) to a high-NaCl diet (HSD, 4%) at day 7 of the infusion (n = 6-8/group).

Results: Mean arterial BP (MAP), measured by radiotelemetry, was 10-15 mm Hg lower in C57 mice (relative to TH) at baseline, fell days 2-5 of infusion, then rose days 7-14, so that by day 14, it was no longer different from TH. Pulse pressure (PP) was constant. In TH, MAP was relatively resistant to insulin, while PP fell (~40%). Light-to-dark ratio of MAP (indicator of diurnal rhythm) was elevated in TH in the baseline and increased in both strains with HSD. Urine was measured for nitrites plus nitrates (NOx) at baseline and days 1, 7, and 14 of the infusion. Mean urine NOx increased in both strains (30-40%) between baseline and day 1, but fell to ~55% of baseline by day 14. Plasma NOx concentration was significantly higher in untreated TH (relative to C57), but fell ~40% with insulin infusion (with either NSD or HSD). In contrast, plasma NOx rose in C57 with insulin infusion (13%) and an additional 23% with insulin plus HSD. NOS activity (per mg tissue) was increased by insulin infusion in renal cortex (CTX) in both strains, but in the medulla the increase was restricted to the C57. Western blotting of kidney revealed that coupled (150 KDa) and uncoupled (120 KDa) eNOS band densities were higher in TH, and insulin plus HSD substantially increased the uncoupled band especially in TH.

Conclusions: In summary, insulin infusion for 14 days abrogates BP differences between C57 and TH mice suggesting hyperinsulinemia may primarily underlie the modest hypertension in TH mice. Furthermore, progressive renal eNOS uncoupling and impaired NO production may play a role in the development of hypertension associated with insulin resistance.

SA-PO1075

Renal Oxygenation during Chronic Nitric Oxide Synthase Inhibition as Recorded by Telemetry Tonja Emans,[2,1] Jaap A. Joles,[1] C.T.P. (Paul) Krediet.[2] *[1]Nephrology & Hypertension, UMC Utrecht, Utrecht, Netherlands; [2]Internal Medicine-Nephrology, AMC-UvA, Amsterdam, Netherlands.*

Background: Renal hypoxia has been advanced as a crucial factor in the vicious circle of disease progression leading to kidney failure. Nitric oxide (NO) is involved in renal vascular regulation. NO synthase (NOS)-inhibition leads to hypertension while decreasing renal blood flow and thus oxygen delivery. Furthermore, NO inhibits mitochondrial oxygen consumption. Therefore, we hypothesized that NOS inhibition would induce renal hypoxia. We now report telemetrically monitored mean arterial pressure and oxygen pressure (pO_2) in renal cortex and medulla in conscious rats during chronic NOS inhibition.

Methods: Oxygen sensitive electrodes were implanted in either renal cortex (n=6) or medulla (n=7) in healthy rats. After recovery and stabilization, baseline pO_2 was recorded for one week. Then, to inhibit NOS, L-NNA (40mg/kg/day) was administered via drinking water for two weeks. A separate group of rats (n=6), instrumented with blood pressure recording telemeters, followed the same protocol. Terminal glomerular filtration rate (GFR), renal blood flow (RBF), renal oxygen extraction and natriuresis were assessed under isoflurane anesthesia in all L-NNA rats (n=19) and in untreated controls (n=6).

Results: NOS inhibition rapidly induced hypertension (164 ± 6 vs. 108 ± 3 mmHg, p<0.001) and progressive proteinuria (82 ± 13 vs. 17 ± 2 mg/day, p<0.01). After an initial dip, cortical oxygenation returned to baseline. In contrast, medullary oxygenation decreased progressively (up to -23 ± 8% vs. baseline; p<0.05). Terminal GFR (1334 ± 74 vs. 2036 ± 166 µl/min) and RBF (4840 ± 343 vs. 8986 ± 938 µl/min) were reduced vs. control (both p<0.01). Terminal sodium reabsorption efficiency (TNa/QO2) also decreased (12.7 ± 1.1 vs. 22.8 ± 2.2 µmol/µmol, p<0.01).

Conclusions: Chronic NOS inhibition induced temporal changes in renal pO_2. Cortical pO_2 was not persistently altered, despite reduced RBF and therefore oxygen supply. In contrast, medullary pO_2 decreased progressively. Chronic NO deficiency leads to decreased renal perfusion and reabsorption efficiency (possibly of mitochondria) resulting in progressive medullary hypoxia. This suggests that juxtamedullary nephrons are particularly sensitive to chronic NO depletion. Supported by: Netherlands Organisation for Health Research (ZonMW, 40007039712461)

SA-PO1076

The Role of Plasma Cells in Autoimmune Associated Hypertension Erin Taylor,[2] Michelle T. Barati,[3] David W. Powell,[3] Michael J. Ryan.[1] *[1]Univeristy of Mississippi Medical Center, Jackson, MS; [2]University of Mississippi Medical Center, Jackson, MS; [3]University of Louisville, Louisville, KY.*

Background: Systemic lupus erythematosus (SLE) is a chronic autoimmune disorder that is characterized by the loss of immune tolerance leading to the production of pathogenic autoantibodies, and is associated with prevalent hypertension, renal injury, and cardiovascular disease. Because long-lived plasma cells produce the majority of serum immunoglobulins (Ig) and are the primary source of autoantibodies in SLE, we hypothesized that depletion of plasma cells using the proteasome inhibitor bortezomib would lower autoantibody production and attenuate hypertension.

Methods: Thirty week old female NZBWF1 and control (NZW) mice were injected i.v. with vehicle (0.9% saline) or bortezomib (0.75 mg/kg) twice weekly for four weeks.

Results: Percentages of $CD138^+$ intracellular-κ $light\ chain^+$ plasma cells in the bone marrow were lower in bortezomib treated SLE mice compared to vehicle-treated SLE mice (1.7±0.19% vs. 0.95±0.18%, p<0.05), as assessed by flow cytometry. Circulating B and T cells were not altered after bortezomib treatment. Total plasma IgG was higher in SLE mice as compared to control mice (5.02±1.2 vs. 2.88±0.78 mg/mL, p<0.05), and were lower in SLE mice treated with bortezomib (1.5±0.5 mg/mL, p<0.05 vs. SLE-vehicle). In addition, bortezomib treatment reduced circulating anti-dsDNA IgG levels in SLE mice (1.36±0.25 vs. 0.44±0.11 OD450, p<0.01). This was associated with reduced glomerular IgG deposition in bortezomib treated SLE mice compared to vehicle treated SLE mice (1752±402 vs 916±57 fluoresence/µm², n=5-6, p<0.05) Urinary albumin excretion was increased in SLE mice as compared to controls (16.8±10.1 vs. 0.015±0.002 mg/day, p<0.05) and was lower in bortezomib treated SLE mice (0.24±00.16 mg/day, p<0.05 vs. SLE-vehicle). Mean arterial pressure (MAP; mmHg) measured in conscious mice by carotid artery catheter was higher in SLE mice than in control mice (142±5 vs. 118±3, p<0.001). MAP was significantly lower in SLE mice treated with bortezomib when compared to vehicle treated mice (119±4 vs. 142±5, p<0.001).

Conclusions: These data suggest that production of autoantibodies by plasma cells in SLE mechanistically contribute to the pathogenesis of hypertension.

Renal Dendritic Cells from Hypertensive Mice Transferred Hypertension and Modified Renal Sodium Handling Patricio A. Araos,[4,1] Carolina E. Prado,[2] Edison S. Salas-Huenuleo,[3,5] Marcelo Kogan,[3,5] Rodrigo Pacheco,[2] Luis F. Michea.[4,1] *[1]ICBM, Facultad de Medicina, Universidad de Chile, Santiago, Chile; [2]Fundacion Ciencia y Vida, Santiago, Chile; [3]Depto. de Química toxicológica y Farmacológica, Facultad de Cs. Químicas y Farmacéuticas, Universidad de Chile, Santiago, Chile; [4]Millennium Institute on Immunology and Immunotherapy, Santiago, Chile; [5]Advanced Center for Chronic Diseases ACCDiS, Santiago, Chile.*

Background: High Angiotensin II (AngII) induce hypertension (HT). Previously, using genetically modified mice that allowed the systemic ablation of Dendritic Cells (DCs), we observed that DCs are necessary for the development of HT.The kidney is a tissue rich in DCs, which are present in the interstitial space. We hypothesized that renal DCs have pro-hypertensive properties that are acquired after HT.

Methods: In this study, we evaluated if renal DCs from hypertensive mice (AngII infusion, osmotic minipump, 1.042 µg/Kg/min, 14d) can transfer HT. We compared the transfer of renal DCs and splenic DCs from control (WT) and hypertensive mice ($CD11c^+$ cells, magnetic beads isolation). Isolated DCs from control and hypertensive mice were characterized (CD86, CD80, MHC-II and CX_3CR_1, flow cytometry). We monitoring blood pressure (BP, tail cuff method), and tracked DCs location after transferring (tail vein injection) by labeling DCs with a DiR dye (In vivo FX Pro system, Bruker). To evaluate the effect of DCs transferring on renal Na^+ handling, we challenged recipient mice with the injection of isotonic saline solution (saline test, 10% of BW, i.p. injection) and measured 4h-natriuresis 24h post-DCs transfer.

Results: Renal DCs obtained from hypertensive mice showed increased abundance of CD80, CD86, MHC-II, and CX_3CR_1 (MFI fold of induction: 1.6±0.2; 1.6±0.4; 1.4±0.3 and 3.2±0.8 respectively p<0.05 vs control; n=4-8). Transfer of renal DCs from hypertensive mice transiently increased BP (basal=102.5±4.4; day 1=123.3±4.4; mmHg; n=5, p< 0,001 vs basal). In contrast, transfer of splenic DCs did not modify BP. Renal DCs showed renal-preferential location 24 hours post injection, irrespective of the origin (control or hypertensive kidney). Recipients of hypertensive renal DCs showed decreased renal sodium excretion (basal urinary Na^+ excretion=10.2±1.9 vs. 8.2±0.8 µEq/BW/4h 1 day after transfer; p<0,05 n=5).

Conclusions: Renal, but not splenic, hypertensive DCs presented a preferential homing to kidney, transferred hypertension and transiently reduced natriuresis. These results suggest that renal DCs have a pro-hypertensive phenotype, acquired after the development of hypertension, which confers the ability of modulating sodium renal handling. Leukocyte Angiotensin II Type 1 Receptor-Associated Protein as a Surrogate Marker and Inhibitory Factor of Inflammation Kotaro Haruhara,[1,3] Hiromichi Wakui,[1] Ryu Kobayashi,[1] Daisuke Kurotaki,[2] Nobuo Tsuboi,[3] Takashi Yokoo,[3] Kouichi Tamura.[1] *[1]Department of Medical Science and Cardiorenal Medicine, Yokohama City University Graduate School of Medicine, Yokohama, Japan; [2]Department of Immunology, Yokohama City University Graduate School of Medicine, Yokohama, Japan; [3]Division of Nephrology and Hypertension, Department of Internal Medicine, The Jikei University School of Medicine, Tokyo, Japan.*

Background: Previous studies have shown that the leukocyte gene expression of the renin-angiotensin system, particularly type1 angiotensin II receptor (AT1R), is involved in the pathogenesis of non-communicable diseases (NCD) and its target organ diseases. We found that AT1R-associated protein (ATRAP) is a novel molecule that specifically binds to AT1R and promotes internalization of AT1R along with the suppression of activated AT1R signal in animal models of NCD. The aim of this study was to determine the factors that may regulate the gene expression of ATRAP in leukocytes.

Methods: Blood samples were obtained from healthy volunteers and NCD patients. We examined the relationships between leukocyte ATRAP mRNA and clinical variables. Bone marrow ATRAP-deficient chimeric mice and bone marrow wild-type mice as control were generated by a procedure of bone marrow transplantation. After injection

of low-dose lipopolysaccharide, these mice were sacrificed and measured inflammatory cytokines mRNA expression in leukocytes.

Results: ATRAP was expressed predominantly in granulocytes and monocytes from healthy volunteers. In blood samples from 86 patients (mean age 63 years, hypertension in 95%, dyslipidemia in 76%, chronic kidney disease in 63%), the ATRAP mRNA was positively correlated with the age, neutrophil count, monocyte count, and serum CRP. These associations remained significant after adjustment for age, sex, estimated glomerular filtration rate, and urinary albumin excretion. Furthermore, the ATRAP mRNA was positively correlated with the IL-1β, TNF-α and MCP-1 mRNA in leukocytes. In addition, these cytokines were upregulated in bone marrow ATRAP-deficient chimeric mice in comparison to control mice after injection of low-dose lipopolysaccharide.

Conclusions: These results suggest that leukocyte ATRAP expression is associated with systemic and leukocyte inflammatory status and increases to compensate for inflammation.

Macrophage COX-2 Deletion Activates Renal T Cells and Transporter Activity in Response to High Salt Intake Ming-Zhi Zhang, Zhilian Li, Sungjin Chung, Yinqiu Wang, Aolei Niu, Xiaofeng Fan, Raymond C. Harris. *Vanderbilt University Medical Center, Nashville, TN.*

Background: Chronic use of non-selective NSAIDs or selective cyclooxygenase-2 (COX-2) inhibitors leads to increases in blood pressure. Recently, the immune system has been shown to play an important role in the pathogenesis of hypertension. Both interleukin-17 (IL-17) and interferon γ (IFNγ) production by aberrantly activated effector T cells contribute to angiotensin II-mediated and DOCA/salt-induced hypertension. Bone marrow-derived cells are known to be a rich source of prostaglandins and COX-2-derived prostaglandins modulate and affect both macrophage and T cell function. We recently reported that bone marrow cell COX-2 promotes non-inflammatory, alternatively activated M2 phenotypes in renal macrophages, and bone marrow cell COX-2 deletion led to salt-sensitive hypertension. In the current studies we investigated the potential activation of renal T lymphocytes in response to high salt intake when macrophage COX-2 is deleted.

Methods: Male COX-$2^{f/f}$ (WT) and CD-11b Cre; COX-$2^{f/f}$ (macrophage COX-2-/-) mice (FVB background) were fed a high salt diet (8% NaCl) for 5 weeks. Renal macrophages and T lymphocytes were isolated with CD11b and CD90.1 microbeads, respectively.

Results: Renal macrophage COX-2 mRNA was efficiently deleted in macrophage COX-2-/-. Renal macrophages from high salt-treated macrophage COX-2-/- mice expressed increased IL-23, known to activate Th17 cells. In kidneys from high salt-treated macrophage COX-2-/- mice, there were increased CD4-positive T cells, which expressed increased IFNγ and IL-17, but there were decreased regulatory T cells (Tregs). Cleaved epithelial sodium channel (ENaC) levels, an indicator of its activation, were much higher in high salt treated macrophage COX-2-/- mice.

Conclusions: These results suggest that deletion of macrophage COX-2 leads to aberrant activation of T lymphocytes, with subsequent increased production of IL-17 and IFNγ and activation of sodium transporters in response to chronic salt intake and may contribute to salt-sensitive hypertension.

β-Catenin Activity Is Dependent on Mouse Strain in Angiotensin II Induced Renal Hypertensive Injury Priyantha S. Kulatilake, Elena Wolodimeroff, Helen Williams, Sarah Higgins, Carl J. May, Gavin I. Welsh, Sarah J. George. *University of Bristol, Bristol, United Kingdom.*

Background: Hypertensive kidney injury has been well established; however, little is known about the involvement of Wnt/β-catenin signalling in this process. Here, we induced hypertension with Angiotensin II (AngII) infusion in two strains of mice to determine the effect on β-catenin activity and renal physiology.

Methods: DBA2/J (DBA) mice and mice crossed on a C57/Bl6x129S1/SvImJ background (129/Bl6) were implanted with subcutaneous osmotic pumps containing AngII for 28 days. Blood pressures (BP) were measured and kidneys were excised and processed for RNA, protein and histological analysis.

Results: At baseline DBA mice were significantly more proteinuric than 129/Bl6 mice (n=8 $p<0.05$). However, AngII infusion increased mean arterial BP and albuminuria in both strains of mice (n=8 $p<0.01$). This confirmed AngII induced hypertensive kidney injury. We observed significant changes in renovascular remodelling in both strains with AngII infusion. Increased renovascular fibrosis was induced with AngII in DBA mice (n=8 $p<0.05$); however, it was reduced 129/Bl6 mice (n=8 $p<0.05$). Interestingly, only 129/Bl6 mice developed generalised renal cortical fibrosis with AngII infusion (n=8 $p<0.05$). Levels of active β-catenin only significantly increased in DBA mice that received AngII (n=8 $p<0.01$) and immunohistochemistry showed a renal tubular distribution of β-catenin in kidney paraffin sections. A Wnt focused microarray showed increased β-catenin pathway signalling with altered downstream cell cycling markers. *In vitro* work showed that β-catenin blockade with 25μM iCRT resulted in decreased proliferation (n=3 $p<0.05$) and increased permeability (n=3 $p<0.05$) of HK-2 cells (proximal tubular).

Conclusions: Firstly; these results suggest β-catenin activity in renal hypertension is strain dependent. Secondly; that β-catenin plays an important role in proximal tubular cell proliferation and permeability; therefore β-catenin activity could prove to be a mechanism by which proteinuria develops in DBA mice with AngII induced hypertension.

SA-PO1081

Mocetinostat Attenuates Renal Injury and Dysfunction via the Inhibition of HDAC in Npr1 Gene-Targeted Mutant Mouse Models Prerna Kumar, Christian Nguyen, Venkateswara R. Gogulamudi, Ramachandran Samivel, Kailash N. Pandey. *Tulane University Health Sciences Center and School of Medicine, New Orleans, LA.*

Background: Mice lacking functional guanylyl cyclase/natriuretic peptide receptor-A (GC-A/NPRA) gene (*Npr1*) exhibit hypertension and heart failure. The objective of the present study was to elucidate the effect of class I histone deacetylase (HDAC) inhibitor, mocetinostat (MGCD) on the regulation of *Npr1* expression and repair of renal injury and dysfunction in *Npr1* heterozygous mutant mice.

Methods: Male *Npr1* gene-disrupted heterozygous (1-copy; $Npr1^{+/-}$), wild-type (2-copy; $Npr1^{+/+}$) and gene-duplicated (3-copy; $Npr1^{++/+}$) mice were injected intraperitonealy with MGCD (2 mg/kg) at alternate days for 2-weeks.

Results: The treatment with MGCD significantly increased renal NPRA protein and cGMP levels in all three mice genotypes ($Npr1^{+/-}$, $Npr1^{+/+}$, and $Npr1^{++/+}$) compared with vehicle-treated controls. The $Npr1^{+/-}$ mice exhibited significantly increased renal HDAC activity and HDAC1/2 protein levels compared with $Npr1^{+/+}$ and $Npr1^{++/+}$ mice. MGCD treatment attenuated HDAC activity by 48% and HDAC1/2 protein levels by 42% in $Npr1^{+/-}$ mice compared with wild-type mice. Heterozygous $Npr1^{+/-}$ mice exhibited higher systolic blood pressure (SBP, mm Hg) (130 ± 6 vs. $Npr1^{+/+}$, 102 ± 3 and $Npr1^{++/+}$ mice, 93 ± 3) and lower creatinine clearance (μl/min) (51 ± 10 vs. $Npr1^{+/+}$ mice, 130 ± 14; $p < 0.05$). MGCD-treated $Npr1^{+/-}$ mice showed significantly reduced SBP (106 ± 3; $p < 0.001$) and increased creatinine clearance (105 ± 13; $p < 0.05$) compared with vehicle-treated $Npr1^{+/-}$ mice. Higher urinary total protein and albumin to creatinine ratios were also detected in $Npr1^{+/-}$ mutant mice compared with $Npr1^{+/+}$; however, both of these parameters were dramatically reversed after MGCD treatment.

Conclusions: The present results demonstrate that HDAC inhibitor, MGCD upregulates *Npr1* expression *in vivo* and repairs renal injury in $Npr1^{+/-}$ mice. These findings will have important implications in the treatment and prevention of hypertension and renal injury and dysfunction in humans.

Chronic Hypoxia Attenuated Hypertension and Renal Injury in an L-NAME Model Lisienny C. Rempel, Amanda H. Albino, Karin C. Oliveira, Fernanda F. Zambom, Simone C. Arias, Victor F. Avila, Camilla Fanelli, Claudia R. Sena, Vivian L. Viana, Denise M. Malheiros, Niels O. Camara, Clarice K. Fujihara, Roberto Zatz. *Univ of Sao Paulo, Sao Paulo, Brazil.*

Background: Tissue hypoxia has been postulated as a central factor in the pathogenesis of Chronic Kidney Disease (CKD). We showed recently that, rather than worsening renal injury, chronic hypoxia promoted renoprotection in the remannt kidney model. Here we investigated whether chronic hypoxia promotes similar renoprotection in the chronic NO inhibition model

Methods: Male Munich-Wistar rats received Nω-nitroarginine methylester (NAME) in drinking water (80 mg/Kg/day). Sixteen C (Cnor) and 13 NAME rats (NAMEnor) remained in normoxia (21% O2), while 16 C (Chyp) and 16 NAME rats (NAMEhyp) were kept in a normobaric hypoxia chamber (12% O2). After 4 weeks, we assessed: body weight (BW, g), hemoglobin (Hb, g/dL), tail-cuff pressure (TCP, mmHg), urine albumin/creatinine (Ualb/Ucr), glomerulosclerosis (GS, %), ischemic glomeruli (IG, **%),** cortical interstitium (INT, %), interstitial macrophages (MΦ, cells/mm2) and Angiotensin II positive cell (AngII, cells/mm2) as well as nuclear p65 content (NF-kB, x Cnor). Renal hypoxia was confirmed by pimonidazole immunohistochemistry.

Results: Hypoxia was confined to the outer medulla in Cnor and spread to the cortical area in Chyp. In NAMEnor, hypoxia also extended to the cortical area, a process that was intensified in NAMEhyp. In agreement with our findings in the remnant kidney model, hypoxia attenuated hypertension, inflammation and renal injury, in association with decreased infiltration by Ang II+ cells.

Conclusions: As in the remnant kidny model, chronic hypoxia limited inflammation as well as glomerular and interstitial injury in the chronic NO inhibition model, suggesting that this may be a universal effect. FAPESP/CNPq

SA-PO1083

Podocyte Injury Enhances Intrarenal Angiotensin II Generation and Sodium Retention Dependently on Megalin Masahiro Koizumi,[3] Fumio Niimura,[3] Akira Nishiyama,[1] Motoko Yanagita,[2] Masafumi Fukagawa,[3] Taiji Matsusaka.[3] *[1]Kagawa University Medical School, Kita-Gun, Japan; [2]Kyoto University Graduate School of Medicine, Kyoto, Japan; [3]Tokai University School of Medicine, Isehara, Japan.*

Background: We have previously shown that podocyte injury enhances glomerular filtration of liver-derived angiotensinogen (Agt) and intrarenal angiotensin (A) II

generation (*KI* 2014) and that filtered Agt is reabsorbed by proximal tubular cells dependently on megalin (*JASN* 2012). In the present study, we aimed to study the role of megalin in generation of renal AII and sodium handling during nephrotic syndrome.

Methods: We generated proximal tubule-specific megalin knock out (KO) mice by crossing megalin-loxP, Ndrg-Cre, and Kap-Cre mice. Furthermore, to induce podocyte injury, we crossed these megalin KO mice and NEP25 mice, in which podocyte-specific injury can be induced by injection with immunotoxin.

Results: At baseline without podocyte injury, renal Agt staining was markedly diminished, with increase in urinary Agt in KO mice. However, renal AII levels were similar between KO (n=12) and control (n=16) mice (108 ± 11 vs. 101 ± 17 fmol/g tissue). We next tested the effect of megalin KO on AII generation in the kidney with abnormally increased filtered load of Agt in mice with podocyte-specific injury. Control NEP25 mice (n=10) showed markedly intense renal Agt staining and enhanced renal AII levels (450 ± 61 fmol/g tissue) 7 days after the induction of podocyte injury. Megalin KO/NEP25 mice (n=12) showed diminished renal Agt staining and significantly attenuated renal AII levels (119 ± 23 fmol/g tissue, $p < 0.01$). Compared with control NEP25 mice, megalin KO/NEP25 mice excreted more sodium in urine (U-Na/Cr: 2.06 ± 0.83 vs. 0.58 ± 0.26, $p < 0.001$). Four days after the induction of podocyte injury, when tubulointerstitial damage is milder, the result was comparable. Blood pressure levels were similar between the two groups. Quantitative RT-PCR showed that *NKCC2* mRNA in megalin KO/NEP25 mice were 70.6% to that of control ($p < 0.01$).

Conclusions: These indicate that, in podocyte injury, abnormally increased filtered load of Agt is reabsorbed via megalin by proximal tubular cells and induces the inappropriate activation of intrarenal renin-angiotensin system, which may contribute to sodium retention and edema formation.

Relationship between Blood Pressure and Estimated Glomerular Filtrating Ratio or Proteinuria without a Life-Related Disease Masatoshi Kawashima,[2] Akihiro Kuma,[1] Kazuhiko Enta.[3] *[1]Shizuoka Office, Health Care Center, Central Japan Railway Inc., Shizuoka, Japan; [2]Tokyo Office, Health Care Center, Central Japan Railway Company, Tokyo, Japan; [3]Health Care Center, Central Japan Railway Company, Nagoya, Japan.*

Background: Both estimated glomerular filtrating ratio (eGFR) and proteinuria influences to systolic and diastolic blood presure. We examined the relationship between blood pressure and estimated glomerular filtrating ratio or proteinuria in the absence of a life-related disease.

Methods: We collected the yearly medical examination data from 2008 to 2015 of workers in a railway company in Japan. The data of individuals without a life-related disease, such as hypertension, diabetes mellitus, dyslipidemia, and hyperuricemia, were selected. The selected individuals were classified into 3 categories by average eGFR from 2008 to 2015. Categories I, II, and III were ≥90, 60–90, and <60 ml/min/1.73m^2, respectively. The individuals were next classified into 3 categories by the number of proteinuria reports from 2008 to 2015. Categories 0, 1, and 2 were 0, 1, and ≥2 reports, respectively. Category I–III and Category 0–2 were then combined to form 9 categories (Category I0-III2) and their relationship to systolic and diastolic blood pressure in 2014 examined using ANCOVA with adjusted age and gender.

Results: The selected group of workers included 7,042 (female 336) workers of 24–64 years old in 2015. For systolic blood pressure, significant differences showed in 2 combinations (II0 and II2 P=0.029, and II1 and II2 P<0.001) in association with the proteinuria category. For diastolic blood pressure, a significant difference showed in 2 combinations (II0 and II2 P=0.027, and II1 and II2 P=0.003) in association with the proteinuria category. There were no significant differences detected in comparisons of the eGFR categories with systolic and diastolic blood pressures.

Conclusions: A relationship was detected between proteinuria and blood pressure, which appeared to be a stronger relationship than the relationship between eGFR and blood pressure.

A Critical Role of Angiotensin II Type 1 Receptor Binding Molecule in Hypertension in a CKD Model Ryu Kobayashi,[3] Hiromichi Wakui,[3] Kazushi Uneda,[3] Kotaro Haruhara,[3] Akira Nishiyama,[1] Katsuyuki Tanabe,[2] Yohei Maeshima,[2] Kouichi Tamura.[3] *[1]Kagawa University Medical School, Kita-Gun, Japan; [2]Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Science, Okayama, Japan; [3]Yokohama City University Graduate School of Medicine, Kanazawa-Ku, Japan.*

Background: The renin-angiotensin system plays a key role in the maintenance of cardiovascular and renal homeostasis, principally via appropriate activation of Ang II type 1 receptor (AT1R). We previously identified an AT1R-associated protein (ATRAP/Agtrap), which promotes AT1R internalization along with suppression of hyperactivation of tissue AT1R signaling. We hypothesized that dysregulation of renal ATRAP expression and subsequent AT1R hyperactivation contributes to development of hypertension that occurs as a complication of the remnant kidney CKD model.

Methods: We compared changes in endogenous ATRAP expression and blood pressure between 129/Sv and C57BL/6 mice using the remnant kidney model after 5/6 nephrectomy. We also examined the effect of ATRAP deficiency in C57BL/6 mice (with a hypertension-resistant strain background) on blood pressure regulation after 5/6 nephrectomy. To more directly examine the mechanism of hypertension, ATRAP-knockout (KO) mice were treated with the soluble TNF-α receptor, etanercept, or with vehicle after 5/6 nephrectomy.

Results: We first examined the effect of 5/6 nephrectomy on endogenous ATRAP expression in the kidney of C57BL/6 and 129/Sv mice. While 129/Sv mice that underwent 5/6 nephrectomy showed decreased renal ATRAP expression and developed hypertension, C57BL/6 mice exhibited increased renal ATRAP expression and resistance to progressive hypertension. Consequently, we hypothesized that downregulation of renal ATRAP expression is involved in pathogenesis of remnant kidney CKD model-related hypertension. To investigate this, we performed 5/6 nephrectomy in ATRAP-knockout (KO) mice on the hypertension-resistant C57BL/6 background. ATRAP-KO mice that underwent 5/6 nephrectomy showed hypertension with increased plasma volume. Moreover, in ATRAP-KO mice compared with wild-type C57BL/6 mice after 5/6 nephrectomy, renal expression of the epithelial sodium channel α-subunit and tumor necrosis factor-α was significantly enhanced, concomitant with increased plasma membrane AT1R in the kidneys.

Conclusions: These results indicate that renal ATRAP downregulation is involved in onset and progression of blood pressure elevation caused by renal mass reduction, and implicates ATRAP as a therapeutic target for hypertension in CKD.

SA-PO1086

The Effect of Serine Protease Inhibition on Glomerular Injuries in Salt-Sensitive Hypertension Yasunobu Iwata,[1] Yutaka Kakizoe,[1] Terumasa Nakagawa,[1] Yuichiro Izumi,[1] Takashige Kuwabara,[1] Masataka Adachi,[1] Kenichiro Kitamura,[2] Masashi Mukoyama.[1] *[1]Department of Nephrology, Kumamoto university graduate school of medical sciences, Kumamoto, Japan; [2]Internal Medicine III, University of Yamanashi Faculty of Medicine, Chuou, Japan.*

Background: We previously reported that a synthetic serine protease (SP) inhibitor, camostat mesylate (CM), suppressed epithelial sodium channel (ENaC) activation by SPs and exerted an antihypertensive effect in Dahl salt-sensitive (DS) rats. Furthermore, CM significantly attenuated proteinuria even before it exerted BP lowering effect, suggesting that some SPs are involved in glomerular injuries independently of BP. Recently, it was reported that plasminogen filtered through damaged glomeruli was activated to plasmin by tPA expressed on the surface of podocytes, and that plasmin could directly cause podocyte injuries. We conducted this study to identify SPs which could be associated with glomerular injuries and to explore therapeutic effects of SP inhibition on glomerular injuries in salt-sensitive hypertension.

Methods: Four-week-old male DS rats were divided into following three groups: control group (0.3% NaCl), high-salt (HS) group (8% NaCl diet), and HS+CM group (HS+0.1%CM diet). After systolic BP measurement and 24h urine collection were performed, rats were sacrificed at day 7. SP activities were evaluated by zymography.

Results: HS group did not develop hypertension but displayed significant proteinuria at day 7, which was attenuated in HS+CM (Urinary TP (mg/day); control 4.09±1.17, HS 42.01±3.72, HS+CM 14.31±7.63). CM did not mitigate glomerular hyperfiltration reflected by increased creatinine clearance (Ccr) with salt loading (Ccr (mL/h); control 0.3±0.1, HS 0.8±0.1, HS+CM 0.8±0.2). Urinary plasmin activation was induced by HS, which was substantially inhibited by HS+CM. Furthermore, CM also suppressed albuminuria as early as at day 1-2 even when any apparent activation of SPs was not detected in urine.

Conclusions: Our current study indicates that plasmin and other unknown SPs would be involved in the pathogenesis of glomerular injuries, suggesting that SP inhibition could be a new strategy for the treatment of renal injuries in salt-sensitive hypertension.

SA-PO1087

PGE2 EP1 Receptors Contribute to Hypertensive Injury in Mouse Kidney Jamie Ghossein, Rania Nasrallah, Alex Gutsol, Richard L. Hebert. *University of Ottawa, Ottawa, ON, Canada.*

Background: Prostaglandin E2 (PGE2) derived from COX-2 is upregulated in hypertension and diabetes, and we previously reported that the PGE2 EP1 receptor is involved in glomerular injury and proteinuria in the diabetic mouse. We hypothesize that EP1 contributes to renal injury in hypertension.

Methods: Using a genetic model of hypertension, where TTRhRen mice overexpress renin (Htn), we studied the effects of EP1 deletion using 4 mouse groups at 24 weeks of age: wildtype (WT), EP1-/-, Htn, and HtnEP1-/-. All male mice were placed in metabolic cages, and 24 hour urine was collected. Urine osmolality was determined by freezing point depression and albumin levels were measured by ELISA. Glomerular filtration rate was determined by FITC-Inulin clearance, and systolic blood pressure was measured by tail-cuff plethysmography. Kidneys were fixed and PAS stained for pathological analysis of glomerular, mesangial, and capillary areas using ImageJ photo analysis software.

Results: Urine osmolality was decreased by 33% in Htn mice compared to WT mice, and further decreased by 17% in HtnEP1-/- mice compared to Htn mice. Urine albumin was elevated by 10 fold in Htn mice compared to WT mice, and further increased in HtnEP1-/- mice by 2.5 fold compared to Htn mice. Blood pressures were elevated by 25mmHg in Htn mice compared to WT mice, but this hypertensive state was unaffected by EP1 deletion. FITC-inulin clearance was unchanged in Htn mice, but reduced by 50% in HtnEP1-/- mice compared to WT. Pathological analysis revealed that mesangial cell numbers were unchanged in Htn mice, but stimulated 1.5 fold in both groups lacking EP1 receptors compared to WT. Glomerular and mesangial volume were increased by 1.25 fold and 1.5 fold in Htn mice compared to WT respectively, and mesangial volume was significantly higher in HtnEP1-/- mice compared to Htn mice, reaching 1.95 fold of WT. In contrast, capillary volumes were unchanged in Htn mice, but significantly reduced by 50% in EP1-/- and HtnEP1-/- mice compared to WT mice.

Conclusions: Taken together, the data suggest that the EP1 receptor maintains glomerular permeability and prevents hypertension induced glomerular injury, independent of effects on blood pressure.

SA-PO1088

PGE2 EP1 Receptor Regulates Renal Aquaporin and Sodium Transporter Expression and Inhibits AVP-Dependent Water Reabsorption and Sodium Transport in Mouse Collecting Duct Rania Nasrallah,[1,3] Joe A. Zimpelmann,[1,3] Jamie Ghossein,[1,3] Chris R. Kennedy,[1] Kevin D. Burns,[2,1] Richard L. Hebert.[1,3] *[1]Kidney Research Centre, Ottawa, ON, Canada; [2]The Ottawa Hospital - Riverside Campus, Ottawa, ON, Canada; [3]University of Ottawa, Ottawa, ON, Canada.*

Background: Prostaglandin E2 (PGE2) regulates glomerular hemodynamics, renin secretion, and tubular transport. The purpose of this study was to determine the contribution of PGE2 EP1 receptors to salt and water homeostasis, given that we previously reported no effect on blood pressure in mice lacking EP1.

Methods: Male FVB EP1-/- mice were bred with hypertensive TTRhRen mice (Htn) to evaluate kidney aquaporins, sodium transporters, and transport function at 8 wks of age in 4 groups: wild-type (WT), EP1-/-, Htn, HtnEP1-/-. Total RNA was isolated from renal cortex and medulla, and microdissected proximal tubules (PT), thick ascending limb (TAL), and cortical (CCD) and inner medullary collecting ducts (IMCD) for quantitative PCR analysis. CCD and IMCD were microdissected for in vitro perfusions to determine tubular fluid reabsorption in response to PGE2 and vasopressin (AVP), and transepithelial voltage in CCD stimulated with PGE2. CCD were also pre-treated with amiloride (ENaC inhibitor) or hydrochlorothiazide (pendrin inhibitor) prior to PGE2 stimulation.

Results: Cyclooxygenase (COX)-1 and microsomal PGE2 synthase mRNA were increased and COX2 was decreased in mice lacking EP1, along with increases in EP3 and reductions in EP2 and EP4 mRNA throughout the nephron. PT sglt1, NHE3, and AQP1 were increased in HtnEP1-/-, but sglt2 was increased in EP1-/- mice. TAL NKCC2 was reduced in the cortex but increased in the medulla. IMCD AQP1 and ENaC were increased, but AVP V2 receptor and urea transporter-1 were reduced in all mouse groups compared to WT. In WT and Htn mice, PGE2 inhibited AVP-stimulated water transport in the IMCD, but not in EP1-/- or HtnEP1-/- mice. Similarly, PGE2 depolarized the transepithelial voltage (inhibited sodium transport) in mouse CCD via EP1 in WT and Htn mice, but not in in mice lacking EP1; both amiloride and hydrochlorothiazide attenuated the inhibitory response of PGE2.

Conclusions: Taken together, the data suggest that EP1 regulates renal aquaporins and sodium transporters, and EP1 plays a major role in attenuating AVP-mediated water transport and inhibiting sodium transport in the mouse collecting duct. The inhibition of sodium transport in response to PGE2 is mediated by both ENaC and pendrin-dependent pathways.

Previous Aerobic Exercise Increases Vo2 Peak in Rats with Kidney Chronic Disease Wesley Silva,[2] Rafael Luiz,[1] Alexandre Saud,[1] Natalia Reinecke,[1] Samuel T. Filho,[1] Kleiton A. Silva,[3] Rodolfo R. Rampaso,[1] Luciana Jorge,[1] Nestor Schor.[1] *[1]Universidade Federal de São Paulo, São Paulo, Brazil; [2]Universidade Federal de São Paulo, Sao Paulo [SP], Brazil; [3]University of Missouri, Columbia, AL.*

Background: Chronic Kidney Disease (CKD) contributes to harm the renal and cardiovascular function. The Aerobic exercise training have been used widely to modulation of renal and cardiovascular environment, reducing cardiovascular risk-associated diseases. **Aim**: To evaluate the effects of the previous exercise training (PET) on oxygen consumption peak (VO2 peak) and renal function of rats submitted to nephrectomy 5/6

Methods: Wistar rats (n=5), were randomically divided in four groups: Exercise + NX + exercise (ENXE), exercise + NX + sedentary (ENXS), sedentary + NX + sedentary (SNXS). Treadmill exercise was performed at 40 to 60% of VO2 peak for 8 weeks. NX surgery was perfomed on 4th week of exercise training protocol

Results: The VO2 peak and exercise capacity were improved in NXES and NXEE groups compared to NXSS. Exercise training decreased proteinuria, although, it was not observed changes in creatinine clearance, serum creatinine and urinary volume. Systolic arterial pressure decreased in NXEE when compared to NXSS and NXES

Conclusions: The data suggest that exercise training may be applied to patients with CKD, especially when performed previous onset of the disease. Thus it demonstrated that exercise were effective to prevent death in NXES and NXEE and could be an addition strategy to treatment of CKD patients

Chronic Treatment with Tadalafil Prevented Renal Dysfunction and Hypertension Caused by High Salt Intake and Preserved Serum SDF-1α Levels in Dahl Salt-Sensitive Rats Natsumi Tomita,[1] Yuji Hotta,[1] Aya Naiki-Ito,[2] Tomoya Kataoka,[3] Yasuhiro Maeda,[1] Satoru Takahashi,[2] Kazunori Kimura.[1,3] *[1]Hospital Pharmacy, Graduate School of Pharmaceutical Sciences, Nagoya City University, Nagoya, Japan; [2]Experimental Pathology and Tumor Biology, Graduate School of Medical Sciences, Nagoya City University, Nagoya, Japan; [3]Clinical Pharmaceutics, Graduate School of Medical Sciences, Nagoya City University, Nagoya, Japan.*

Background: Phosphodiesterase inhibitors (PDE5is) are reported to prevent renal damage and/or blood pressure (BP) elevation in an ischemic-reperfusion model. It is uncertain whether PDE5is are effective against salt sensitive hypertension; thus, we investigated the effects of a PDE5i, tadalafil, on hypertension and renal dysfunction induced by high salt intake using an animal model.

Methods: Eight-week-old male Dahl salt-sensitive rats were divided into three groups (n=6); normal salt (NS), high salt (8% NaCl-included diet; HS), and high salt and tadalafil treatment (10 mg/kg/day, p.o; Tad). Blood urea nitrogen, serum creatinine (SCre), proteinuria, and BP were evaluated at 0, 4, and 8 weeks. The kidney was extracted at 8 weeks and PAS staining was performed. Serum stromal cell-derived factor 1 (SDF-1)-α level, which is associated with the repair of vascular endothelial injury, was also evaluated at the 8 week timepoint.

Results: BP and proteinuria significantly increased in the HS group (P<0.01), while tadalafil treatment attenuated proteinuria and BP elevation at 8 weeks (P<0.01 vs. HS) (Fig.1). While SCre did not increase in the Tad group, it increased in the HS group (P<0.05) at 8 weeks. Glomerulosclerosis and atherosclerosis in the kidney also increased in the HS group (P<0.01), although they were suppressed in the Tad group (P<0.01 vs. HS). Serum SDF-1α level significantly decreased (P<0.01) in the HS group and normalized in the Tad group (P<0.05 vs. HS).

Conclusions: Tadalafil may be an effective treatment for salt-sensitive hypertension, atherosclerosis, and renal dysfunction and maintains SDF-1α level.

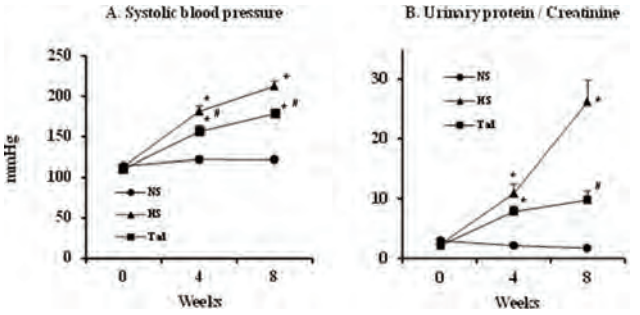

Fig.1 Variations in systolic blood pressure (A) and urinary protein to creatinine ratio (B) in each group (n=6). ANOVA and Bonferroni-type multiple *t*-test. * P<0.01 vs. NS, # P<0.01 vs. HS

SA-PO1091

Urinary L-Type Fatty Acid-Binding Protein Is Useful for Evaluation of the Renoprotective Effect of Bardoxolone Methyl, a Nuclear Factor Erythroid 2-Related Factor 2 Activator Mikako Hisamichi,[1] Takeshi Sugaya,[1] Kenjiro Kimura,[2] Yugo Shibagaki,[1] Atsuko Ikemori.[1] *[1]Division of Nephrology and Hypertension, St Marianna University Hospital, Kawasaki, Japan; [2]Tokyo Takanawa Hospital, Tokyo, Japan.*

Background: Nuclear 1 factor related factor 2 (Nrf2) activator has an anti-oxidant effect and is expected to be a new strategy for chronic kidney disease. Urinary tubular marker, L-type fatty acid-binding protein (L-FABP), is known to accurately reflect tubular damage in a variety of renal stress, especially in oxidative stress. The aim of this study is to reveal the utility of urinary L-FABP as an indicator of the renoprotective effect of bardoxolne metyl (BM), a Nrf2 activator, in renal injury model due to oxidative stress.

Methods: We used an aldosterone (Ald)- and salt-induced renal injury model, in which oxidative stress is strongly associated with onset of tubulointerstitial damage. Tubulointerstitial damage with urinary L-FABP was evaluated using human L-FABP chromosomal transgenic (L-FABP$^{+/-}$) male mice. Male L-FABP$^{+/-}$ mice were divided into three groups: The Ald group received systemic aldosterone infusions via an osmotic minipump and were given 1% NaCl water for 35 days. The Ald-Nrf2 group was given BM intraperitoneally in addition to an injection of aldosterone and salt. The dose of the Nrf2 activator was gradually increased every 7 days, reaching 10mg/kg/daily and continued for 14 days. The control group was only given a vehicle.

Results: The administration of BM significantly increased renal expression of the Nrf2 target antioxidant gene. Tubulointerstitial damage was significantly ameliorated in the Ald-BM group compared to the Ald group. The increase in reactive oxygen species in the kidneys of the Ald group was significantly prevented in the Ald-BM group. The upregulation of human L-FABP expression induced in the kidneys and the increase in urinary L-FABP in the Ald group were significantly suppressed by BM administration. The dynamics of L-FABP were significantly and strongly correlated with the prevention of the tubular damage (r=0.63), inflammatory infiltration(r=0.68) and fibrosis (r=0.72) by the administration of BM.

Conclusions: Urinary L-FABP is a useful marker reflecting the therapeutic efficacy of BM in Ald- and salt-induced renal injury.

Metformin Treatment Downregulates Intrarenal Renin-Angiotensin System in Angiotensin II Infused Mice Rodrigo Alzamora,[3,5] Victor M. Barrientos,[4] Pablo A. Leon,[2] Luis F. Michea.[1] *[1]Facultad de Medicina, U de Chile, Santiago, Chile; [2]Universidad de Chile, Santiago, Chile; [3]Instituto de Ciencias Biomédicas, Facultad de Medicina, Universidad de Chile, Santiago, Chile; [4]University of Chile, Santiago, Chile; [5]The Millennium Nucleus of Ion Channels-Associated Diseases (MiNICAD), Santiago, Chile.*

Background: Activation of an intrarenal renin-angiotensin system (irRAS) is a characteristic of angiotensin II (AngII) induced hypertension. The irRAS contributes to the development and progression of hypertension, by increasing tubular sodium reabsorption, and promotes kidney tissue damage. Recent data have suggested an antihypertensive effect of metformin in several animal models of hypertension. Metformin activates the AMP-activated protein kinase (AMPK), which has been reported to downregulates the activity of renal sodium channels and transporters. We evaluated the effect of metformin treatment on blood pressure (BP) and the expression of components of the irRAS.

Methods: Changes in BP and expressions of angiotensinogen (AGT), renin, AngII type-1 receptor (AT1R) and angiotensin converting enzyme (ACE) were measured in kidney tissue from AngII-infused C57/BL6 mice with or without metformin treatment.

Results: Metformin-treatment prevented the AngII-induced increase in SBP compared to control mice (AngII 153±6 vs. AngII+Met 105±5 mmHg, *P*>0.05, n=4) and decreased renal expressions of renin, ACE and AT1R but did not modified the induction of AGT. As compared to control mice, phosphorylation of AMPK (T172) was decreased in AngII-infused mice (52% reduction, *P*>0.05, n=4) but restored by metformin-treatment. Additionally, metformin-treatment prevented the induction of Na^+-H^+-exchanger-3 (NHE3) expression in kidney cortex from Ang-II infused mice. In contrast, metformin-treatment had no effect on BP, irRAS components and NHE3 expression in control mice.

Conclusions: Metformin has protective effects, by preventing AngII-induced increase in BP, the induction of irRAS and the upregulation of NHE3 caused by AngII infusion. Supported by FONDECYT 1151423 and 1130550, The Millennium Nucleus of Ion Channels-Associated Diseases (MiNICAD). The Millennium Institute on Immunology and Immunotherapy (MIII) P09/016-F (ICM).

SA-PO1093

Effects of Neurogenic CGRP on Renal Afferent Peptidergic Neurons Kristina Rodionova,[1,2] Giulia Raschke,[1] Tilmann Ditting,[1,2] Martin Hindermann,[1,3] Chrstian Ott,[1,2] Roland E. Schmieder,[1] Kerstin U. Amann,[3] Roland Veelken.[1,2] *[1]Dept. of Nephrology, Friedrich-Alexander-University Erlangen, Erlangen, Germany; [2]Paracelsus Medical University Nuremberg, Nuremberg, Germany; [3]Department of Nephropathology, Friedrich-Alexander Universität Erlangen, Erlangen, Germany.*

Background: Although release of the proinflammatory vasodilator CGRP from peptidergic afferent nerves is generally unquestioned the matter is far less investigated with respect to afferent renal innervation that is said to be involved in sympathetic control and blood pressure regulation. Furthermore, it is not known in how far released neurogenic CGRP will affect renal afferent innervation in return. Hence we wanted to test the hypothesis that CGRP elicits action potential production related to TRPV1 receptor stimulation in cultured neurons with afferent projections from the kidney in vivo.

Methods: Cultured dorsal root ganglion neurons (Th11-L2) of rats with renal afferents in vivo were investigated in current clamp mode to asses action potential generation or in voltage clamp mode to investigate inward currents during stimulation of TRPV1 receptors with acid of pH 6 (-80mV holding voltage) and/or administration of CGRP (0,5 µmol). Furthermore, renal slices were incubated during baseline, experimental stimulation period and recovery to study CGRP release due to TRPV1 receptor stimulation (capsaicin 10^{-6} M, increased proton concentrations). CGRP concentrations in the organ bath were assessed with a commercial kit. Capsazepine was used for TRPV1 receptor blockade

Results: More than 90 DRG neurons with renal afferents were tested. Addition of CGRP did not change action potential generation nor inward currents. Proton stimulation (ph 6) of TRPV1 markedly increased long-term inward currents (baseline -361,7 +/- 89,6 pA vs. -1393,3+/-337,3 pA, p<0,05, mean +/- SEM). The co-stimulation of renal neurons with protons (pH 6) and CGRP led to an impairment of sustained inward current as compared to proton stimulation alone (baseline -478,2 +/-54,4 pA vs. -767,6+/-89,6 pA, p<0,05, mean +/- SEM). Baseline CGRP release of renal slices (2.5 to 6 pg/ml) increased significantly after TRPV1 receptor stimulation (on average: 21+4 pg/ml CGRP).

Conclusions: In contrast to our hypothesis CGRP could not elicit action potentials in afferent neurons related to the kidney but even impaired electric currents in general after TRPV1 receptor stimulation. Hence, renal CGRP secretion from peptidergic afferent nerves might decrease further neuronal CGRP release.

SA-PO1094

Voluntary Exercise Decreases Blood Pressure, Angiotensin II, and Aldosterone without Changing Glomerular Filtration Rate in Two-Kidney One-Clip Hypertensive Rats Brian M. Waldman,[1] Robert A. Augustyniak,[1] Haiping Chen,[1] Noreen F. Rossi.[1,2] *[1]Wayne State University, Detroit, MI; [2]John D. Dingell VAMC, Detroit, MI.*

Background: Voluntary dynamic exercise promotes sympathoinhibition and decreases blood pressure in two-kidney one-clip (2K1C) rats, a model of renovascular hypertension. Renal sympathetic nerves increase renin secretion and tubular sodium (Na^+) reabsorption. We hypothesized that daily spontaneous wheel running exercise by 2K1C rats will decrease mean arterial pressure (MAP), plasma angiotensin II (Ang II) and aldosterone (Aldo), and normalize urinary Na^+ and potassium (K^+) excretion independent of glomerular filtration rate (GFR).

Methods: Five week-old male Sprague Dawley rats underwent sham clipping (Sham) or right renal artery clipping (2K1C). Rats were randomly assigned to standard caging (SED) or cages with access to running wheels (EX). After 12 weeks, rats were assigned to 1) collection of aortic blood for measurement of Ang II and Aldo or 2) assessment of inulin clearances and excretory function.

Results: Running distances were comparable in both EX groups. MAP was lower in 2K1C EX vs 2K1C SED rats (191±4 vs 169±2 mmHg; *P*<0.05). Elevated plasma Ang II in 2K1C SED rats (187.4±43.6 fmol/ml) was lower in 2K1C EX rats (48.9±7.5 fmol/ml; *P*<0.05) which did not differ from Sham SED or Sham EX rats (29.3±8.1 and 47.3±7.1 fmol/ml). Aldo levels paralleled those of Ang II. Clipped kidney weights were significantly lower in both 2K1C groups (*P*<0.05), but GFR and urine flow rates were no different from right and left kidneys among the four groups. Total and fractional Na^+ excretion from the unclipped kidney of 2K1C SED rats was higher vs either Sham group (*P*<0.05). Values in 2K1C EX rats were similar to the Sham groups. Total and fractional K^+ excretion was higher from the unclipped kidney of 2K1C SED rats (*P*<0.05); results of exercise paralleled those of Na^+ excretion.

Conclusions: These findings show that voluntary dynamic exercise, known to promote renal sympathoinhibition, lowers blood pressure and decreases plasma Ang II and Aldo levels in the 2K1C model of renovascular hypertension without deleterious effects on GFR. The effects on Na^+ excretion underscore the impact of pressure natriuresis

despite elevated plasma Ang II and Aldo in sedentary 2K1C rats. In contrast, K^+ excretion appears to be primarily regulated by circulating Aldo levels and distal Na^+ delivery.

Phosphoinositide-3 Kinase γ Regulates Inflammation and Renal Fibrosis in Angiotensin II-Induced Hypertension Changlong An,[1,2] Sandhya S. Thomas,[1,2] Zhaoyong Hu,[1] William E. Mitch,[1] Yanlin Wang.[1,2] *[1]Baylor College of Medicine, Houston, TX; [2]Michael E. DaBakey VA Medical Center, Houston, TX.*

Background: We have recently shown that CXCL16/CXCR6 axis plays a critical role in recruiting inflammatory cells and bone marrow-derived fibroblasts into the kidney resulting in renal injury and fibrosis. However, the underlying signaling mechanisms are not known. In the present study, we examined the role of phosphoinositide-3 kinase γ (PI3Kγ) in recruitment of inflammatory cells and bone marrow-derived fibroblasts into the kidney and development of renal injury and fibrosis in an experimental model of hypertension.

Methods: Wild-type (WT) and PI3Kγ knockout (KO) mice were treated with angiotensin II via subcutaneous osmotic minipumps at 1500 ng/kg/min for 4 weeks following uninephrectomy. All the mice were given 1% NaCl in drinking water ad lib. Blood pressure, kidney function, proteinuria, and renal histology were evaluated. Immunostaining was performed to examine the number of inflammation cells and myeloid fibroblasts in the kidney. Proinflammatroy molecule expression was assessed by rela-time RT-PCR. Renal fibrosis and extracellular matrix protein production were determined by sirius red staining, immunostaining and Western blot. Transwell migration assay was performed to determine the role of PI3Kγ in the regulation of cell migration in vitro.

Results: WT and PI3Kγ KO mice had virtually identical blood pressure at baseline. Angiotensin II treatment led to an increase in blood pressure that is similar between WT and PI3Kγ KO mice. Compared with WT mice, PI3Kγ KO mice were protected from angiotensin II-induced renal dysfunction and injury and developed less proteinuria. PI3Kγ deficiency suppressed bone marrow-derived fibroblast accumulation and myofibroblast formation in the kidney and inhibited total collagen deposition and ECM protein production in the kidney in response to angiotensin II. PI3Kγ deficiency inhibited infiltration of $F4/80^+$ macrophages and $CD3^+$ T cells into the kidney and reduced gene expression levels of proinflammatory cytokines in the kidney following angiotensin II treatment. Inhibition of PI3Kγ with AS605240 suppressed CXCL16-induced Akt activation and monocyte migration in vitro.

Conclusions: Our results indicate that PI3Kγ plays a pivotal role in the development of hypertensive kidney injury and fibrosis through regulation of macrophage and T cell infiltration and bone marrow-derived fibroblast accumulation.

SA-PO1096

A Novel Approach for Evaluation of Cleavage of Angiotensin Peptides by Their Angiotensinase Partners Jan Wysocki, Tilman Müller, Pan Liu, Jing Jin, Daniel Batlle. *Division of Nephrology and Hypertension, The Feinberg School of Medicine, Northwestern University, Chicago, IL.*

Background: Angiotensin (1-7) formation from AngII (1-8) occurs via a release of a single c-terminal phenylalanine (Phe). ACE2 and prolylendopeptidase (PEP) are angiotensinases known to cleave Phe from Ang II to form Ang1-7. To capture physiologically important enzymatic conversion of other biologically active angiotensins, such as Ang III (2-8), we used a new quantitative fluorimetric assay which detects the cleaved c-terminal Phe. Since Phe is relatively stable in tissue lysis conditions, this method should provide new insights into specific angiotensinase activities involving Phe cleavage in complex biological samples, such as the kidney, an organ rich in angiotensins and angiotensinases.

Methods: An assay detecting the release of Phe from Ang Peptides in a reaction with the Phe ammonia lyase was used in vitro with recombinant (r) angiotensinases (ACE2, PEP) and ex vivo using kidneys from C57bl/6 mice.

Results: *In vitro*, rACE2 and rPEP caused Phe release from Ang II to form Ang 1-7, as anticipated. Ex vivo incubation of kidney lysates with Ang II and Ang III (10^{-3}M) resulted in a marked generation of Phe. Of note, *Ex vivo* Phe generation from Ang II was significantly higher than that of Ang III (2373±98 vs. 1820±153 RFU/ug prot, n=5, $p<0.05$, respectively). Aminopeptidase A (APA), which is abundant in the kidney, converts Ang II to Ang III (2-8) and the subsequent cleavage of Ang III to Ang (2-7) could generate Phe as well. Consistent with this, an APA inhibitor amastatin (10^{-5}M) reduced significantly Phe cleavage from Ang II in kidney lysates (2373±98 vs. 1906±101, n=5, $p<0.01$, respectively). In addition, purified rACE2 and rPEP caused Phe release from Ang III showing that both enzymes convert Ang III to Ang 2-7. This shows that a substantial portion of Phe formation within kidney during Ang II exposure occurs downstream of this main peptide and that Ang III (2-8), an active metabolite, is also efficiently degraded by endogenous angiotensinases such as ACE2 and PEP.

Conclusions: The new assay detects c-terminal Phe cleavage from Ang II(1-8) but also other Ang peptides, such as Ang III, by ACE2 and PEP, angiotensinases not previously known to cleave this important peptide. This method provides a new tool in evaluating kidney enzyme activities involving cleavage of Phe from bioactive peptides that have this amino acid in c-terminal position.

SA-PO1097

Renin-Independent Blood Pressure Development in Dahl Salt-Sensitive Rats Daria Ilatovskaya,[2] Vladislav Levchenko,[2] Denisha R. Spires,[2] Tengis S. Pavlov,[1] Alexander Staruschenko.[2] *[1]Henry Ford Health System, Detroit, MI; [2]Medical College of Wisconsin, Milwaukee, WI.*

Background: RAAS is considered to be the central regulator of water and salt homeostasis; angiotensin receptors' and/or ACE inhibitors are widely employed to control blood pressure (BP) in humans. Here we used renin knockout ($Ren^{-/-}$) rats created on the Dahl Salt-Sensitive (SS) rat background to study renin-independent BP development; these rats exhibit polyuria, reduced weight and lower mean arterial pressure (MAP) compared to wild type controls.

Methods: To test the involvement of renin in the BP regulation of the Dahl SS rats, 9 week old $Ren^{-/-}$ rats and their wild type littermates were kept on 0.4% NaCl diet since weaning (normal salt, NS), and then challenged with sodium deficient (SD, 0.01%) or high salt (HS, 4% NaCl) diets for 11 days. BP was recorded via telemetry, and kidney function and tissue damage were assessed.

Results: On NS diet $Ren^{-/-}$ rats have a significantly lower MAP compared to littermates (65.9 ± 2.1 vs 121.9 ± 1.9 mmHg). After a HS diet was introduced, we observed a very fast raise in MAP in the $Ren^{-/-}$ rats (ΔMAP was 60.4 ± 7.1 mmHg over a 5 day period, compared to 5 ± 0.4 mmHg in the littermates). In the $Ren^{-/-}$ group HS diet caused mortality within 8 days, which was not observed in the littermates. SD diet did not affect BP and survival rates in either group. 24 hr urinary output was increased in the wild type littermates on HS (not measured in the $Ren^{-/-}$ group due to mortality). However, in all SD diet fed groups urinary output was reduced (15.7 ± 1.7 vs 2.5 ± 0.2 ml/100g before diet switch, and 1.9 ± 0.7 vs 4.8 ± 0.9 ml/100g on SD diet ($Ren^{-/-}$ vs littermates)). On NS diet GFR was found to be lower in the $Ren^{-/-}$ rats (0.18 ± 0.03 ml/min/100g vs 0.54 ± 0.04 in littermates), and HS diet induced an increase in GFR in the littermates on day 10, whereas SD diet did not affect GFR in either group. No difference was found in electrolyte excretion between groups fed a SD diet. Histological analysis revealed exacerbated damage to the hearts and kidneys of the $Ren^{-/-}$ rats fed a SD diet compared to wild type littermates.

Conclusions: BP in the $Ren^{-/-}$ Dahl SS rat increases in response to salt intake, which suggests an involvement of the non-renin components in this mechanism; however, $Ren^{-/-}$ animals are able maintain homeostasis when challenged a SD diet. These data open new avenues to understanding the role of RAAS in SS hypertension.

SA-PO1098

Thymosin β4 Deficiency Accelerates Renal Fibrosis and Damage in Angiotensin-II Hypertension Nitin Kumar, Tang-Dong Liao, Cesar A. Romero, Mani Maheshwari, Oscar A. Carretero. *Henry Ford Hospital, Detroit, MI.*

Background: Angiotensin-II (Ang-II)-induced hypertension is associated with renal fibrosis and damage. Thymosin β4 (Tβ4) regulates cell morphology, inflammation and fibrosis in several organs and administration of exogenous Tβ4 is protective in diabetic nephropathy. However, role of endogenous Tβ4 in hypertension-induced renal damage is unknown. We *hypothesize* that, loss of Tβ4 accelerates renal fibrosis and damage in Ang-II hypertension.

Methods: Tβ4 knockout (Tβ4 KO) and wild-type (WT) C57BL/6 mice (n=6-14) were infused continuously for six-weeks with either Ang-II (980 ng/kg/min) or vehicle via osmotic minipumps. Blood-pressure was measured weekly by non-invasive tail-cuff method. Urinary albumin (24 hours urine collection) and renal cortex collagen were measured by ELISA and hydroxyproline assay, respectively. Renal cortex expressions of nephrin and α-smooth muscle actin (α-SMA) were evaluated by western blot.

Results: All the results are presented in table 1. In Ang-II infusion, systolic blood-pressure was not different between WT and Tβ4 KO mice (Table 1). Interestingly, urinary albuminuria was significantly higher in Tβ4 KO mice compared to WT mice by Ang-II infusion. Tβ4 is highly expressed in the glomeruli along with the high expression of nephrin, an important protein in the filtration barrier of the kidney. In Ang-II infusion, nephrin protein expression was greatly reduced in mice deficient of Tβ4, suggesting that loss of nephrin is one of the mechanisms for elevated urinary albumin in Tβ4 KO mice. Additionally, renal fibrosis in the cortex was higher in Tβ4 KO mice and this was accompanied by elevated profibrotic α-SMA protein expression. Susceptibility to Ang-II induced kidney damage in Tβ4 KO mice may be associated with the observed high mortality rate in these mice.

Conclusions: These data indicate that, in Ang-II hypertension, loss of endogenous Tβ4 caused significant renal fibrosis, damage and mortality, suggesting renal protective role of Tβ4.

Funding: Other NIH Support - NHLBI

Aldosterone Breakthough Does Not Affect Central Hemodynamics Andrew Beenken,[2] Andrew S. Bomback.[1] *[1]Columbia University, New York, NY; [2]New York Presbyterian/Columbia University, New York CIty, NY.*

Background: Angiotensin converting enzyme inhibitors (ACEi) and angiotensin receptor blockers (ARB) are widely used in patients with congestive heart failure (CHF) and chronic kidney disease (CKD), but up to 40% of patients on these agents experience aldosterone breakthrough, with aldosterone levels rising above pre-treatment levels after 6-12 months of RAAS blockade. Aldosterone breakthrough has been associated with worsening CHF and CKD, yet the pathophysiology remains unclear. While aldosterone breakthrough has not been associated with elevated peripheral blood pressure (PBP), no studies have yet evaluated the effect of breakthrough on central blood pressure (CBP).

Methods: In this cross-sectional study, 19 subjects with well-controlled PBP (<140/90), on stable doses of ACEi/ARB for >1 year, had aldosterone levels checked and CBP parameters measured using the SphygmoCor® system. The CBP parameters of subjects with or without breakthrough, defined as serum aldosterone >15 ng/dL, were compared.

Results: Of 19 subjects, 6 had breakthrough with a mean aldosterone level of 33.8 ng/dL, and 13 were without breakthrough with a mean level of 7.1 ng/dL. There was no significant difference between subjects with and without breakthrough in any of the CBP parameters (mmHg), including CBP (92 ± 16 vs. 95 ± 8, p=0.5), central pulse pressure (40 ± 10 vs. 34 ± 11, p=0.2), augmentation pressure (10 ± 5 vs. 7 ± 6, p=0.3), and augmentation index (16 ± 8 vs. 16 ± 12, p=0.4).

Conclusions: We found no correlation between aldosterone breakthrough and CBP. Accordingly, the clinical impact of aldosterone breakthrough on CKD and CHF likely depends on its non-genomic, pro-fibrotic, and pro-inflammatory effects rather than its regulation of extracellular volume.

SA-PO1100

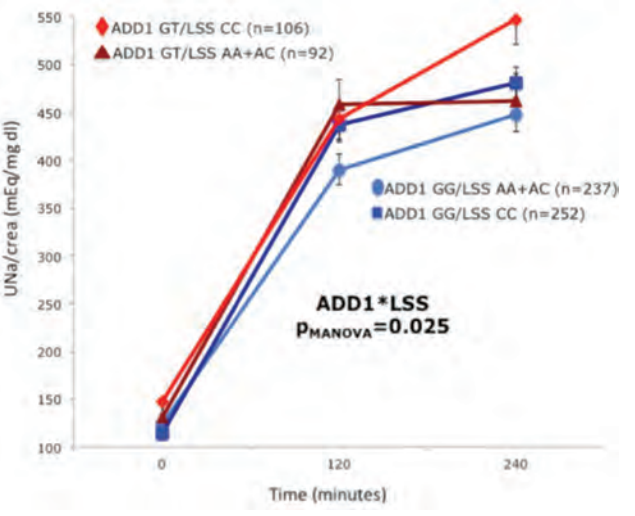
Alfa-Adducin and Lanosterol Synthase Interaction Cause Renal Impairment in Salt Sensitive Hypertension Chiara Lanzani,[4] Simone Fontana,[7] Chiara Maggioni,[4] Laura Zagato,[2] Elisabetta Messaggio,[6] Lorena Citterio,[8] Marco Simonini,[4] Elena Brioni,[9] Simona Delli carpini,[3] John Hamlyn,[5] Paolo Manunta.[1] *[1]HSR-Nefrologia, Milano, Italy; [2]Ospedale San Raffaele, Milano, Italy; [3]San Raffaele Hospital, Milano, Italy; [4]San Raffaele Scientific Institute, Milan, Italy; [5]University of Maryland, Baltimore, Baltimore, MD; [6]Università San Raffaele, Milano, Italy; [7]Università Vita Salute San Raffaele, Milan, Italy; [8]Università Vita-Salute - Ospedale San Raffaele, Milano, Italy; [9]ospedale San Raffaele, Milan, Italy.*

Background: The study of genes involved in the development of renal damage and salt sensitive hypertension (SSH) are still unknown. Impaired renal function is considered the major determinant of salt sensitive hypertension. To explore the role of alpha-adducin (ADD1) and lanosterol synthase (LSS) genes coding for two structural proteins of cell membrane, we studied their genetic interactions that regulate renal function and arterial pressure after saline loading in naïve hypertensive patients (NHP).

Methods: Acute saline load (NaCl 308 mEq/2 h e.v.) was performed in 701 NHP (age 44.95 ± 9.61 years, male 568, female 133), where functional and hormone renal parameters were tested.

Results: Under baseline conditions NHP carriers of the genotype LSS AA (n = 57, 114.8±3.8 ml/min) have a significantly reduced GFR (p = 0.039) compared to homozygous LSS CC subjects (126.08 ± 1.6 ml /m). After acute saline test both are able to increase the filtrate. Carriers of the LSS AA genotype show a slight increase in EO from 231 ± 29 to 242 ± 35, compared to LSS CC, where instead a significant (p=0.05) reduction is observed from 252 to 220 ± 15 pMol/L. The analysis of gene*gene interactions demonstrates that NHPs carrying mutated GT ADD1 and homozygous for LSS C variants excreted the sodium load more rapidly than their wild type ADD1*LSS polymorphism counterparts (Fig 1).

Conclusions: The results of this work demonstrate: First, patients with LSS AA genotype have a reduced glomerular filtrate under basal conditions; second, LSSAA should be define EO non modulator, since the are not able to decrease EO; third, the ADD1*LSS interaction may identify those NHPs with exaggerate natriuresis after saline load.



SA-PO1101

Combination of High Fructose and High Salt Increases Renal Sodium Reabsorption and Blood Pressure That Is Dependent on Ketohexokinase Takahiro Hayasaki,[1] Takuji Ishimoto,[1] Tomohito Doke,[1] Tomoki Kosugi,[1] Miguel A. Lanaspa,[2] Naotake Tsuboi,[1] Richard J. Johnson,[2] Shoichi Maruyama.[1] *[1]Nagoya University Graduate School of Medicine, Nagoya-shi, Japan; [2]University of Colorado Denver, Aurora, CO.*

Background: High fructose intake has been reported to induce metabolic syndrome in laboratory animals and humans. Although it has been also reported that fructose intake enhances sodium reabsorption and causes the elevation of blood pressure (BP), its mechanism is unclear. Here, we examined whether fructose metabolism by the primary enzyme of fructose, ketohexokinase (KHK) regulates sodium reabsorption and BP by using KHK deficient mice (lacking both isoform A and C, KHK-KO).

Methods: Male, C57BL/6, wild-type mice (WT) and KHK KO were used. Study 1; WT and KHK KO were fed with control diet (CD) or 4% high salt diet (HSD), and 10% fructose water (Fr) or tap water (Wa). BP was measured every week (tail cuff), and samples were collected at 5 weeks. Pathological analysis was done, and renal and jejunal KHKs and NHE3 (sodium-hydrogen exchanger 3) expressions were assessed. Study 2; To investigate the effect of fructose intake on renal sodium reabsorption without intestinal absorption, control WT and KHK KO mice and those fed CD and Fr for 5 weeks were administered intraperitoneally with 1.5 ml of normal saline, then urine was collected 6 hours later.

Results: Study 1; KHK was colocarized immunohistochemically with NHE3 in proximal tubular cells in WT. Combination of HSD and Fr for 5 weeks induced the elevation of BP with the decrease of urinary sodium excretion and the increase of renal expression of KHK-C and NHE3 in WT, but not in KHK KO. WT fed HSD without Fr did not show the elevation of BP nevertheless of higher amount of sodium intake than WT fed HSD and Fr. Jejunal NHE3 was tend to increase in WT fed HSD and Fr than KHK KO. Study 2; Urinary sodium excretion after intraperitoneal sodium loading was reduced in WT given Fr compared with that of the control WT. In KHK KO, that reduction was not observed, and renal NHE3 expression was lower than WT.

Conclusions: These results suggest that fructose metabolism by KHK is involved in the development of salt-sensitive hypertension through increases of renal sodium reabsorption by NHE3.

Na/K-ATPase Signaling as an Amplifier of Oxidative Stress Contributes to the Increased Salt Sensitivity of Obese Hypertension Yanling Yan, Muhammad A. Chaudhry, Ying Nie, Jung Han Kim, Zi-jian Xie, Joseph I. Shapiro, Jiang Liu. *Marshall University School of Medicine, Huntington, WV.*

Background: Na/K-ATPase acts as a receptor for reactive oxygen species (ROS) and amplifies ROS signaling, regulating renal sodium excretion (JBC, 2011&2013; JAHA, 2016). Whether or not these pathways are involved in the pathogenesis of obese hypertension due to impaired Na/K-ATPase signaling has not been investigated.

Methods: Blood pressures were measured using the tail-cuff method. Na/K-ATPase signaling activation was assessed in the kidney cortex from high fat (HF)-induced obese C57BL/6J (B6) mice, polygenic obese TALLYHO/JngJ (TH) mice and obese Zucker rats by measuring the phosphorylation of c-Src and ERK1/2 by Western blot. Protein carbonylation (DNP) and heme oxygenase 1 (HO-1) as a commonly used marker for oxidative stress were used to measure the levels of ROS. Renal function curve was constructed with high salt diets (HS, 2, 4, and 8% NaCl).

Results: In the kidney cortex tissue, the Na/K-ATPase signaling (c-Src and ERK1/2 phosphorylation) and oxidative stress (protein carbonylation and HO-1) were activated and were not stimulated by HS diets in obese TH mice (comparing to B6 mice, Figure

A, left panel). Moreover, in salt-loading experiments (with 2, 4, and 8% NaCl), we demonstrated that obese TH mice exhibited an increased salt sensitivity of blood pressure, characterized by a right-shifted, reduced slope in renal function curve (Figure A, right panel, p<0.01). We also observed had a higher baseline oxidative stress and Na/K-ATPase activation in Obese Zucker rats (comparing to lean Zucker rats, Figure B) and high fat-induced obese B6 mice.

Conclusions: Na/K-ATPase signaling activation as a commonly featured characteristic in obese mice and rat was implicated in the increased salt sensitivity of obese hypertension. Further studies targeting Na/K-ATPase signaling will explore the potential nodes for therapeutic intervention and precise target localization to render the required pharmacologic therapy more effective, minimizing the need for medications.

Loss of Urine Concentration and Subsequent Dehydration Characterizes Hypertension in Rats with Chronic Renal Failure Johannes J. Kovarik,[11] Kento Kitada,[5] Adriana Marton,[9] Steffen Daub,[1] Yahua Zhang,[9] Tetyana Pedchenko,[10] Yan Zhao,[10] Janet D. Klein,[2] James L. Bailey,[4] Nada Cordasic,[7] Karl F. Hilgers,[8] Jeff M. Sands,[3] Akira Nishiyama,[6] Jens Titze.[9] *[1]Department of Clinical Pharmacology, Vanderbilt University Medial Center, Nashville, TN; [2]Emory University, Atlanta, GA; [3]Emory University Renal Division, Atlanta, GA; [4]Emory University School of Medicine, Atlanta, GA; [5]Kagawa University, Kagawa, Japan; [6]Kagawa University Medical School, Kita-Gun, Japan; [7]University Hospital of Erlangen, Erlangen, Germany; [8]University of Erlangen, Erlangen, Germany; [9]Vanderbilt University, Nashville, Romania; [10]Vanderbilt University Medical Center, Nashville, TN; [11]Division of Clinical Pharmacology, Vanderbilt University, Nashville, TN.*

Background: The pressure-natriuresis concept suggests that blood pressure-driven increase in renal salt excretion in parallel normalizes the extracellular volume (ECV). In contrast to this traditional view, we have recently shown, that the biological principle of renal salt excretion is urea-driven ECV control by the renal concentration mechanism. We tested the hypothesis, whether hypertension in rats with experimental renal failure (5/6Nx) is characterized by body water loss due to an inability to concentrate the urine.

Methods: We investigated urine flow, osmolyte excretion, urine concentration, arterial blood pressure, and hepatic and extrahepatic urea generation in 5/6Nx (n=23; renal mass ablation) and sham-operated (n=19) Sprague-Dawley rats.

Results: 7 weeks after renal mass ablation, 5/6Nx rats increased their arterial blood pressure by 24.4±20.1 mmHg (P<0.05). Hypertensive 5/6Nx rats showed dehydration with a 13.8±7.0 mOsm/kg increase in plasma osmolality (P<0.001) and reduced ability to concentrate the urine (urine osmolality reduced by -771±590 mOsm/kg; P<0.001). In anesthetized animals, we found a direct relationship between 2Na+2K+Urea osmolyte excretion and urine flow (y=1.24x-3.3; R^2=0.75), indicating osmotic diuresis. 5/6Nx rats showed pronounced 2Na+2K+Urea osmolyte loss (+13.2±5.1 mmol/d) with predominant urea loss (+13.4±4.9 mmol/d) which increased the urine volume by +19.5±7.4 ml/d (all P<0.001) and was paralleled by only discrete Na^+ loss and K^+ retention. In conscious 5/6Nx rats, the urea-driven loss of the renal concentration ability was coupled with a +37.9±15.1 ml/d increase in free-water clearance, indicating renal water loss. The renal urea leak resulted in compensatory increases in urea osmolyte generation in skeletal muscle (arginase activity: +8.7±6.7 units/L/kg, P<0.05; urea content: +1.9±1.2, P<0.01) in 5/6Nx rats.

Conclusions: Hypertension in a rat model of chronic renal failure is characterized by urea-driven loss of the renal concentration mechanism, which leads to increased renal water loss and extracellular volume contraction. Our findings indicate that sodium retention with subsequent volume overload is not the underlying cause of blood pressure increase in 5/6Nx rats.

SA-PO1104

Intrarenal High Salt Administration Causes Tonic Inhibition of Renal Sympathetic Nerve Activity (RSNA) Martin Hindermann,[1,3] Kristina Rodionova,[1,2] Amelie Dietz,[1] Tilmann Ditting,[1] Chrstian Ott,[1,2] Roland E. Schmieder,[1] Kerstin U. Amann,[3] Roland Veelken.[1,2] *[1]Dept. of Nephrology, Friedrich-Alexander-University Erlangen, Erlangen, Germany; [2]Paracelsus Medical University Nuremberg, Nuremberg, Germany; [3]Dept. of Nephropathology, Friedrich-Alexander-University Erlangen, Erlangen, Germany.*

Background: Afferent renal nerve fibers from the kidney likely counterregulate salt sensitive blood pressure increases by decreasing renal sympathetic nerve activity. We recently reported on a long-lasting tonic sympatho-inhibition due to intrarenal afferent renal nerve stimulation eliciting a TRPV1 dependent neuro-humoral pathway. We wanted to test the hypothesis that sodium influences this afferent sympatho-depressory mechanism.

Methods: Groups of anesthetized SD rats (n=8) were equipped with femoral catheters (blood pressure (BP) & heart rate (HR) recording, drug application), a renal arterial catheter for intrarenal administration (IRA) of high salt (10 % NaCl, 10 µl) or Capsaicin (CAP 3.3, 6.6, 10, $33*10^{-7}$ M, 10 µl) and a bipolar electrode for RSNA recordings; eventually an intravenous (iv) bolus of the NK_1-receptor blocker RP67580 ($10*10^{-3}$M, 15 µl) was given. Cultured dorsal root ganglion neurons (Th11-L2) of rats with renal afferents were investigated in current clamp mode to assess action potential generation or in voltage clamp mode to investigate inward currents during 10 sec exposure to 4.5 % NaCl or equi-osmotic 20% mannitol. Results are given in mean±SEM.

Results: IRA high salt and IRA CAP decreased RSNA from baseline 4.1±0.6 µV*sec to 2.2±0.8 µV*sec (10% NaCl, p<0.05) and 3.9±0.5 µV*sec to 0.9±0.2 µV*sec (CAP, p<0.01). Suppressed RSNA in high salt groups and CAP could be unmasked by systemic (i.v.) administration of the NK_1-blocker (2.7±1.8 µV*sec to 5.8±2.2 µV*sec; p<0.05 (10% NaCl); 1.0±0.2 µV*sec to 6.1±1.5 µV*sec; p<0.01 (CAP)). Cultured renal neurons exhibited production of action potentials (3.5±0.8*, from baseline, p<0.05) and increased sustained inward currents from baseline during exposure to NaCl 4.5 % (-10708.8±3546.5 pA*, from baseline, p<0.05). No responses to mannitol 20%.

Conclusions: Increased intrarenal sodium concentrations might induce long-lasting sympatho-depression via a neuro-humoral TRPV1 dependent and tachykinin mediated afferent nerve pathway from the kidney. Impairment of this sympatho-depressory mechanism could be involved in salt sensitive hypertension.

SA-PO1105

Identification of an miRNA That Regulates Sodium-Hydrogen Antiporter 1 Expression in the Medullary Thick Ascending Limb of a High Sodium Induced Hypertension Rat Model Patrizia Lombari,[4] Massimo Mallardo,[6] Joseph amruthraj Nagoth,[7] Oriana Patrazzuolo,[3] Giuseppe Fiume,[2] Sara Damiano,[3] Diego Ingrosso,[5] Anna Iervolino,[1] Giovambattista Capasso.[1] *[1]University of Campania Luigi Vanvitelli, Napoli, Italy; [2]Università degli Studi di Catanzaro ?Magna Graecia?, Catanzaro, Italy; [3]Università degli studi della Campania, Naples, Italy; [4]Department of Cardio-Vascular Medicine, Università degli studi della Campania, Naples, Italy; [5]Università degli studi della Campania "L. Vanvitelli", Naples, Italy; [6]Università degli studi di Napoli "Federico II", Naples, Italy; [7]Department of Cardio-Vascular Medicine, Università degli studi della Campania, Naples, Italy.*

Background: The kidney is one of the principle candidate organs involved in the etiology of essential hypertension. In particular, the medullary thick ascending limb (MTAL) of kidney is important in maintaining acid-base balance by reabsorbing most of the filtered bicarbonate, which is not reabsorbed by the proximal tubule. Microarray expression profiling studies in human revealed different expression profiles of microRNAs in hypertensive vs normotensive patients. In this study, we analyzed miRNA expression profiles in isolated MTAL taken from high sodium intake induced hypertensive rats (HSD) versus their normotensive counter parts (NSD).

Methods: Male Sprague Dawley rats weighing about 185-298 g (Charles river) were allowed free access to standard rodent chow (NIH 31 diet, Ziegler Bros., Gardeners, PA) and drinking solution up to the time of experiments. Control rats were fed with normal drinking water (NSD) and rats on HS-in were fed with 0.28 M NaCl in drinking water (HSD) for 15 days. Renal tubule isolation was performed following method described on Hofmeister, M. V. et al (Am J Physiol Renal Physiol 2009; **296**:F194-203) and the total RNAs was analyzed by genome-wide miRNAs expression profile in MTAL dissected from rats upon HSD or NSD

Results: We have identified seven miRNAs, involved in the onset of salt sensitive hypertension, among them one was the most strongly down-regulated. We identified the sodium-hydrogen antiporter 1 (NHE1) mRNA as a putative target of this miRNA, by in silico analysis. Our data showed that this miRNA is downregulated in the MTAL of HSD rats while NHE1 is upregulated, we also checked whether the levels of protein NHE1 could be lowered by overexpression of the identified miRNA. To verify this hypothesis we overexpressed this miRNA in MTAL cell line, by retroviral infection, and observed a downregulation of NHE1 protein.

Conclusions: Our result indicate NHE1 as a target of the identified miRNA and that the expression of this miRNA is influenced by high sodium intake in thick ascending limbs of rats.

Reciprocal Regulation between the Renal Endothelin and Circadian Rhythm Systems Michelle L. Gumz,[1,2] Lauren G. Douma,[1] I. Jeanette Lynch,[1] Kristen Solocinski,[1] Kit-yan Cheng,[1] Brian D. Cain,[1] Charles S. Wingo.[1,2] *[1]University of Florida, Gainesville, FL; [2]NF/SG Veterans Health System, Gainesville, FL.*

Background: Mice lacking the circadian rhythm gene Per1 exhibit non-dipping hypertension in response to a high salt diet plus mineralocorticoid treatment (HS/DOCP). We hypothesized that Per1 knockout (KO) mice have a renal Na handling defect involving ET-1 that contributes to non-dipping hypertension. ET-1 can mediate renal injury in salt-sensitive hypertension.

Methods: Twelve hour urine collections were made in metabolic cages to determine the night:day ratio of urine Na excretion in WT vs. Per1 KO mice in response to HS/DOCP. We assessed Per1 transcriptional activity using quantitative real time RT-PCR.

Kidney cortex RNA was collected from WT and Per1 KO mice on control or HS/DOCP treatment at noon, the time when BP dips in WT mice but remains high in Per1 KO mice.

Results: WT mice exhibited a high night:day ratio of Na excretion but, Per1 KO had a significant reduction in the night:day Na excretion ratio (WT:6, KO:2, P<0.05). To explore the molecular mechanisms underlying this phenotype, we examined expression of *Edn1* which encodes the peptide hormone endothelin-1 (ET-1). ET-1 mRNA levels did not change in WT in response to HS/DOCP. In contrast, Per1 KO mice exhibited increased expression of ET-1 mRNA in the renal cortex (40% increase, p<0.01). To test the hypothesis that there is reciprocal regulation between ET-1 and the molecular clock, we measured Per1 mRNA expression in the kidneys of collecting duct-specific ET-1 KO mice compared to WT controls after HS/DOCP treatment. Per1 expression was reduced by 50% in the renal medulla of CD ET-1 KO mice relative to WT mice (p<0.01).

Conclusions: The reduced night:day ratio in urine Na excretion suggest that a renal Na handling defect may contribute to non-dipping hypertension in Per1 KO mice. Per1 appears to be a negative regulator of ET-1 expression during HS/DOCP, whereas ET-1 may play a role in the positive regulation of Per1 expression. These data indicate that reciprocal regulation between renal ET-1 and the molecular clock, specifically Per1, occurs and may constitute a new feedback loop in mineralocorticoid-sensitive renal Na handling.

Dietary Sodium-Induced Changes in the Microcirculatory System of the Skin Are Associated with Blood Pressure Response in Healthy Males Eliane F. Wenstedt, Rik H. Olde Engberink, Nienke M. Rorije, Bert-jan Van den born, Jan Aten, Liffert Vogt. *Academic Medical Center, Amsterdam, Netherlands.*

Background: Studies indicate that not only the kidney but also the skin microcirculation might be pivotal for a sodium-sensitive blood pressure (BP) response. While high sodium diet (HSD) is associated with reduced density of blood capillaries, animal studies showed an increment of skin lymphatic capillaries in both amount and size. We investigated sodium-induced changes in both lymphatic and blood skin microcirculation of healthy males in relation to blood pressure (BP).

Methods: We performed a randomized crossover study in healthy males. All subjects pursued an 8-day low sodium diet (LSD: <50 mmol Na+/day) and HSD (>200 mmol Na+/day). Diet order was randomized and time in-between diets was 1-2 weeks. After each diet, BP measurements and skin biopsies were obtained. Endothelia of blood (CD31) and lymphatic capillaries (D2-40) were identified through immunohistochemistry.

Results: Overall (n=12, mean age 22 years), there was no BP increase after HSD vs. LSD (mean arterial pressure (SD): 78 (5) vs. 78 (5), p=0.66). HSD increased lymphatic cross sectional surface area (p=0.01). No differences in lymphatic or blood capillary density were observed. There was a correlation between lymphatic and blood capillary density after LSD but not after HSD (fig 1a). Differences in mean arterial pressure between LSD and HSD correlated with changes in blood capillary density (fig 1b), but not with lymphatic capillary density or cross sectional surface area.

Conclusions: HSD is associated with skin lymphangiogenesis and a loss of correlation between the lymphatic and blood microcirculation. Blood microcirculatory changes correlate with BP response, possibly playing a role in sodium-sensitive hypertension development.

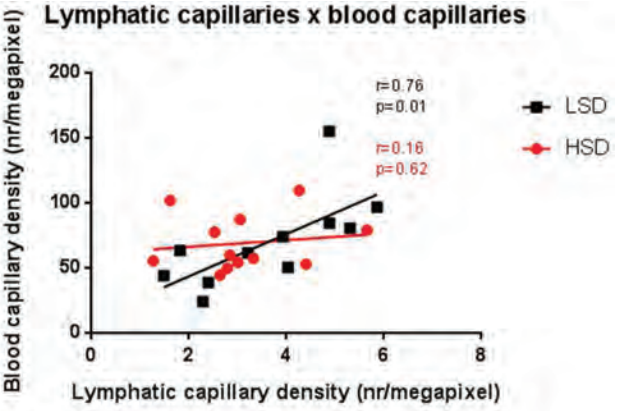

Fig 1A. Correlation between lymphatic capillary density and blood capillary density after low sodium diet (LSD) and high sodium diet (HSD). Densities are expressed as the number of lymphatic/blood capillaries per megapixel (= 1.000.000 pixels).

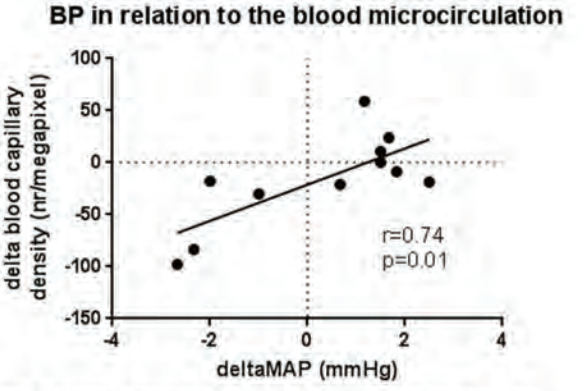

Fig 1B. Absolute differences in mean arterial pressure (MAP) between high sodium diet (HSD) and low sodium diet (LSD) in relation to absolute differences in blood capillary density between HSD and LSD.

SA-PO1108

Changes in Phosphorylation and Expression of Sodium Transporters in Pre-Eclampsia Detected in Urinary Exosomes Peter F. Mount,[1,4] CHIH-CHIANG Hu,[5] Marina Katerelos,[1,5] Suet-Wan Choy,[1,3] Natasha Cook,[1] Amy A. Crosthwaite,[1,3] Gabrielle L. Pell,[3] Kathy Paizis,[2,3] Susan P. Walker,[3,4] David A. Power.[1,4] *[1]Austin Health, Melbourne, VIC, Australia; [2]Austin health, Heidelberg, NSW, Australia; [3]Mercy Health, Melbourne, Vic, NSW, Australia; [4]University of Melbourne, Melbourne, VIC, Australia; [5]Kidney Laboratory, Institute for Breathing and Sleep, Melbourne, VIC, Australia.*

Background: PE (pre-eclampsia) is characterized by hypertension, vasoconstriction, proteinuria and renal sodium retention. It is unknown whether expression or phosphorylation of the distal renal tubular sodium transporters (NKCC2, NCC and EnaC) changes in women with PE.

Methods: A cross-sectional study of 18 PE patients, 22 normotensive pregnant women (NP) and 20 normal women (NC) was performed. Exosomes were isolated from urine by ultracentrifugation. Expression of sodium transporters was analysed by Western Blot corrected for expression of the exosome marker CD9. Statistical comparisons were made by ANOVA and a post-hoc test.

Results: Expression of NKCC2 was increased 1.6-fold in PE (ANOVA p=0.046, post-hoc=ns). Phosphorylation on the SPAK/OSR1 activation site T101/105 was reduced 1.9-fold (ANOVA p=0.030; PE vs NP p<0.05) while phosphorylation of the activating PKA S130 site was increased 2.8-fold (ANOVA p<0.001; PE vs NP p<0.01) in PE compared to NP. There was no difference in expression of NCC but phosphorylation of the SPAK/OSR1 site T60 was reduced 2.5-fold (ANOVA p=0.008; PE vs NP p<0.05). Expression of the alpha (ANOVA p<0.001; PE vs NP p<0.01) and full-length gamma ANOVA (p<0.001; PE vs NP p<0.05) subunits of ENaC was increased 6.0-fold and 2.7-fold, respectively, in PE compared to NP. There was a non-significant trend to increased expression of the cleaved 50 kD form of gamma ENaC in PE (ANOVA p=0.06).

Conclusions: These data suggest a role for increased activity of ENaC and NKCC2 in mediating sodium-retention in PE, occurring despite reduced signalling through the WNK/SPAK/OSR1 pathway.

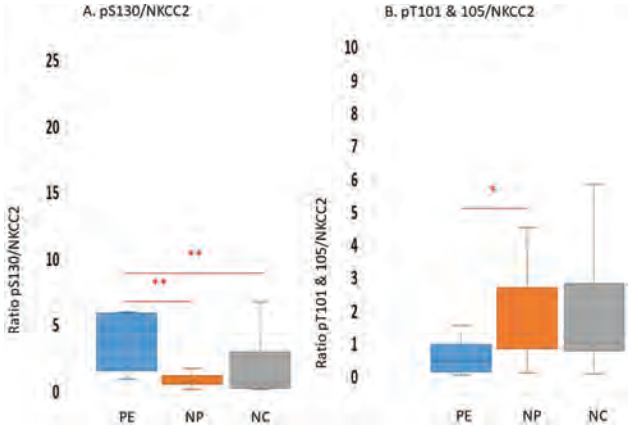

Fig. 1: Phosphorylation of NKCC2 on S130 and T101/105. S130 is a PKA and AMPK phosphosite. T101 and 105 are SPAK/OSR1 phosphosites. (A) pS130/NKCC2: ANOVA p<0.001. PE vs NP, p<0.01; PE vs NC p<0.01. (B) pT101&105/NKCC2: ANOVA p=0.03. PE vs NP, p<0.05.

SA-PO1109

In Obese ZSF1 Rats, Females Show Increased Salt-Sensitivity Compared to Males Isabel T. Nguyen, Bart Boermans, Jaap A. Joles, Marianne C. Verhaar. *Nephrology & Hypertension, UMCU, Utrecht, Netherlands.*

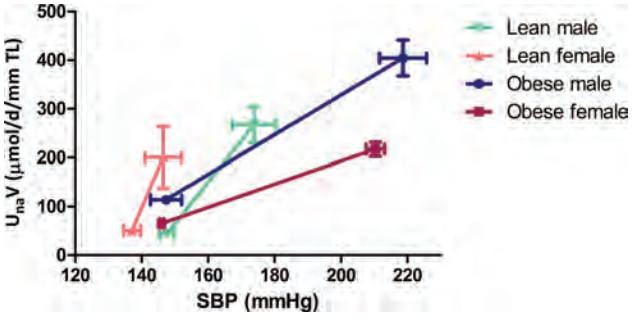
Background: The obese Zucker fatty/spontaneously hypertensive heart failure F1 hybrid (ZSF1) rat has been proposed as a viable animal model to study the metabolic cardiorenal syndrome as these rats spontaneously develop diastolic heart failure and chronic kidney disease in the presence of obesity, hyperglycemia and hypertension. Risk factors associated with the metabolic syndrome correlate strongly with salt-sensitivity of blood pressure. We investigated the interaction of obesity and sex on salt-sensitivity in obese and lean ZSF1 rats. We hypothesized that obesity and male sex would both promote salt-sensitive hypertension.

Methods: Male and female ZSF1 rats, lean as well as obese (n=6/subgroup), were either implanted with a deoxycorticosterone acetate (DOCA) pellet and fed a high salt diet (6% NaCl) or a placebo pellet and fed a normal salt diet from 19 weeks of age. Every two weeks, from 18 (i.e. prior to pellet implantation) to 26 weeks of age, systolic blood pressure (SBP, tail-cuff) and 24-hour natriuresis were measured.

Results: SBP was higher in both obese compared to lean DOCA+6% salt groups (p<0.0001). Natriuresis was higher in male obese vs. lean DOCA +6% salt groups (p<0.05). The SBP response to high salt intake occurred in a stepwise manner in all four DOCA+6% salt groups (with constant SBP from 22 to 24 weeks). Comparison of slopes of the natriuresis-pressure relations using 18 and 26-week data (figure) showed differences between male obese and lean (p=0.01) and female obese and lean (p=0.02) ZSF1 rats, suggesting that obesity promotes salt-sensitivity. Additionally, the slopes between obese males and females differed (p=0.02) suggesting that salt-sensitivity was most marked in female obese ZSF1 rats.

Conclusions: Our results in ZSF1 rats indicate i) a phased blood pressure response to high salt intake, ii) an adverse effect of obesity on salt-sensitivity, and iii) a further increased salt-sensitivity in obese females vs. obese males.

Funding: Private Foundation Support



Natriuresis-pressure relations in ZSF1 rats corrected for mm tibia length (TL).

SA-PO1110

Influence of Dietary K on Angiotensin II Hypertension in Females Luciana C. Veiras,[1] Jessica E. Prescott,[1] Donna Ralph,[2] Alicia A. McDonough.[1] [1]*Keck School of Medicine of USC, Los Angeles, CA;* [2]*University of Southern California, Los Angeles, CA.*

Background: Male Sprague Dawley rats (SDR) infused with angiotensin II, "AngII HTN" (400 ng/kg/min, 14 days) exhibit increased Na^+ transporter activation by phosphorylation (p) or cleavage (cl) in cortical TAL (NKCC2), DCT (NCC), CNT/CD (ENaC) and increased SPAK kinase. Doubling dietary K^+ during AngII HTN prevents NCC, NCCp activation, attributed to ENaC driven K loss. Female SDR at baseline, compared to males, exhibit lower PT transporter activity, higher volume flow from PT (estimated with lithium clearance, CLi), and more abundant NCC, NCCp and ENaC-cl.

Methods: This study aimed to determine the effect of doubling dietary K (1% to 2%) on female SDR at baseline (1K vs 2K) and during AngII HTN (as above, 1KAngII, 2KAngII), n=6/group.

Results: In 2K vs.1K fed female SDR: plasma [Na] and [K] were unchanged and [aldosterone] doubled; in overnight urine: UV was unchanged, UK doubled, UNa increased 1.5 fold (p=0.02); CLi increased 1.7 fold (p=0.02). 2K vs. 1K diet had no effect on NHE3, NKCC2, NCC, ENaC or SPAK abundance or activation assessed by quantitative immunoblot. AngII treatment in female SDR raised BP to 193 ± 8 mmHg, not different in 2K vs 1K. UV increased 1.7 (1KAngII) and 1.8 fold (2KAngII) (both p<0.02). UNaV and UKV were not further changed by AngII in either group. CLi increased in 2KAngII vs 2K by 1.7 fold (p=0.04). In PT paracellular Cldn2 increased 2.2 fold (1KAngII) and 3.8 fold (2KAngII) (p<0.006), AngII increased NHE3 1.4 fold in both 1K and 2 K fed, and increased NHE3p (an inactivation indicator) 1.4 fold in 1KAngII alone. Cortex (not medulla) NKCC2 and NKCC2p were increased 2.2 and 1.8 fold (p=0.002) in the 1KAngII, and the effect was blunted in 2KAngII (to 1.6 and 1.3 fold, p > 0.1). NCCp was borderline increased in 1KAngII (1.4 fold, p = 0.06) and suppressed 50% in 2KAngII vs 1KAngII (p=0.007). Cortex (not medulla) SPAK, was increased 3 fold in both groups. Alpha ENaC was activated in cortex and medulla (>2 fold, p < 0.01) in both groups. Cldn7 increased 25 (1KAngII) and 50% (2KAng).

Conclusions: The results indicate that in female SDR: 1) doubling K intake reduces apparent PT reabsorption (CLi) independent of abundance of PT transporters or plasma [K] associated with natriuresis and the expected kaliuresis. 2) 2K diet during AngII HTN further increases CLi as well as Cldn2, Cldn7 and blunts the effect of AngII on NKCC, NKCCp and NCCp activation.

SA-PO1111

Urinary Sodium-to-Potassium Ratio Associated with Normal Blood Pressure Tanushree Banerjee,[3] Anthony Sebastian,[1] Lynda A. Frassetto.[2] [1]*San Francisco, CA;* [2]*University of California San Francisco, San Francisco, CA;* [3]*University of California, San Francisco, San Francisco, CA.*

Background: Higher levels of sodium intake are reported to be associated with higher blood pressure (BP). Whether this relationship is stronger with urinary sodium to potassium ratio (U[Na/K]) and in those with diagnosed and pre hypertension is not well determined.

Methods: We studied 188 older healthy patients randomized to potassium bicarbonate 30, 60, or 90 mmol/d (KBC treatment) or placebo, for up to 36 months. The 24-hour urine and arterialized blood collections were done at baseline and then at the subsequent follow-up visits. The simple Pearson correlation coefficients (r) between urinary sodium, potassium and U[Na/K], urine pH and systolic and diastolic BP levels were calculated at baseline. The correlation coefficients were also calculated for the dietary equations estimating acid load described as net endogenous acid production (NEAP) by Frassetto, and potential renal acid load (PRAL) by Remer and Manz with urine pH. The association of U[Na/K] and arterial BP was investigated using mixed-effects model, with adjustment for age, weight, height, creatinine clearance, and treatment.

Results: Correlation analyses results are shown in Table 1. Mean arterial BP increased significantly with an increase in the urinary Na/K ratio (β [95% CI]: 0.28 [0.17-0.44]). There was effect modification by treatment (p interaction=0.02). Stratified models by treatment showed a significant association between U[Na/K] and mean arterial BP in those receiving KBC (0.32 [0.20-0.47]) while no significant association was observed in case of placebo (0.24 [-0.02-0.51]). In case of diagnosed and pre hypertension, we did not find a significant association between U[Na/K] and arterial BP (0.05 [-0.22-0.18] in diagnosed and 0.02 [-0.31-0.24] in undiagnosed hypertension). However, in normotensives a significant association was noted (0.31 [0.18-0.49]).

Conclusions: The ratio of urinary Na/K was independently associated with arterial BP even after adjustment for potential confounders, and this association may be more pronounced in normotensives.

PUB001

Urinary Retinal Binding Protein (uRBP) in Systemic AL Amyloidosis: A Pilot Study Tamer Rezk,[3,5] Rabya H. Sayed,[4] Helen J. Lachmann,[5] Philip N. Hawkins,[5] Christianne Guillotte,[5] Sharon Shreeves,[6] Simon D. Packer,[1] Julian D. Gillmore,[5] Stephen B. Walsh.[2] *[1]BBI Solutions Ltd, Sittingbourne, United Kingdom; [2]UCL, London, United Kingdom; [3]Center for Nephrology, UCL Division of Medicine, London, United Kingdom; [4]University College London, London, United Kingdom; [5]National Amyloidosis Centre, London, United Kingdom; [6]BBI Solutions, Kent, United Kingdom.*

Background: Renal involvement causing progressive proteinuric CKD is present in 70% of patients with systemic AL amyloidosis at diagnosis. Prolonged patient survival, renal survival and preservation of renal function are associated with free light chain (FLC) suppression by chemotherapy. uRBP, an indicator of renal tubular injury, has been used to detect early renal involvement in multiple myeloma. FLCs are known to be toxic to proximal tubules causing cast nephropathy and Fanconi's syndrome. Systemic chemotherapy (proteasome inhibitor based) to suppress FLC production can itself be associated with AKI. We hypothesized that a significant number of patients with systemic AL amyloidosis have proximal tubular dysfunction at baseline and that this may predict renal outcomes.

Methods: All patients with newly diagnosed systemic AL amyloidosis who attended the National Amyloidosis Centre from September 2016 to April 2017 and were enrolled into the ALchemy prospective observational study underwent uRBP analysis along with routine clinical, biochemical and scintigraphy assessments.

Results: Median age was 68yr, eGFR 67ml/min/1.73m^2, and urinary protein creatinine ratio (uPCR) was 311mg/mmol. Median uRBP was 282µg/L (normal range 0–16mg/mmol). There was a significant correlation between uRBP and serum creatinine (Pearson correlation p<0.0001, R 0.6129) and uRBP and uPCR (Pearson correlation p<0.0001, R 0.5323). There was a strong positive correlation between altered fractional excretion of both phosphate and urate with uRBP (Pearson correlation, p<0.0001, R 0.6524).

Conclusions: A significant proportion of patients with systemic AL amyloidosis have both preserved renal excretory function and absence of significant proteinuria but elevated uRBP levels. There is a significant correlation between low molecular weight proteinuria indicating proximal tubular dysfunction with serum creatinine and uPCR. The association between uRBP and fractional excretion of both phosphate and urate indicates genuine proximal tubular dysfunction as opposed to simply 'overflow' from heavy unselective glomerular proteinuria in patients with untreated systemic AL amyloidosis. uRBP excretion may be a novel biomarker of renal involvement in systemic AL amyloidosis and may predict long term renal outcomes in this disease.

PUB002

Modulation of HO-1 Potentiates CI-AKI in Diabetic Rats via NO Sheila M. Fernandes,[1] Cassiane D. da Fonseca,[1] Maria De Fatima Vattimo,[1] Mirian Watanabe,[1] Fernanda T. Borges,[2] Edson A. Pessoa,[2] Luciana soares C. Santos.[1] *[1]School of Nursing, University of São Paulo, Carapicuíba, Brazil; [2]Universidade Federal de São Paulo, São Paulo, Brazil.*

Background: CI-AKI is a toxic nephropathy with generation of oxygen species (ROS). Diabetes Mellitus (DM) preexisting has been described as a risk factor for CI-AKI. HO-1 has a renoprotective effect in renal disease models, but its potential action in diabetic nephropathy has not been concluded. This study evaluated the role of HO-1 and NO in CI-AKI in diabetic rats.

Methods: Adult male Wistar rats were randomized in 5 groups. Physiological parameters; renal function (inulin clearance); renal hemodynamics; oxidative injury (urinary peroxides-UP, tiobarbituric acid reactive substances–TBARS, urinary nitric oxide-NO and thiols in renal tissue); gene expression and protein syntesis of HO-1 and iNOS and kidney histological analysis were evaluated.

Results: DM+IC+ZnPP group showed reduced renal function and increased renal vascular resistance. Also, ZnPP in DM+IC group elevated urinary peroxides, NO and TBARS and reduced thiols in renal tissue compared that DM+IC. ZnPP administration induced elevation on gene expression and protein syntesis of HO-1 and iNOS. Renal histology showed cell flattening and hyalinization in renal tissue.

Conclusions: The data highlighted that modulation of HO-1 potentiates CI-AKI in diabetic rats confirmed by reduced function, renal hemodynamic changes and oxidative damage, possibly due to NO participation.

Heme Oxygenase-1 Role in Contrast-Induced AKI in CKD Rats Cassiane D. da Fonseca,[2] Maria De Fatima Vattimo,[2] Sheila M. Fernandes,[2] Daniel M. Martins,[2] Mirian Watanabe,[2] Fernanda T. Borges,[4] Edson A. Pessoa,[5] Luciana soares C. Santos,[3] Natalia A. Oliveira.[1] *[1]Organization University of São Paulo, São Paulo, Brazil; [2]Experimental of Laboratory of Animals Models, School of Nursing, Sao Paulo, Brazil; [3]Universidade de São Paulo, SÃO PAULO, Brazil; [4]UNIFESP, São Paulo, Brazil; [5]Universidade Federal de São Paulo, São Paulo, Brazil. Group/Team: Research Group on Acute Kidney Injury-GERA.*

Background: Contrast Induced -acute kidney injury (CI-AKI) is the third cause of hospital acquired AKI, specially in the presence of CKD. Heme oxygenase-1 (HO-1) is part of a cytoprotective system that is involved with nitric oxide (NO) syntesis and modulates renal dysfunctions and oxidative damage in AKI models. This study evaluated the role of the HO-1 inhibitior, zinc protoporphyrin (ZnPP), in CI-AKI rats with CKD.

Methods: Adult male Wistar rats were randomized in 4 groups. Sham (control group), Nx5/6 (CKD group), Nx5/6+IC (CKD+iodinated contrast group), Nx5/6+IC +ZnPP. Renal function (inulin clearance); renal hemodynamics; oxidative injury (urinary peroxides-UP, tiobarbituric acid reactive substances–TBARS, urinary nitric oxide-NO and thiols in renal tissue); gene expression and protein syntesis of HO-1 and iNOS and kidney histological analysis were evaluated.

Results: Inulin clearance was reduced due to an elevation on renal vascular resistance, while urinary NO levels were increased in Nx5/6+IC+ZnPP group when compared to the Nx5/6+IC group. Gene expression and protein syntesis of HO-1 and iNOS were elavated in Nx5/6+IC+ZnPP group. Kidney histology showed tubular cells vacuolization and edema in IC animals.

Conclusions: These data highlight that the heme oxygenase -1 inhibitor mitigates CI-AKI in the presence of CKD risk factor most likely via NO.

AKI Due to Antibiotic Spacer Kamron Saleem, Benjamin K. Sarsah, Amy N. Sussman, Bijin Thajudeen. *University of Arizona, Tucson, AZ.*

Background: This is a case of a 58 y.o. woman who underwent right total hip arthroplasty 4months prior to admission. Intraoperatively 10 mL of RapidCure loaded with 2 g of vancomycin and 2.4 g of tobramycin were placed in deep layers around the hip as prophylaxis and she was discharged with 1 week of oral antibiotics. She returned after 2 months with an infection involving the right hip. 11 days later, she went to the OR for exploration, placement of antibiotic spacer containing 4g vancomycin, 3g cefuroxime and 2.4g tobramycin. In addition, 20 mL of Rapid Cure containing 4g vancomycin and 4.8g tobramycin was placed into the deep tissue layers around the hip. Admission renal function was normal with sCr of 0.7mg/dl and on the day of surgical explantation, renal function remained normal. Intraop hypotension occurred, treated with volume resuscitation. On postop day 2, Vancomycin trough and tobramycin levels increased markedly. sCr increased 1.2 mg/dL and continued to worsen. Due to concern

for tobramycin and vancomycin toxicity, orthopedic surgery was asked to remove the spacer. Removal was deemed high risk and nephrology was asked to medically manage her renal dysfunction. Due to concern for continuous release of tobramycin from the spacer, hemodialysis was initiated for tobramycin clearance. She remained nonoliguric throughout. Roughly 1 million joint arthroplasties are performed each year in the USA. Between 1% and 2% result in a prosthetic joint infection. Two-stage arthroplasty is the current treatment of choice for infected hip and knee joint prostheses. Aminoglycosides and vancomycin are the most commonly used. The high local antibiotic level exceeds the MIC of many potential organisms. Data on spacer induced AKI is limited. No standard of care is available to determine the amount of antibiotics to be placed in a spacer. We propose a multidisciplinary approach between the Orthopedic, Nephrology, Infectious Diseases, and Pharmacology communities to formulate a standard criteria for antibiotic dosing in antibiotic-impregnated cement spacers. It would be helpful to re-analyze existing data using a more standardized definition of AKI per KDIGO. Further studies are needed to evaluate long-term prognosis in this group of patients.

Protective Effect of Sulforaphane in Maleic Acid-Induced Nephropathy Alfredo Briones-Herrera,[2] Sabino H. Avila Rojas,[2] Omar E. Aparicio-Trejo,[2] Magdalena Cristobal,[1] L. Gabriela Sanchez-Lozada,[1] Edilia Tapia,[1] José Pedraza-chaverri.[2] *[1]INC Ignacio Chavez, Mexico City, Mexico; [2]National Autonomous University of Mexico, Mexico City, Mexico.*

Background: Sulforaphane (SF) is able to activate the antioxidant response by inducing the Nrf2 transcriptional factor; it has been observed that it has protective effects by improving the mitochondrial function. Maleic acid (MA) injection induces a nephropathy characterized of impaired urine acidification and by proteinuria, phosphaturia and glycosuria, inhibition of the Krebs cycle, induction of oxidative stress and alterations in mitochondrial function. The objective of this work was to study if SF diminishes the oxidative stress and renal damage provided by MA.

Methods: Male Wistar rat (230-260 g) were used and divided in four experimental groups, Control (CT) group that received vehicle, MA-treated group received a single dose of MA (400 mg/kg, ip), MA-SF group received a pretreatment of 1 mg/kg/day ip of SF four days and the MA dose in the fourth day, and SF group received the pretreatment with SF for four days. Twenty-four h after the MA injection proteinuria, urinary N-acetyl-β-D-glucosaminidase (NAG) activity, plasma creatinine and glutathione peroxidase (GPx) activity were measured. Glomerular filtration rate (GFR), renal blood flow (RBF), renal perfusion and oxygenation (pO_2) were also measured by dissecting the left kidney; then rats were sacrificed. Mitochondrial bioenergetics were determined in isolated mitochondria from renal cortex and oxidative stress parameters were measured in renal cortex homogenates.

Results: Twenty-four h after MA injection proteinuria and urinary NAG raised up. MA decreased plasma GPx, RBF, renal cortex pO_2 and perfusion. MA impaired mitochondrial bioenergetics associated to the complex I (O_2 consumption, mitochondrial membrane potential and respiratory control index) and increased the mitochondrial production of reactive oxygen species, augmented the oxidized proteins and lipid peroxidation and decreased the content of thiol groups. SF prevented all these alterations.

Conclusions: MA nephropathy was diminished by the pretreatment with SF by preserving mitochondrial bioenergetics, ameliorating oxidative stress and improving pO_2 in renal cortex.

Curcumin Prevents Kidney Potassium Dichromate-Induced Renal Hypoxia Sabino H. Avila Rojas,[2] Alfredo Briones-Herrera,[2] Omar E. Aparicio-Trejo,[2] Edilia Tapia,[1] L. Gabriela Sanchez-Lozada,[1] José Pedraza-chaverri.[2] *[1]INC Ignacio Chavez, Mexico City, Mexico; [2]National Autonomous University of Mexico, Mexico City, Mexico.*

Background: Curcumin is a polyphenolic compound, a bifunctional antioxidant that exhibits various therapeutics properties. $K_2Cr_2O_7$-induced nephropathy has been associated with oxidative stress ROS production affects renal oxygenation and it has been proposed that this as a causal agent of the progression of renal damage. However, it has not been explored if the $K_2Cr_2O_7$ induces this alteration.

Methods: Male Wistar rats (290-320 g) were used. Rats were treated with a daily intragastric dose of curcumin (400 mg/Kg) for 10 days prior to receive an injection of $K_2Cr_2O_7$ (12.5 mg/Kg, s.c). Animals continued to receive treatment with curcumin for 48 h following $K_2Cr_2O_7$ administration. At the end treatment, renal function (Uprot, Pcreat, BUN and GFR), hemodynamics parameters (RBF, MAP, RVR and FF), $O_2^{\bullet-}$ production by NADPH oxidase (NOX) and nitric oxide synthase (NOS) in renal cortex, renal perfusion (cortex and medulla) and renal oxygen tension (cortex and medulla renal) were evaluated. In addition, studies were carried out on isolated mitochondria from renal cortex (mitochondrial membrane potential and mitochondrial H_2O_2 production).

Results: $K_2Cr_2O_7$-induced renal damage showed an increase of proteinuria, plasma creatinine, BUN, MAP, RVR, $O_2^{\bullet-}$ production by NOX and NOS, and mitochondrial H_2O_2 production compared to control. In the same way, $K_2Cr_2O_7$ administration decreased GFR, RBF, RPF, mitochondrial membrane potential, as well as renal perfusion and renal oxygen tension in both the renal cortex and renal medulla. Renal oxygen tension positively correlated with the fall in the renal perfusion. All the above-described alterations were prevented with the curcumin pretreatment.

Conclusions: Curcumin treatment prevented $K_2Cr_2O_7$-induced renal damage. The protective effect of curcumin was associated with its ability to prevent the increase in the O_2 consumption ($O_2^{\bullet-}$ production), as well as the reduction in the O_2 supply (RBF, renal perfusion and renal tension oxygen)

ANCA and IgA Glomerulonephritis All in One: Prevalence, Prognosis, and Complications Pitchaphon Nissaisorakarn,[3] Kisra Anis,[3] Vivette D. D'Agati,[2] Belinda Jim.[1] *[1]Albert Einstein College of Medicine, New Hyde Park, NY; [2]Columbia University College of Physicians and Surgeons, New York, NY; [3]Jacobi Medical Center, Bronx, NY.*

Background: Co-existing IgA nephropathy and pauci-immune ANCA-associated crescentic glomerulonephritis has rarely been reported. Both entities are prevalent separately but their co-existence is less common with a reported prevalence of 0.2-2%.

Methods: A 75 year-old Hispanic woman with PMH of DM, HTN, HLD and CKD stage III presented to the ED for abdominal pain with nausea, vomiting and hematuria for 3 days. She had been treated for pneumonia with azithromycin 1 month prior. On physical exam, she was afebrile, BP 155/71 mmHg, HR 78; exam was normal except for right CVA tenderness. She was found to have acute kidney injury and nephrotic range proteinuria with positive myeloperoxidase antibody and required HD. A renal biopsy revealed IgA nephropathy with superimposed pauci-immune ANCA-associated crescentic glomerulonephritis. She was subsequently treated with pulse intravenous methylprednisolone, cyclophosphamide IV and plasmapheresis. Unfortunately, her renal function did not improve and she continued to require HD. One week after administering her 2nd dose of cyclophosphamide, the patient was re-admitted to the ICU for infectious complications of herpes zoster on her right trunk, influenza A virus, bacteremia secondary to the pansensitive Rothia species, and C. difficile negative diarrhea. She required a prolonged course of IV antibiotics and was subsequently able to be discharged home on HD.

Results:

Conclusions: The co-existence of ANCAs and IgA may be a coincidence or may be pathogenic. One possibility is that patients may have pre-existing IgA deposits in the mesangium, which are then further complicated by the presence of ANCAs. On the other hand, patients with crescentic IgA could have coincident ANCA autoantibodies with no additional pathogenic potential. Some case series, however, have found a distinctive clinical and histologic picture of IgA and ANCA positivity, suggesting pathogenicity. The cornerstone for treatment is aggressive therapy with immunosuppressive agents. Current literature suggests that reduced dose immunosuppression for the elderly have been shown to have similar efficacy and might have a more favorable safety profile.

PUB008

Vitamin D and FGF 23 Prognostic Indicators of the Severity of AKI Joseph Saabiye,[1] Jeanne Kamal,[1,2] Firas Safa,[1] Julie Zaidan,[1] Rania El Mais,[1] Christine Boumitri,[1,3] Patricia Nasr,[1,4] Suzanne E. El Sayegh,[1,5] Elie El-Charabaty.[1,5] *[1]Internal Medicine, Staten Island University Hospital, Staten Island, NY; [2]Nephrology, NYULMC, New York, NY; [3]Gastroenterology, University of Missouri, Columbia, MO; [4]Nephrology, Tufts University, Boston, MA; [5]Nephrology, Staten Island University Hospital, Staten Island, NY.*

Background: Vitamin D (VD) and Fibroblast Growth Factor 23 (FGF 23) are two molecules that have been correlated with different diseases including kidney dysfunction. Acute kidney Injury (AKI) is a common and serious complication occurring in hospitalized patients. Markers helping early recognition of patients at risk and predicting recovery are still lacking. This raises the interest of studying VD and FGF 23 as new markers for AKI progression.

Methods: Patients with normal kidney function at baseline (Glomerular filtration rate (GFR) >60) admitted with the diagnosis of AKI based on the KDOQI criteria were included in the study. VD, FGF 23 levels and Serum creatinine (SCr) were collected within 24h of admission (D1). Daily VD intake was estimated using a Food Frequency Questionnaire (FFQ). Patients were divided into 2 groups based on SCr at day 3 (D3) : AKI recovery (return to baseline GFR or 50% decrease in SCr D3) vs AKI progression. VD levels were collected at D3 for patients who failed to recover.

Results: 102 patients were enrolled, 69.7% were men, mean age was 65.7, mean BMI was 31.3. 64.6% recovered from AKI. D1 1,25-dihydroxy VD (1,25 VD) levels correlated negatively with SCr on D1, D3 and peak SCr levels (r -0.38 p 0.0001; r -0.35 p 0.0007; r -0.39 p 0.0001 respectively). D1 1,25 VD levels were significantly higher in patients whom kidney function improved (40.5 vs 25.2 p 0.0002). Moreover D3 1,25 VD correlated negatively with SCr D3(r -0.55, p 0.01). FGF 23 had a negative correlation with D1 1,25 VD (r -0.57 p 0.0001) and Scr D3 (r -0.43 p 0.001). Per FFQ analysis, 25-Hydroxy VD levels correlated with daily VD consumption (r 0.32 p 0.001) and a cut off of 663.7 units/ day of VD intake was needed for sufficient levels.

Conclusions: FGF 23 lowers 1,25 VD levels in patients with chronic kidney disease. In our study, patients with AKI with normal kidney function at baseline had elevated levels of FGF 23. Those whom kidney function did not improve had lower levels of 1,25 VD and higher levels of FGF 23 at presentation. Could these molecules be used as prognostic markers and eventually new targets for therapies in patients with AKI?

PUB009

Deficiency of Proangiogenic Factor Vasohibin-2 Exacerbates AKI via Impaired Renal Tubular Cell Survival Katsuyuki Tanabe, Hiromasa Miyake, Kana Masuda, Satoshi Tanimura, Hitoshi Sugiyama, Jun Wada. *Okayama university Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Okayama, Japan.*

Background: A number of mediators including angiogenesis-related factors have known to be involved in the progression of acute kidney injury (AKI). Understanding the role of such mediators in AKI may lead to development of novel therapeutic strategies. Vasohibin-2 (VASH2) is a proangiogenic factor secreted by tumor cells and its expression has been associated with higher grade of the malignancies. However, its physiological and pathogenic roles in kidney has not been elucidated yet. In the present study, we examined the effects of endogenous VASH2 deficiency on renal function and histology in murine AKI model.

Methods: Ischemic-reperfusion (I/R) injury was induced by clumping bilateral renal pedicles for 25 min in eight to nine-week-old C57BL6/J wild type (WT) and VASH2 knockout ($VASH2^{LacZ/LacZ}$) mice (n=6 in each group). Blood samples were collected and kidneys were harvested 24 hours after the reperfusion. Cultured human tubular epithelial cells (HK-2) was transfected with human VASH2 using adenoviral vectors and treated with 500 μM of hydrogen peroxide (H_2O_2) for 12 hours.

Results: Increase serum creatinine and blood urea nitrogen caused by I/R in WT were significantly accelerated in $VASH2^{LacZ/LacZ}$ mice. Histologically, ATN score and number of TUNEL-positive nuclei following I/R in $VASH2^{LacZ/LacZ}$ mice was significantly exuberated compared with WT mice. Increased accumulation of malondialdehyde and 4-hidroxynonenal was more prominent in $VASH2^{LacZ/LacZ}$ I/R mice. Whereas decreased number of peritubular capillaries after I/R was greater in $VASH2^{LacZ/LacZ}$ mice, decreased VEGF mRNA was comparable between WT and $VASH2^{LacZ/LacZ}$ I/R mice. Renal VASH2 mRNA was markedly elevated after I/R and immunostaining revealed that the increased VASH2 expression was localized in renal tubular cells. Adenoviral overexpression of VASH2 in HK-2 led to prominent Akt phosphorylation. H_2O_2-induced upregulation of pro-apoptotic factor Bax was prevented by VASH2 overexpression.

Conclusions: These results suggested that endogenous VASH2 was upregulated in renal tubular cells in I/R injury to improve renal tubular cell survival.

PUB010

Necrostatin-1 Attenuates Sepsis Associated AKI through Promoting Autophagosome Elimination of Renal Tubular Epithelial Cells Wei Dong, Xinling Liang. *Division of Nephrology, Guangdong General Hospital, Guangdong Academy of Medical Sciences, Guangzhoou, China.*

Background: The aim of the present study was to investigate the protective effect of necrostatin-1 (Nec-1) in sepsis associated AKI (SA-AKI).

Methods: The SA-AKI mice model was established by intraperitoneal injection of lipopolysaccharide (LPS). Nec-1 was delivered to SA-AKI mice. Renal function and histology changes were observed. LC3-II and p62, the markers for autophagy flux, were detected. Autophagosome and autolysosome of renal tubular epithelial cells were identified using electron microscopy.

Results: Pretreatment with Nec-1 could reverse increased blood urea nitrogen (BUN) (LPS+Nec-1 vs. LPS group, 15±4.14 mmol/l vs 32.54±5.46 mmol/l, P<0.001) or serum creatinine (SCr) (11.50±1.67 μmol/l vs. 30.08±4.18 μmol/l, P<0.001) induced by LPS. There were no significant differences in tubular epithelial cell necrosis between the groups. Protein analysis showed LC3-II and p62 were increased while transcription analysis showed neither LC3-II nor p62 mRNA was increased. Massive autophagosomes and paucity of autolysosome were observed using electron microscope. When mice were pretreated with Nec-1, LC3-II and p62 decreased and a large number of autolysosomes were observed using electron microscope. These results indicate Nec-1 improved autophagosome elimination of renal tubular epithelial cells impaired by LPS.

Conclusions: In conclusion, Nec-1 could prevent sepsis-associated acute kidney injury through promoting autophagosome elimination in renal tubular epithelial cells.

Funding: Government Support - Non-U.S.

The Role of Growth Arrest and DNA Damage-45γ in Cyclosporine A-Induced Renal Tubular Cell Death Gyu Tae Shin,[1] Jieun Park,[1] Seung-Jung Kim.[2] *[1]Ajou University School of Medicine, Suwon, Republic of Korea; [2]Ewha Womans University, Seoul, Republic of Korea.*

Background: Nephrotoxicity is the major adverse effect of cyclosporine A (CsA) and it has been shown that CsA directly damages renal tubular cells. Growth Arrest and DNA Damage-45γ (GADD45γ) is a stress-responsive molecule, and our previous studies showed GADD45γ might contribute to the progression of chronic kidney disease [Kidney Int. 2008, Am J Nephrol. 2009]. In the present study, we investigated the role of GADD45γ in CsA-induced renal tubular cell death.

Methods: Human renal epithelial (HRE) cells that are of kidney tubular origin were incubated with CsA 25 ug/ml for 48 hours in the presence or absence of zVAD, necrostatin-1 or ferrostatin-1. To knockdown GADD45γ expression, stable cell lines expressing GADD45γ shRNA were generated. The recombinant adenovirus containing the GADD45γ gene was synthesized to overexpress GADD45γ protein. The degree of apoptosis and necrosis were evaluated using flow cytometry after staining with Annexin V and propidium iodide.

Results: We found that CsA significantly induced GADD45γ expression by HRE cells. Treatment of CsA provoked HRE cell death by inducing apoptosis and necrosis. Inhibition of caspases by zVAD significantly decreased CsA-induced apoptosis as well as necrosis, which is considered to be secondary to apoptosis, leading to a significantly increased cell survival. Inhibition of receptor-interacting serine/threonine-protein kinase 1 by necrostatin-1 reduced necrosis but not apoptosis, leading to an increased overall cell survival but to a lesser degree than zVAD. This result suggests that CsA induces cell death by mainly apoptosis as well as by necroptosis (primary necrosis). Inhibition of ferroptosis by ferrostatin-1 was ineffective in preventing cell death. GADD45γ overexpression augmented CsA-induced apoptosis while decreasing necrosis without affecting overall cell survival, indicating the switch of the mode of cell death from necrosis to apoptosis. Accordingly, GADD45γ overexpression activated apoptosis-related caspases but not necroptosis-related mixed lineage kinase domain like protein. GADD45γ knockdown cell lines showed significantly decreased CsA-induced apoptosis as well as necrosis, and the rescue of GADD45γ expression restored CsA-induced apoptosis.

Conclusions: GADD45γ knockdown prevents CsA-induced renal tubular cell death by blocking apoptosis and secondary necrosis.

PUB012

Effect of Physical Preconditioning in AKI Induced by Renal Ischemia-Reperfusion in Rats Frederico Fazan,[1] Lucas F. Almeida,[1] Heloisa D. Francescato,[1] Natany G. Reis,[1] Cleonice Silva,[1] Fernando S. Ramalho,[2] Terezila M. Coimbra.[1] *[1]Physiology, Ribeirao Preto Medical School, Ribeirao Preto, Brazil; [2]Pathology, Ribeirao Preto Medical School, Ribeirao Preto, Brazil.*

Background: Acute kidney injury (AKI) is one of the most common kidney illnesses. Manny factors can cause AKI including ischemia-reperfusion (I/R). An increasing number of evidence show that ischemia-reperfusion of the kidneys can provoke renal lesions through inflammatory pathways and endothelial dysfunction. Several studies show a relation between physical exercise and healthy vascular function with imunomodulatory roles. The objective of this study was to evaluate the effect of previous physical exercise in the AKI induced by renal ischemia-reperfusion in rats.

Methods: Male Wistar rats were divided into four groups: 1-Sedentary Sham; 2-Sedentary I/R; 3-Trained Sham; 4-Trained I/R. The trained animals were subjected to mild intensity treadmill training 5 days a week during 9 weeks. After the training, the animals underwent surgical procedure of bilateral renal artery occlusion for 45 minutes. After that, the clamps were removed and 48 hours after the urine and blood samples were collected for renal function evaluation and the kidneys were removed for histological and immunohistochemical examination.

Results: The trained group presented, after I/R induced injury, a small reduction of renal function and structure when compared to sedentary group. They showed plasmatic creatinine levels of 2.03±1.24 mg%, fractional sodium excretion of 2.97±4.66% and plasma osmolality of 317.9±15.5 mOsm/Kg H2O, when in the sedentary animals the plasma creatinine level was 6.89±2.02 mg%; fractional sodium excretion 29.3±19.6% and plasma osmolality 367.8±13.0 mOsm/Kg H2O. The structural lesions were also reduced as the sedentary animals kidneys, avaliated by scores, ranging from 0 to 4 (smallest to widest extension of lesion) was 3.5±0.3 in the sedentary animals and 2.4±0.9 in trained animals. The inflammation was also reduced in the trained animals as the group showed a smaller number of macrophage cells in the renal cortex and outer medulla, 17.11±1.52 cells/0.45mm2 for the trained animals and 36.35±1.7 cells/0.45mm2 for the sedentary animals, $p<0.05$.

Conclusions: Physical preconditioning attenuated the decrease in renal function and structure. These disturbances were associated with inflammation that was also less intense in the kidneys of the animals of the training group.

The Role of XBP1 in AKI to CKD Progression through G2/M Arrest and Fibrotic Induction Chia-Hsien Wu,[1,4] Yuan-Siao Chen,[1] Jia-Rong Jheng,[3] Chih-Kang Chiang,[1,2] Shing-Hwa Liu.[1] *[1]Graduate Institute of Toxicology, National Taiwan University, College of Medicine, Taipei, Taiwan; [2]Department of Integrated Diagnostics & Therapeutics, National Taiwan University Hospital, Taipei, Taiwan; [3]Department of Internal Medicine, National Taiwan University, College of Medicine, Taipei, Taiwan; [4]Division of Endocrinology and Nephrology, University of Tokyo, Graduate School of Medicine and Faculty of Medicine, Tokyo, Japan.*

Background: X-box binding protein 1 (XBP1), one of the key molecules of unfolded protein responses (UPRs), is responsible for induction of UPR signaling. Studied have revealed UPRs associated with various kidney diseases. However, there is no report discussed about the role of UPRs during the transition from acute kidney injury (AKI) to chronic kidney disease (CKD).

Methods: C57BL/6 mice was clamped by micro-clips on left renal pedicle for 30 mins, then complete reperfused to generate unilateral ischemia/reperfusion injury (UIRI) model. Mice were sacrificed after 1, 3, 5, 11, 15 days after surgery. Serum BUN and Cr were analyzed, and tissue histology, including H&E, Periodic Acid-Schiff and Masson's trichrome were evaluated. Furthermore, UPRs-related initiators were evaluated by Western blot and qPCR. In vitro, the proliferation and cell cycle analysis of XBP1-deficient HK2 cells was analyzed by MTS assay, Western blot and flow cytometry, respectively.

Results: The expression level of UPRs initiators PERK, IRE1α are relatively higher in UIRI group than in sham group, however, expression of both spliced and unspliced XBP1are decreased during CKD progression. Besides, XBP1 expression level has a negative correlation with fibrosis progression. Recently, renal tubular epithelial cells arrest in G2/M contributes to renal fibrosis progression through releasing fibrogenesis factors and obstructing the repairing process has been reported. Here we then hypothesis that losing XBP1 in epithelial cells may result in cell cycle arrest and contribute to the fibrosis progression after AKI. In the following experiments, knock-down XBP1 in cell line derived from human proximal epithelial cells cause cell cycle arrest in G2/M, and the cell growth is retard. Wee1 expression and the ratio of cyclin B1 to cyclin D1 are higher after knockdown of XBP1, indicate the G2/M arrest of cells. Expression level of the DNA damage marker, phospho-H2AX is also higher after knockdown of XBP1. Furthermore, it induced a higher expression of profibrotic factor CTGF and COL4A1, and secreted a higher level of TGF-β in culture medium after knockdown of XBP1.

Conclusions: In conclusion, these results indicate that XBP1 plays a role in maintaining DNA repair process and losing XBP1 cause renal tubular epithelial cells cell cycle arrest in G2/M, following worsen the fibrosis after AKI.

Development of a Novel Model of Contrast-Induced AKI in Mice Atsushi Uchida,[1] Kengo Kidokoro,[2] Hajime Nagasu,[1] Minoru Satoh,[1] Tamaki Sasaki,[3] Naoki Kashihara.[1] *[1]Kawasaki Medical School, Kurashiki, Japan; [2]Kawasaki Medical school, Kurashiki Okayama, Japan; [3]None, Kurashiki, Japan.*

Background: Contrast-induced acute kidney injury (CI-AKI) is characterized by the abrupt loss of kidney function following the intravascular administration of iodinated contrast media. CI-AKI has been found to be strongly associated with morbidity and mortality of the patients. CI-AKI may be caused by sustained contrast-induced renal arteriolar vasoconstriction, outer medullary and tubular hypoxia or direct cytotoxicity due to ischemia-mediated oxidative stress. However, the mechanism of CI-AKI has not been completely elucidated. One of the seasons is lack of established CI-AKI model. The purpose of this study is to create a clinically relevant and functionally obvious CI-AKI mouse model corresponding to the risk factors of CI-AKI, which provides feasibility for the mechanism study of CI-AKI.

Methods: Dehydration and higher dose of the contrast medium are known as risk factors for CI-AKI. So, in all experiments, contrast medium or saline (Control) was injected from tail vein with water deprivation from 24 hr before injection to 24 hr after injection (total 48 hr). Dose of the contrast medium is three times as much as the previous reports (iohexol:18 ml/kg). Underlying renal insufficiency and diabetes are also known as risk factors for CI-AKI. So, (1) Adenine induced renal failure model mice and (2) Akita diabetic model mice were used. Oxidative stress and endothelial dysfunction are thought to contribute CI-AKI development. So, (3) Nrf2 knockout mice as high sensitivity to oxidative stress model and (4) eNOS knockout mice as endothelial dysfunction model were used. In experiment (1), adenine containing diet was given for 14 days before contrast injection. In experiment (2-4), mice were subjected to left kidney nephrectomy 7 days before contrast injection. These mice were euthanized 48h after contrast injection, and the blood samples were collected.

Results: In all experiments, serum creatinine and blood urea nitrogen were not elevated by contrast injection compared to Control. AKI was not induced by contrast medium in murine.

Conclusions: In the murine, it is hard to establish AKI model caused by contrast media. As the injection of contrast media alone does not cause overt AKI in mice, multiple insults are necessary for inducing histopathological and functional decline.

PUB015

Endothelial Prostacyclin Protects the Kidney from Ischemia-Reperfusion Injury Cao Ying, Chuan-Ming Hao. *Huashan Hosp., Shanghai, China.*

Background: Ischemia-reperfusion injury (IRI) is one of the most common causes of AKI. Prostacyclin, or PGI_2, is one of metabolites of arachidonic acid via cyclooxygenase and PGI synthase (PGIS). In the kidney, PGI_2 is reported to play an important role in maintaining the renal blood flow. This study explores the role of endothelium derived prostayclin in IRI.

Methods: To genetically suppress the expression of PGI_2, we generated a mouse line whose PGIS gene was specifically deleted in endothelial cells (TEK-CRE $PGIS^{fl/fl}$). The IRI animal model was established by right nephrectomy and left renal pedicle clamping for 25 minutes. Animals were sacrificed at different time point after reperfusion, and blood and renal samples were collected for further analyses. Nephrotoxic AKI was induced by folic acid (250mg/Kg by ip). Kidney damage was assessed by BUN, kidney histology and TUNEL assay.

Results: The kidney PGIS protein expression markedly increased following IRI in the wild mice but not in the TEK-CRE $PGIS^{fl/fl}$ mice. TEK-CRE $PGIS^{fl/fl}$ mice had a significantly more severe acute kidney injury following IRI than wild type mice (at 24 hours, BUN 162.5 ± 4.747 VS 57.61 ± 5.083mg/dl,$P<0.001$). Histologic changes were consistent with BUN changes. No blood pressure difference was observed between wild type mice and endothelial PGIS deletion mice (108.3 ± 2.361 vs 102.2 ± 2.942). Iloprost, an analogue of PGI_2, administrated (0.05mg/Kg by ip) 30 minutes before the IRI, markedly attenuated renal damage induced by IRI in both wild type mice (BUN 57.61 ± 5.083 VS 33.66 ± 5.847 mg/dl,$P<0.001$) and TEK-CRE $PGIS^{fl/fl}$ mice (BUN 162.5 ± 4.747 VS 88.94 ± 6.214 mg/dl,$P<0.001$). Further studies show that kidney p-PKA expression significantly increased after IRI in wild type mice but not in the PGIS deletion mice, suggesting that the protective effect of PGIS is IP receptor dependent. Folic acid also induced marked kidney injury, however endothelial PGIS deletion did not worsen kidney injury compared with wild type mice (BUN 117.3 ± 13.32 VS 99.04 ± 12.08, mg/dl,$P>0.05$).

Conclusions: In conclusion: PGIS derived PGI2 can protect the kidney from acute injury caused by ischemic reperfusion and could be a potential intervention target for AKI. The protective effect of PGI_2 was not observed in the nephrotoxic AKI model induced by folic acid.

PUB016

Community Acquired AKI in a Mexican Emergency Department Julio A. Gutierrez, Denisse Arellano, Javier Soto-Vargas, Perla T. Figueroa-Gonzalez, Hugo E. Chavez. *Mexican Institute of Social Security, Regional General Hospital 46, Guadalajara, Mexico.*

Background: Acute kidney injury (AKI) is a common and serious medical condition associated with increases in morbidity, mortality, and cost of care. As the main 2nd level hospital in Mexico for the Mexican Institute of Social Security with more than 1.5 million afilliated beneficiaries and more than 600 beds our purpose was to identify the prevalence of community acquired acute kidney injury (CA-AKI) in an Emergency Department (ED) in one month regardless of the consultation to the nephrologist, and to describe its prognosis at 120 days.

Methods: A prospective-observational study in which the serum creatinine (SCr) of all adult patients admitted to the ED in the period of December 1-31, 2016, were analyzed at 24-48 hours of stay in the ED to identify AKI by SCr criteria from the AKI KDIGO guidelines. We investigated the prevalence, neprhology consultation, and the 120-days mortality of patients with CA-AKI.

Results: A total of 1244 patients were treated in the ED in the study period. For the analysis only 944 patients who had complete information were included. The prevalence of CA-AKI was 5.5% (52 patients), of whom 57.7% were KDIGO 1, 17.3% KDIGO 2, and 21.2% KDIGO 3. Nephrology consultation was only requested in 9.6% (5/52 patients) of CA-AKI cases and only 4 of 11 cases of AKI KDIGO 3. 19 (36.5%) patients had follow-up at 30 days, 9 (17.3%) at 60 days, and only 6 (11.5%) at 120 days. The 120-days mortality according to our electronic medical records was 34.5% (20/52 patients with CA-AKI) and according to the severity of AKI was 22.2%, 55.6% and 81.8%, in AKI KDIGO 1, 2 and 3, respectively (Figure 1).

Conclusions: The division of nephrology of our hospital urgently needs to implement an AKI rapid response team. The prevalence in our population is similar to previous reports, but have a great impact on mortality at day 120, the lack of nephrology consultations could represent lack of awareness of this entity and its impact on outcomes.

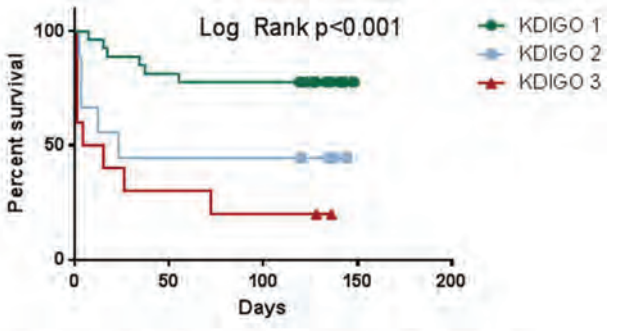

Figure 1. Survival curves of 120-day mortality according to AKI severity.

PUB017

Mechanistic Toxicity Testing of Old and New Polycationic Polypeptide Antibiotics Using a Kidney Proximal Tubule "Organ-on-a-Chip" Elijah Weber,[1] Martti Vaara,[5] Timo Vaara,[5] Thomas Neumann,[3] Maria beatriz Monteiro,[4] Jonathan Himmelfarb,[2] Edward J. Kelly.[1] *[1]University of Washington, Seattle, WA; [2]Kidney Research Institute, Seattle, WA; [3]Nortis, Inc., Seattle, WA; [4]Harvard Medical School, Boston, MA; [5]Northern Antibiotics Ltd., Espoo, Finland.*

Background: The renal proximal tubule is susceptible to drug-induced injury, which can be attributed to concentrative transport processes. Our lab has developed a microphysiological system (MPS) using proximal tubule epithelial cells (PTECs) in a three-dimensional flow-mediated culture which recapitulates both the functional and structural aspects of the proximal tubule. The purpose of this study is to define the mechanism(s) of drug-induced injury using the kidney MPS. The polymyxin class of antibiotics contains polycationic polypeptides with high biological efficiency. However, polymyxin use has been associated with a high incidence of acute kidney injury and the precise mechanisms remain unclear. The safety of Polymyxin B (PMB) to next generation polymyxins (NAB739 and NAB741) was evaluated.

Methods: PTECs are cultured for ~1 week (reaching maximum confluency) before being treated with 0uM PMB (ctrl), 50uM of PMB, or 50uM NAB739/741. Treatment duration was 48 hours with effluent collection in 24 hour intervals and analyzed for both kidney injury molecule-1 (KIM-1) and miRNA content. Nephrotoxicity was determined by evaluating urinary injury response (KIM-1, miRNA), cell-associated injury (via the induction of heme-oxygenase-1, HO-1), and transcriptional response via RNA-seq technologies.

Results: We observed consistent polymyxin-induced toxicity as measured by cell-associated HO-1 induction and both effluent KIM-1 and miRNAs (miR-155-5p and -200c-3p). Transcriptional analysis revealed significant differences between the treated (50uM PMB) and control group lending evidence toward polymyxin-induced apoptosis via the induction of tumor necrosis factor alpha (TNF-α) as well as induction of the cholesterol biosynthesis pathway. Furthermore, polymyxin-analogues (NAB739/741) were shown to have increased safety by demonstrating injury profiles similar to that of the control group. The transcriptional response to NAB-exposure is currently being evaluated.

Conclusions: Using the kidney MPS, we have shown that new structural variants of PMB are less cytotoxic with a predicted improved safety profile. Additionally, we have made advances towards clarifying the previously unknown mechanisms of polymyxin-induced nephrotoxicity by observing the transcriptional response to PMB exposure.

PUB018

A Risk Prediction Score for AKI in Amazon Intensive Care Units Fernando de Assis F. Melo,[6,3] Ana Caroline F. Bezerra,[7] Emmanuel A. Burdmann,[4] Dirce M. Zanetta,[5] Ravindra L. Mehta,[2] Etienne Macedo.[1] *[1]UCSD, San Diego, CA; [2]University of California San Diego Medical Center, San Diego, CA; [3]University of Sao Paulo, Rio Branco, Brazil; [4]University of Sao Paulo Medical School, Sao Paulo, Brazil; [5]University of São Paulo, S Paulo, Brazil; [6]Acre Federal University, Rio Branco, Brazil; [7]SESACRE, Rio Branco, Brazil.*

Background: In Amazon Intensive Care Units (ICU) AKI is a common complication, associated with increased morbidity and mortality. In resource-constrained areas, early identification of high-risk patients is a fundamental step to improve patient care and outcomes. In this study, we aim to validate a risk score for AKI development in a cohort of ICU patients in the Amazon region.

Methods: All patients admitted to three Intensive Care Units (ICU's) from Feb 2014 to Feb 2016 were screened. We applied a risk score for AKI development based on chronic diseases and acute risk factors (Table 1) within 48 h of ICU admission. The discriminative ability of the risk model was assessed by the area under the receiver operating characteristic curve (AUROC)

Results: Of 1073 screened patients, 52% developed AKI and 31.8% were classified as high risk for AKI. The score had a good calibration and discrimination, with an AUROC of 0.78 [95% confidence interval (CI) 0.74–0.83]. Sensitivity, specificity, positive predictive value, negative predictive value for patients with score ≥ 5 points were 89.2%, 41.5%, 62.3%, 78%, respectively. Mortality rate were significantly higher (38.6% vs 23.1% ; $p = 0.017$) in the high risk group

Conclusions: AKI is common in ICU patients in the western Brazilian Amazon. A simple risk score integrating chronic comorbidities and acute events at ICU admission can identify patients at high risk to develop AKI. In resource constrain areas, the application of this risk assessment tool could help clinicians to stratify patients for more active renal function surveillance, and early drug adjustment and therapeutic interventions to improve care and outcomes of ICU patients

Morphology of Bevacizumab Associated Glomerulopathy Fermin J. Person,[5,9] Silke R. Brix,[8,9] Sonia Wulf,[5] Maria de las Mercedes Noriega,[6] Oliver M. Steinmetz,[7,9] Jessica Schmitz,[2] Peter F. Zipfel,[3,10] Jan H. Braesen,[4] Thorsten Wiech.[1,9] *[1]Department of Pathology, University Hospital Hamburg Eppendorf, Hamburg, Germany; [2]Hannover Medical School, Hannover, Germany; [3]Leibniz Institute for Natural Product Research and Infection Biology, Jena, Germany; [4]Medizinische Hochschule Hannover, Hannover, Germany; [5]UKE, Hamburg, Germany; [6]Universitaetsklinikum Hamburg - Eppendorf, Hamburg, Germany; [7]University Hospital Hamburg Eppendorf, Hamburg, Germany; [8]University Hospital Hamburg-Eppendorf, Hamburg, Germany; [9]SFB 1192, Hamburg, Germany; [10]University Jena, Jena, Germany.*

Background: Bevacizumab as a chemotherapeutic agent is a humanized monoclonal IgG1 antibody neutralizing vascular endothelial growth factor (VEGF). It is used for the treatment of different cancer types and of age-related macular degeneration (AMD). As a known side effect it can lead to nephrotic syndrome. Aim of our study was to determine the morphologic correlate in comparison to thrombotic microangiopathy (TMA) and cryoglobulinemic glomerulonephritis (GN).

Methods: We analyzed 13 renal biopsies of patients with nephrotic syndrome after Bevacizumab therapy and compared them to 7 cases of cryoglobulinemic glomerulonephritis, some of them associated with hepatitis C or monoclonal gammopathy and 5 cases of thrombotic microangiopathy (aHUS). First we determined the morphologic pattern in PAS staining. In addition to standard diagnostic immunohistochemical markers (IgA, IgG, IgM, C1q, C3, and fibrin) we stained for IgG1-4, CD61, CD34 and compared electron microscopic features.

Results: All 13 Bevacizumab cases revealed an MPGN like immune complex glomerulopathy with hyaline pseudothrombi, some of them being strongly PAS positive and others being nearly PAS negative in a patchy pattern. Another striking feature was a marked dilatation of the glomerular capillaries filled with these pseudothrombi. Double

contours of the peripheral basement membrane were found in other areas. In contrast to that the thrombi in cryoglobulinemic GN were consistently strongly PAS positive and in TMA cases only weakly positive. In the latter groups dilatation of the capillaries was almost absent. The pseudothrombi were mostly positive for IgG1-3 and only rarely positive for IgG4 with no obvious difference compared to cryoglobulinemic GN. In contrast to TMA cases no CD61 positive thrombi were found. Like TMA cases and to lesser extent also cryoglobulinemic GN cases the pseudothrombi in Bevacizumab cases were frequently accompanied by a loss of surrounding CD34+ endothelial cells.

Conclusions: Bevacizumab associated glomerulopathy often exhibits a unique histomorphologic pattern with a patchy pattern of PAS positive and nearly negative hyaline pseudothrombi in markedly dilated glomerular capillaries with loss of endothelial cells. Recognizing this pattern can be important for differential diagnosis in cancer patients with nephrotic syndrome.

PUB020

Timing for Initiation of Sequential Continuous Renal Replacement Therapy in Patients with Extracorporeal Membrane Oxygenation: A Propensity Score Analysis Anna Lee. *SNUBH, Gyeonggi-do, Democratic People's Republic of Korea.*

Background: Extracorporeal membrane oxygenation (ECMO) is a lifesaving therapy used in critically ill patients with severe cardiopulmonary dysfunction. Continuous renal replacement therapy (CRRT) is added to treat fluid overload, acute kidney injury and electrolyte disturbances during ECMO. However, it is not well defined when to initiate CRRT. We performed this study to identify the optimal timing for CRRT on ECMO.

Methods: We conducted a multicenter retrospective cohort study of 296 patients who received CRRT during ECMO in Seoul National University Bundang Hospital, Yonsei University Hospital and Seoul National University Hospital between 2005 and 2016. We assigned the patients to either an early or late CRRT group depending on the initiation time of CRRT. We considered "early CRRT" to be CRRT instituted within 72 hours of ECMO initiation.

Results: Among 296 patients, 212 patients (71.6%) received early CRRT. After using a method, Ninety-four patients were included in a propensity score matching analysis. No difference in patients' mortality between early and late CRRT groups was found (59.6 vs. 57.4%, $P = 0.834$, respectively). Time from ECMO initiation to CRRT initiation was 1.1 ± 0.9 days in the early CRRT group and 14.6 ± 18.6 days in the late CRRT group. After adjusting all covariables, early CRRT group did not have worse survival than late CRRT group (HR, 0.697; 95% CI, 0.410-1.184; $P = 0.182$). In patients with baseline creatinine levels < 1.3 mg/dL, the late CRRT group showed better patient survival than the early CRRT group (HR, 0.438; 95% CI, 0.196-0.982; $P = 0.045$).

Conclusions: This study showed that early CRRT treatment may not be superior to late CRRT treatment in ECMO patients, and patients with better baseline renal function may allow to delay the initiation of CRRT. Clinical trials may be needed on timing to initiate subsequent CRRT in ECMO patients.

PUB021

The Additive Value of Serum Anion Gap and pH for Mortality in Patients Receiving Concomitant Continuous Renal Replacement Therapy and Extracorporeal Membrane Oxygenation Anna Lee. *SNUBH, Gyeonggi-do, Democratic People's Republic of Korea.*

Background: The anion gap is an easily calculated marker based on analytes typically available from routine chemistry analysis. An increased serum anion gap is known as a risk factor for hypertension, decreased renal function and mortality in critical illness. This study aimed to investigate whether serum anion gap and pH might be predictive of mortality in patients receiving continuous renal replacement therapy (CRRT) and extracorporeal membrane oxygenation (ECMO).

Methods: Patients who received CRRT and ECMO in Seoul National University Bundang Hospital, Yonsei University Hospital and Seoul National University Hospital between 2005 and 2016 were included. The albumin and blood urea nitrogen-adjusted anion gap (AGc) was calculated using this formula : AGc (mmol/L) = serum sodium (mmol/L) – (serum chloride (mmol/L) + serum bicarbonate (mmol/L)) + ([4 – serum albumin (g/dL)] x 2.5) – ([blood urea nitrogen (mg/dL) – 15] ÷ 7)

Results: Among 307 patients, 204 patients died (66.4%). According to the receiver operating characteristic curve analysis, the optimal threshold of AGc and pH for mortality were 14.75 mmol/L (sensitivity 0.782 and specificity 0.434) and 7.34 (sensitivity 0.718 and specificity 0.491). Multivariate analysis showed that patients with AGc above 14.75 mmol/L had 1.5 times higher risk of mortality (HR, 1.533; 95% CI, 1.047-2.244; $P = 0.028$) and patients with pH below 7.34 had 1.9 times higher risk of mortality (HR, 1.869; 95% CI, 1.308-2.670; $P = 0.001$). Patients with AGc ≥ 14.75 and pH < 7.34 increased the risk of mortality than patients with AGc < 14.75 and pH ≥ 7.34 (HR, 3.367; 95% CI, 2.094-5.412; $P < 0.001$). Whereas, albumin-adjusted anion gap did not show any significant predictive value for mortality.

Conclusions: This study showed that AGc and pH may have independent prognostic values and additive effects on mortality in patients receiving CRRT during ECMO.

PUB022

Tenofovir Nephrotoxicity in a Patient With Sepsis Youngjun Park,[3] Prince Singh,[2] Nawsheen Chowdhury,[3] Ismail O. Jimada,[1] James Drakakis,[3] Shayan Shirazian,[3] Minesh Khatri.[3] *[1]Department of Medicine, Division of Infectious Disease, NYU-Winthrop Hospital, Mineola, NY; [2]Department of Medicine, NYU-Winthrop Hospital, Mineola, NY; [3]Department of Medicine, Division of Nephrology, NYU-Winthrop Hospital, Mineola, NY.*

Background: Tenofovir disoproxil fumarate (TDF) is a commonly prescribed antiretroviral medication. We present a case of a HIV+ patient who presented with septic shock and acute kidney injury (AKI) and was found to have TDF nephrotoxicity on renal biopsy.

Methods: A 50-year-old African-American female with HIV infection for the past 15 years presented with one week of altered mental status and fevers. She had been on TDF for HIV viral load suppression for the past 7 years. Other medications include atazanavir, ritonavir, and Bactrim (starting one week prior to admission for CD4 count of 170 cells/mm^3). On initial presentation, she was noted to have altered mental status and was presumed to be in septic shock from multifocal pneumonia with labs significant for lactate of 5.8mmol/L, Cr 5.2mg/dL, albumin 2.3gm/dL, and serum glucose 194mg/dL. Urine studies revealed spot urine protein of 3 gm/gm, glycosuria, and hematuria. Serologies for glomerulonephritis were negative. She was initiated on dialysis for oliguric renal failure. Given the unclear etiology of her renal failure and lack of renal recovery despite hemodynamic improvement, a renal biopsy was done which revealed diffuse and severe proximal tubular interstitial changes, diffuse interstitial edema with scattered rounded eosinophilic intracytoplasmic inclusions in the proximal tubular epithelial cells, as well as enlarged dysmorphic mitochondria on electron microscopy. TDF was discontinued on admission but she remained without renal recovery three weeks later and was discharged on hemodialysis.

Results:

Conclusions: TDF has been shown to cause proximal tubular dysfunction, chronic kidney disease (CKD) and AKI. Other risks factors for TDF nephrotoxicity include advanced age, decreased CD4 count, baseline CKD, concurrent use of protease inhibitors, and genetic defects in renal drug transporter proteins. AKI from TDF nephrotoxicity can occur in isolated settings but can be potentiated by the presence of other nephrotoxins. In this case we largely attributed the patient's AKI to septic shock but believe that this predisposed the patient to TDF nephrotoxicity, which in turn further amplified the renal insult. This case also emphasizes that TDF nephrotoxicity can develop at any time, even after years of uneventful treatment.

Dynamic Changes of Properdin in Mouse Renal Ischemia Reperfusion Injury and Repair Hui Wang,[1] Yuanyuan Wu,[2,3] Aifen Liu,[2] Yufang Zhang,[2] Qian Wang,[1] Wenting Li,[1] Yaping Fan,[1] Bin Yang.[3,1] *[1]Affiliated Hospital of Nantong University, Nantong, China; [2]Nantong University, Nantong, China; [3]University of Leicester, Leicester, United Kingdom.*

Background: Properdin, released predominantly from neutrophils, is an only known positive regulator of alternative pathway of complement activation via stabilizing C3bBb. Our pilot studies revealed that renal ischemia reperfusion (IR) injury at 72 h was significantly aggregated by properdin deficiency in mice. This study, aimed to explore the dynamic changes and effects of properdin *in vivo*.

Methods: IR-related injury was established in mouse kidneys subjected to 30-min ischemia followed by 6-72 h, 1 week reperfusion *in vivo*. Then the expression of properdin and complement activation related protein C3b was investigated, and the changes of renal function, inflammation, apoptosis were also measured. In addition, we make the correlation analysis between properdin and some renal damage markers.

Results: In mouse IR kidneys, serum creatinine (SCr) was significantly increased after 24-h reperfusion and reached the peak at 48 h. The expression of properdin protein was increased in a time-dependent manner and reached the peak at 24 h, while there was no significant change in C3b protein. immunohistochemistry staining results showed that the properdin protein is mainly distributed in the renal tubular area. In addition, the inflammation related protein HMGB-1 and the apoptosis related protein caspase-3 was also increased in a time-dependent manner and reached the peak at 24 h and 12 h, respectively. Furthermore, the protein expression of properdin was significantly positively correlated with HMGB-1 and caspase-3.

Conclusions: Properdin plays an important role in renal IR-related injury and repair. However, whether enhanced properdin could be beneficial in injury repair/recovery and its underlying mechanisms are worthy to be further investigated.

GUT Derived Endotoxin Contributes to the Inflammation of Ischemia-Reperfused Kidney Tao J. Li,[1,2] Chen Yu.[1,3] *[1]Shanghai Tongji Hospital, SHANGHAI, China; [2]TONGJI UNIVERSITY SCHOOL OF MEDICINE, SHANGHAI, China; [3]TONGJI UNIVERSITY SCHOOL OF MEDICINE, SHANGHAI, China.*

Background: Endotoxins from gut are presumed to play an important role that augment organ inflammation in critical ill condition. In the present study, we studied the effects of endotoxins in renal inflammation in renal ischemia-reperfusion rats(IR).

Methods: Sprague-Dawley rats were divided into 4 groups (n=5 per group): Sham+saline, Sham+norfloxacin, IR+saline and IR+norfloxacin. Rats were treated with oral norfloxacin 20 mg/kg/day or saline for 4 weeks before IR operation. For IR induction, the bilateral kidneys experienced a 60 min of ischemia plus 24h reperfusion. The protein expressions of TLR4, NFκBp65 and cytokines of the kidney homogenate were measured. The kidney tissue were stained for TLR4 and NFκB. Endotoxemia was measured using Limulus amoebocyte lysate (LAL) assays. Rat kidney epithelioid cells (NRK-52E) were treated with 20% serum from rats (sham or renal IR group) with or without polymyxin B (PMB), a LPS inhibitor. Cytokines was analyzed by real-time polymerase chain reaction and TLR4-NFκBp65 protein was identified with Western-blotting.

Results: Endotoxemia was alleviated in norfloxacin treated rats. The IR rats with norfloxacin showed significant attenuation of the increased IL-6 and MCP-1 in renal tissue. The upregulations of TLR4 and NFκBp65 were decreased significantly in the norfloxacin treated rats(Figure 1A-I). Norfloxacin failed to improve renal function and tubular injury(Data are not shown). IL-6, MCP-1, TLR4 and NF-κB p65 expressions were increased in the NRK-52E stimulating with **s**erum of renal IR. PMB inhibited IL-6, MCP-1 TLR4 and NF-κB p65 expressions (Figure 2A-B).

Conclusions: Endotoxin contributes to IR induced renal inflammation. Improvement of intestinal barrier dysfunction and inactivation of endotoxins may be novel targets for intervention.

AKI Recovery in Hemodialysis-Dependent Hospital Survivors Discharged to an Acute Rehabilitation Facility Meredith Mcadams,[1] George Vasquez-Rios,[1] Fabiola G. Gianella,[1] B. Peter E. Sawaya,[2] Javier A. Neyra.[2] *[1]University of Kentucky, Lexington, KY; [2]University of Kentucky Medical Center, Lexington, KY.*

Background: Acute kidney injury-requiring dialysis (AKI-D) occurs in about 5% of hospitalized patients and is associated with adverse outcome. Little is known about the incidence of AKI-D recovery post-discharge. We examined AKI-D recovery in hospital survivors that were discharged to an acute rehabilitation facility with the need of acute hemodialysis (HD) therapy.

Methods: Retrospective cohort study of 43 acute rehabilitation facility residents that required nephrology consultation from 8/2015 to 12/2016. Among these, 24 patients were identified that nephrology was consulted on for AKI-D management as they were HD-dependent at the time of discharge from the University of Kentucky Hospitals. AKI-D recovery was defined as the patient no longer requiring HD therapy for AKI. The observation period ended at the time of acute rehabilitation facility discharge.

Results: Mean (SD) age was 61.5 (10.2) years; 70.8% were males and 87.5% whites. AKI-D recovery post-discharge occurred in 14/24 (58.3%) patients. A total of 3/24 (12.5%) patients died during the rehabilitation facility stay, 2/3 (66.7%) without AKI-D recovery. Patients without AKI-D recovery post-discharge had lower baseline eGFR: 45.9 (16.9) vs 78.1 (12.0), p<0.001 and tended to have longer hospitalization days: median (25th-75th percentile) 44 (28–55) vs 33 (21–43) days, p=0.25. Importantly, hospital HD vintage days were significantly higher in those without AKI-D recovery: 54.5 (37.3–96.5) vs 33.0 (20.3–39.0), p=0.04. Similarly, total intradialytic hypotension episodes were more frequent in patients without AKI-D recovery: 10.0 (4.0–15.0) vs 2.5 (1.0–3.3), p=0.07. Critical illness and comorbidity scores were not significantly different among those with vs without AKI-D recovery post-discharge.

Conclusions: At least 1 out of 2 patients discharged to an acute rehabilitation facility with AKI-D diagnosis recovered kidney function no longer requiring HD therapy for AKI. HD-specific characteristics may play a central role in the development of risk-stratification tools for the prediction of AKI-D recovery post-discharge.

PUB027

Oxcarbazepine Induced Rhabdomyolysis Nuray Can usta, Sara Yavuz. *Trabzon Kanuni Training and Research Hospital, Trabzon, Turkey.*

Background: Rhabdomyolysis is a damage of muscle cells and an involvement of systemic circulation of cellular elements. In addition to the direct toxic effect of myoglobulin, the tubular obstruction of direct iron ions also plays a role in the pathogenesis of acute renal failure. We would like to remind the rhabdomyolysis, side effect of oxcarbazepine which is an antiepileptic agent used in the treatment of trigeminal neuralgia due to mortal consequences as acute renal failure.

Methods: 70 year old female patient applied to the clinic with the complaint of pain that affected her right side of her face. Her history contained diabetes mellitus, hypertension, bronchial asthma and hyperthyroidism. Her neurological examination was normal. Laboratory investigation detected only slightly elevated blood glucose. The patient was diagnosed with trigeminal neuralgia and treated with Oxcarbazepine 150mg 2x1. On the third day of the treatment, drowsiness and decreased amount of urine was observed. Patient's serum creatinine levels were 4.0mg/dl. Serum myoglobin and creatin phosphokinase were 1000ng /ml and 765 U/L respectively. Myglobin level of urine was 1700 ng/ml. Acute renal failure caused by rhabdomyolysis was considered. Oxcarbazepine was discontinued. Hydration and support aids were administered. In the follow-ups, it was noted that the apathy state of the patient was mended, there was no need for renal replacement therapy, serum creatinine levels had decreased to 1.2 mg/dl and she was discharged.

Results:

Conclusions: Trigeminal neuralgia is a sharp, intermittent and superficial pain, limited to nerve traces and is caused by demyelination of cranial nerves caused by various factors. Anticonvulsants must be used first. Rhabdomyolysis occurs when muscle cells are damaged and intracellular elements enter systemic circulation. Non-physical causes include alcohol hyperphosphatemia, hyperpotassemia, infections and drug usage such as statins, amphetamines, tricyclic antidepressants, amphotheresin B, antimalarial drugs, cocain, colchicine, corticosteroids, diuretics and central nervous system depressants. Increase in the plasma myoglobin levels is the most reliable test. Creatinine phosphokinase levels 5 or more times higher than the laboratory upper limit is generally enough to make the diagnosis of rhabdomyolysis. Treatment is suitable hydration and bicarbonate infusion and renal plasma treatment must be applied when it is needed.

PUB028

Human Epithelial C5aR1 Signalling Enhances Bacterial Adhesion to Renal Tubular Epithelial Cells through Upregulation of the Expression of Mannosyl Residues (the Ligand for Type I Fimbrae) Ke Li,[2] Wuding Zhou.[1] *[1]King's College London, London, United Kingdom; [2]Xi'an Jiaotong University, Xi'an, China.*

Background: Our recent work has shown that C5aR1 participates in the pathogensis of renal infection in a murine model of ascending urinary tract infection through C5aR1 singalling-mediated upregulation of mannosyl residue (the ligand for type 1 fimbrae) expression on renal tubular epithelial cells which enhances bacterial adhesion and colonization of renal tubular epithelium. However, the relevance of these findings to human is unknown. In the present study, we investigated whether human C5aR1 plays the same roles as mouse C5aR1 in enhancement of bacterial adhesion to renal tubular epithelial cells.

Methods: Normal human kidney tissues were used for detection of C5aR1 (by immunohistochemical staining) and a-mannosyl residue expression (by lectin staining using fluorescence GNL). Parimarry cultures of human renal tubular epithelial cells (RTEC) were used for assessment of bacteria adhesion/uptake, mannosyle residue expression, inflammatory cytokine production and activation of intracellular signaling pathways in response to human C5a stimulation. RT-qPCR and flow cytometry bead array were used for measuring cytokine production. GNL staining was used for detection of a-mannosyl residue expression on the cell surface. CFU assay was used for measuring bacterial binding and uptake. α

Results: C5aR1 and α-mannosyl residues were clearly detected in renal tubules, predominantly localised at the cortical-medullar junction. C5aR1 and) a-mannosyl residues were also detected in RTEC. C5a (10nM) stimulation of RTEC resulted in significant up-regulation of: i) a-mannosyl residue expression, ii) ERK and NF-kB phosphorylation, iii) pro-inflammatory cytokine production (i.e. TNF-a, IL-1β, IL-6) under infection conditions (in the presence of LPS or killed E coli), iv) bacterial binding/ uptake and epithelial barrier damage. C5aR1 blockade using C5aR1 antagonist (PMX53 5mM) effectively inhibited the effect of C5a-mediated up-regualtion of bacterial binding/ uptake in RTEC.

Conclusions: Our findings demonstrate an important role for human C5aR1 in enhancement of bacterial adhesion to renal tubular epithelial cells which has implications for the pathogenesis of human renal infection.

Imbalance between Vasoactive Factors during the Development of Experimental Aristolochic Acid Nephropathy Inès Jadot,[4] Blanche Martin,[4] Olivia Botton,[3] Joelle L. Nortier,[1] Anne-Emilie Decleves,[2] Nathalie Caron.[5] *[1]Hospital Erasme, Brussels, Belgium; [2]Laboratory of Molecular Biology, University of Mons, Belgium, NIMY (MONS), Belgium; [3]UNamur, Namur, Belgium; [4]University of Namur, Namur, Belgium; [5]University of Namur - FUNDP, Namur, Belgium.*

Background: Aristolochic Acid (AA) nephropathy (AAN) is a pertinent example of tubulo-interstitial nephritis characterized by an early phase of acute kidney injury (AKI) leading to progressive fibrosis and chronic kidney disease (CKD). It is now greatly recognized that endothelial cell activation as well as imbalance between vasoactive substances widely contributes to the transition from AKI to CKD. Therefore, in the present study, we aimed to characterize the potential imbalance between vasoactive substances such as nitric oxide (NO), endothelin-1 (ET-1), angiotensin II (Ang II) and urotensin II (UT II) in the successive phases of AAN.

Methods: C57BL/6J male mice were randomly subjected to daily i.p. injection of vehicle or AAI (3,5mg/kg) for 4 days. Mice were euthanized, 5, 10 and 20 days after the beginning of AAI injections.

Results: AA-treated mice developed marked renal injury and histopathological features of AAN were reproduced. Early phase of AKI observed at day 5 was characterized by necrosis of proximal tubular epithelial cells and proteinuria. Later phase of CKD developed at day 20 as attested by tubular atrophy and massive interstitial fibrosis. Oxidative stress and inflammatory cell infiltration were also characterized concomitantly to the progression from AKI to CKD. Regarding the vasoactive factors, our results revealed that AA-intoxicated mice presented: (1) Reduced urinary NO and cGMP levels throughout the protocol whereas renal mRNA expression of *NO synthases* (*eNOS, nNOS, iNOS*) remained unchanged. (2) Reduced renal mRNA expression of *angiotensinogen* (*AGT*), *angiotensin II converting enzyme* (*ACE*) and *angiotensin II receptors* (AT_1 and AT_2) throughout the protocol. (3) Increased urinary and plasma ET-1 levels and increased renal mRNA expression of *ET-1* and its *receptor A* (ET_A) whereas renal mRNA expression of *receptor B* (ET_B) was strongly downregulated. (4) Increased renal mRNA expression of *UT II* and *UT receptor*.

Conclusions: Our findings demonstrated that imbalance between vasoactive substances occurs during AAN progression and could contribute to the transition from AKI to CKD.

Takayasu Arteritis Causing Complete Occlusion of the Infrarenal Abdominal Aorta and Left Renal Artery Stenosis Don H. Esprit, Volodymyr Chornyy, Vikrampal Bhatti, S. Irfan Qadri. *UF Department of Nephrology, Gainesville, FL.*

Background: Takayasu Arteritis is classified as a large-vessel vasculitis which primary affects the aorta and its branches. The renal arteries are of no exception. We present a case of a female patient with complete infrarenal abdominal aorta occlusion and severe left renal artery stenosis.

Methods: The patient was a 50 year old caucasian female with a past medical history significant but not limited to Takayasu arteritis, right renal nephrectomy secondary to right renal artery occlusion when she was 35 years old as a consequence of Takayasu arteritis. She presented with frontal headache and was found to have elevated blood pressure and acute kidney injury with oliguria. CTA of the abdomen and chest showed complete occlusion of the infrarenal abdominal aorta with associated mesenteric collateral consistent with chronic occlusion. [IMAGE A]. The right renal artery was absent and the left renal artery revealed high grade proximal stenosis. [image B]. However a Doppler ultrasound did not reveal any significant flow to the left kidney. [image C]. She was taken to the operating room and underwent aortobifemoral bypass with a 14x7 Hemashield graft and left aortorenal bypass with 6mm Hemashield graft. Luckily she escaped renal replacement therapy.

Results:

Conclusions: Takayasu Arteritis(TAK) is a rare granulomatous vasculitis affecting women of childbearing age. TAK should be suspected based upon clinical findings and specific imaging findings of the aorta and its branches. There are no diagnostic laboratory test for TAK. Erythrocyte sedimentation rate and C-reactive proteins may provide some support for the systemic inflammatory process but normal values should not exclude the diagnosis. Clinicans, nurses, and other clinical staff need to be cognizant of this rare pathology especially in patients who presents with hypertension at a young age. Early diagnosis is vital in order to prevent major complications or even death.

Collagen Type III Degradation Increases Following Ischemia Reperfusion Injury in Rats Signe Holm Nielsen,[2,4] Daniel Guldager Kring Rasmussen,[2,3] Federica Genovese,[2] Morten A. Karsdal,[2] Rikke Norregaard.[1] *[1]Aarhus University, AARHUS N, Denmark; [2]Nordic Bioscience, Herlev, Denmark; [3]Institute of Molecular Medicine, Cardiovascular and Renal Research, University of Southern Denmark, Odense, Denmark; [4]Department of Biomedicine and Biotechnology, Technical University of Denmark, Kgs. Lyngby, Denmark.*

Background: Survival of patients receiving a kidney allograft has increased significantly over the years. However, maintenance of kidney function in allograft kidneys remains challenging, and most allografts develop significant fibrosis within a few years after surgery. It is therefore important to understand and monitor the mechanisms that cause fibrosis at early stages to prevent allograft loss and to be able to identify the most susceptible patients for treatment. Ischemia reperfusion injury (IRI) promotes the development of kidney fibrosis in the allograft. Upon IR, changes in the extracellular matrix (ECM) protein turnover occur, causing tissue remodeling. Collagen type I (COL I) and III (COL III) are the most abundant collagens in the kidney ECM.

Methods: We quantified the degradation of COL III by measuring a neo-epitope of COL III generated by MMP-9 with the uC3M ELISA in urine samples from rats subjected to unilateral nephrectomy (NTx) followed by ischemia reperfusion (NTxIRI). Control rats were subjected to NTx but not to IRI. The correlation between levels of uC3M and levels of plasma creatinine, blood urea nitrogen (BUN), mRNA of markers of kidney injury (KIM-1 and NGAL), and mRNA of markers involved in tissue repair and fibrosis (TNFα, αSMA, fibronectin, TGFβ, and the alpha-1 chain of type I collagen (COL 1a1)) was investigated.

Results: Levels of uC3M did not increase following NTx, but were significantly elevated seven days after ischemia reperfusion injury in NTxIRI compared to animals only receiving NTx. Levels of uC3M correlated with NGAL mRNA (R2=0.82, p=0.0019), but not KIM-1 mRNA in NTxIRI animals (R2=0.25, p=0.21). uC3M correlated with plasma creatinine and BUN in NTxIRI animals, but there was no correlation between uC3M and mRNA of TNFα, αSMA, fibronectin, TGFβ, or Col1a1.

Conclusions: In conclusion, levels of uC3M increased following ischemia reperfusion injury, and correlated with kidney function and NGAL mRNA. This marker may be useful to non-invasively assess the changes in renal tissue remodeling as a consequence of kidney injury.

Angiogenic or Anti-Inflammatory Factor Secreting-Genome Engineered Mesenchymal Stem Cells for the Treatment of AKI Hye-Jeong Park, jeong-in Cho, Eui-Jung Park, Hyo-Jung Choi, Tae-Hwan Kwon. *Kyungpook National University, Taegu, Republic of Korea.*

Background: Acute kidney injury (AKI) is defined as an abrupt reduction of kidney function which is accompanied by renal tubular necrosis, vascular injury and inflammation. AKI is associated with high morbidity and mortality and hence, new strategies directed to reduce renal injury and improve renal function are greatly needed. Stem cell-based therapy with genome engineering has been proposed as a potential strategy. Here, we aimed to generate genome-engineered mesenchymal stem cells (MSCs) to secrete angiogenic factors, VEGF and angiopoietin1 (ANG1), or anti-inflammatory factors, erythropoietin (EPO) and a-melanocyte stimulating hormone (a-MSH), respectively, for therapeutic application.

Methods: To integrate each gene expression cassette into a safe harbor locus, AAVS1, of the human umbilical cord-derived MSCs (hUCMSCs) chromosome, AAVS1-targeting Zinc Finger Nuclease (ZFN) or AAVS1-targeting CRISPR/Cas9 system was used.

Results: ZFN- or CRISPR/Cas9-aided targeted integration was achieved in hUCMSCs which were confirmed by flow cytometry and junction PCR analysis. Genome-engineered hUCMSCs were confirmed to maintain their characteristics of stem cells. Each protein product released from genome-engineered hUCMSCs with AAVS1-targeting ZFN or CRISPR/Cas9 was measured in conditioned media by each protein-specific ELISA (VEGF-hUCMSCs: 12 or 7 ng; ANG1-hUCMSC: 11 or 10 ng; EPO-hUCMSCs: 32 or 5 IU, and α-MSH-hUCMSCs: 0.2 ng per 10^6 cells for 24 h (ZFN only). Then, we made the scaffold-free cell sheet system based on temperature-responsive polymer (poly(N-isopropylacrylamide) to enable transplanted hUCMSCs to be engrafted for a long time to maximize the therapeutic effects.

Conclusions: Taken together, cell sheet system of hUCMSCs secreting angiogenic or anti-inflammatory factors is successfully established. This is to be examined in animal models of AKI to demonstrate the therapeutic effects of stem cell-based regenerative strategy against AKI.

PUB033

Reprogramming of Mitochondrial Metabolism Induces Tubulointerstitial Fibrosis after Ischemic AKI Yang Zhou,[2] Nan Qin,[1] Junwei Yang.[2] *[1]Nanjing Medical University, Nanjing, China; [2]Second Affiliated Hospital, Nanjing Medical University, Nanjing, China.*

Background: Acute kidney injury (AKI) is a global public health concern associated with hospitalizations and is especially common in critically ill patients (up to 40% at ICU admission and 60% during admission). The transition of AKI to consequence chronic kidney disease (CKD) has major clinical significance; however, the pathophysiology of AKI-to-CKD remains largely unknown. Reclaim of fluid, sodium and many solutes from glomerular filtrate by tubule is an energy consumption process relies mainly on mitochondrial metabolism. Whether energy metabolism contributes to the progression of AKI-to-CKD is unknown.

Methods: We generated AKI-to-CKD model using ischemia-reperfusion injury (I/R) and examined alternations of mitochondrial morphology and critical enzymes that govern fatty acid oxidation and glycolysis.

Results: Impairment of renal function and remarkable accumulation of extracellular matrix in the tubulointerstitial spaces were quite evident several weeks after I/R injury. Mitochondria reduction and swellings, as well as lipid droplets deposition suggested metabolic abnormalities of fatty acid. However, increased glycolytic enzyme expression and inhibitory phosphorylation of pyruvate dehydrogenase were exhibited indicating a switch to glycolysis. Furthermore, renal expression of hypoxia-inducible factor 1 a (HIF-1a) was increased and mTOR was activated, which suggested that the glycolytic phenotype may be regulated by mTOR signaling through enhancing HIF-1a activity.

Conclusions: Reprogramming of mitochondrial metabolism from fatty acid oxidation to glycolysis in the context of active mTOR signaling and hypoxia may contribute to pathogenesis of AKI-to-CKD.

PUB034

Udenafil Attenuates Renal Injury through Inhibition of Thrombospondin-1 after Unilateral Ischemia-Reperfusion Injury Jong-Hwan Jung,[2] Seon-Ho Ahn.[1] *[1]Iksan, Jeollabuk-Do, Republic of Korea; [2]Wonkwang University Hospital, Iksan, Republic of Korea.*

Background: Thrombospondin-1 (TSP-1) is a ligand of CD36, transmembrane receptor. TSP-1 shows antiangiogenic effect and plays as an endogenous activator of TGF-ß concerning of renal fibrosis. Udenafil, a cyclic guanosine monophosphate (cGMP)-specific phosphodiesterase type 5 inhibitor is well-known as vasodilator with anti-oxidant effect. Udenafil shows a protective effect through nitric oxide (NO)/cGMP pathway in ischemic kidney, particularly. Herein, we newly investigated a role of udenafil related with TSP-1 in unilateral ischemia-reperfusion injury (IRI).

Methods: Unilateral IRI surgery was performed on male Spraque-Dawley rats with various weights of 200~250 g. All rats, including control (n=6), saline injection (n=7), and udenafil injection (n=8) were at 7 weeks of age. We performed a flank approach to induce IRI. The renal ischemia was induced by vascular clamps over the pedicles for 45 minutes. The udenafil of 20 mg/kg in only udenafil group (n=8) was administrated intraperitoneally with volume of each 5 mg/ml at 24 hours and 0 hour before IRI surgery with volume of 5 mg/ml. At 24 hours after the IRI, kidneys were harvested and fixed in paraformaldehyde for pathological studies.

Results: On western blotting, unilateral IRI increased molecules, such as TSP-1, fibronectin, and P-smad 2/3 compared to control. Pretreatment of udenafil in rats with unilateral IRI also attenuated expression of TSP-1 and fibronectin compared to saline + unilateral IRI rats. There was unfortunately no difference of expression of P-smad 2/3 between udnenafil + IRI and saline + IRI group. There was pathologic findings, including renal tubular epithelial dilatation and severe interstitial inflammation on IRI rats, however, histologic improvement was not shown in rats with udnenafil + IRI compared to rats with saline + IRI.

Conclusions: Generally, udenafil shows anti-angiogenic effect through the activation of NO/cGMP pathway. Thus, udenafil showed beneficial effect in the kidney with renovascular stenosis or ischemia. To date, there were unfortunately rare data for relationship between udenafil and renal fibrosis induced by IRI. Although there was no a histological improvement in udenafil + IRI rats due to severe IRI for 45 minutes, significant change of molecules, such as TSP-1 and fibronectin, supports that udenafil might have a protective or anti-fibrotic effect after IRI.

PUB035

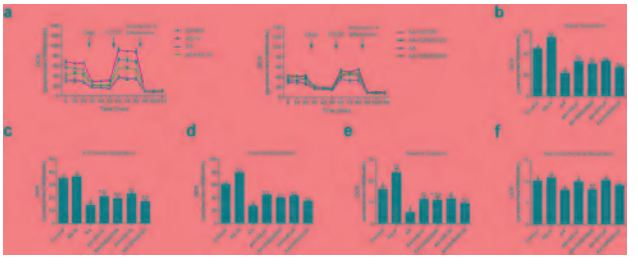
Astragaloside IV Ameliorates Aristolochic Acid-Induced AKI Associated with Antiapoptosis and Reduction of Mitochondrial Injury Xinghua Shao,[1] Shan Mou,[2] Lei Tian,[1] Zhaohui Ni.[1] *[1]Ren Ji Hospital, School of Medicine, Shanghai Jiaotong University, Shanghai, China; [2]Renji Hospital, Shanghai, China.*

Background: Aritstolochic acid nephropathy (AAN) is characterized by AKI subsequently followed by interstitial fibrosis. Apoptosis and mitochondrial injury play a critical role.Astrogaloside IV (AS-IV) has been shown to exert renal protection in many mouse models of AKI, but its role in preventing AA-induced AKI still remain obscure.

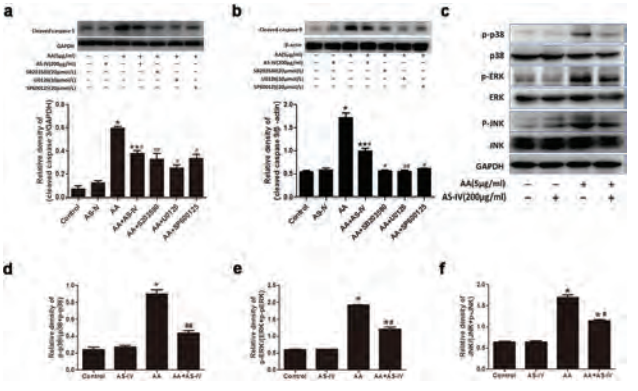
Methods: HK-2 cells induced by AA were used to investigate the protective role of AS-IV in antiapoptosis and reduction of mitochondrial injury. In vivo, mice subjected to AA injection were administered AS-IV by intraperitoneal injection. TUNEL assay, immunofluorescence staining, electron microscopic examination and Immunoblot analysis were ultilized to dectect the protective role of AS-IV in antiapoptosis. Extracellular flux analysis were carried out by Seahorse XF24 analyzer to examine the protective role of AS-IV in reduction of mitochondrial injury.

Results: Results in vivo showed that AS-IV provided morphologic and functional renoprotection against AA-induced AKI via inhibiting apoptosis and reducing mitochondrial morphological change. Further, data in vitro suggested treatment with AS-IV ameliorated mitochondrial respiration damage induced by AA, and inhibition of MAPKs pathways protected apoptosis and mitochondrial respiration.

Conclusions: All these findings indicated a promising effect of AS-IV in protection against AA-induced AKI via anti-apoptosis and reduction of mitochondrial injury, and inhibition of MAPKs pathways might be involved in this process.



AS-IV ameliorated mitochondrial respiration damage induced by AA in HK-2 cells.



Effects of AS-IV on cell apoptosis and activation of MAPKs pathways in HK-2 cells 24 hr after AA incubation.

PUB036

Nesfatin-1 Improves Contrast-Induced Nephropathy in Rats Mehmet Koc,[2,3] Abdullah Shbair,[2] Seda Kutlug Agackiran,[2] Zarife Ozdemir,[3] Ozlem Tugce Cilingir Kaya,[1] Naziye Ozkan,[1] Sule Cetinel,[1] Berrak Yegen.[3] *[1]Marmara University Medical Faculty, Department of Histology, Istanbul, Turkey; [2]Marmara University Medical Faculty, Department of Internal Medicine, Istanbul, Turkey; [3]Marmara University Medical Faculty, Department of Physiology, Istanbul, Turkey.*

Background: Contrast-induced nephropathy (CIN) is the third common cause of acute kidney injury (AKI). Mechanisms of CIN include renal medullar hypoxia, endothelial injury, oxidative stress and direct tubular toxicity of contrast agents. Nesfatin-1 (NS-1) is reported to have anti-inflammatory and antiapoptotic actions in several experimental models. However, the role of NS-1 in the development of CIN has not yet been elucidated. In this study, we aimed to demonstrate the effects of NS-1 on CIN.

Methods: Male Sprague-Dawley rats were injected intraperitoneally with only saline (control group, n=9), while CIN groups were treated with either saline (SL, n=10) or NS-1 (10 mcg/kg/day, n=8) at 0, 24 and 48 hours of the experiment. CIN was established by intravenously injecting indomethacin (10 mg/kg), L-NAME (10 mg/kg) and a high-osmolar contrast agent (Urografin 76%, 6 ml/kg) at 24th h of the experiment. On the 72nd h, kidneys were removed for the assessment of histopathological changes and the determination of glutathione levels and myeloperoxidase activity. Data were analyzed using ANOVA and Student's t-test.

Results: Serum creatinine levels in SL-treated and NS-1-treated CIN groups were elevated as compared to control group ($p<0.05$), while the increase in NS-1-treated group was relatively lower but not significant ($p>0.05$). In contrast to depressed 24-h creatinine clearance in SL-treated CIN group ($p<0.05$), clearance in NS-1-treated group was not different than that of the control group. CIN-induced increase in renal myeloperoxidase activity ($p<0.05$) in SL-treated group was abolished in NS1-treated group ($p>0.05$), Renal glutathione content which was reduced in SL-treated CIN group, was elevated by NS-1 treatment back to the levels observed in control group. Histopathological damage scores obtained by light microscopic examination were significantly increased in the SL-treated CIN group compared to control group ($p<0.05$), while treatment with NS-1 decreased the score ($p<0.001$).

Conclusions: The present data demonstrate that CIN is ameliorated by NS-1, which appears to act by inhibiting the infiltration of neutrophils and preventing the oxidative stress. These data suggest that NS-1 may have a regulatory role in protecting against CIN.

PUB037

Patient with Ethylene Glycol Poisoning and Need for Following Renal Replacement Therapy Erika Székelyová. *FMC, Velká Hledsebe, Czech Republic.*

Background: Ethylene glycol poisoning causes fatal intoxications, even relatively small ingestions of thise alcohol can produce significant toxicity. Rapid recognition and early treatment, including alcohol dehydrogenase inhibition, are crucial. To provide proper management, clinicians must understand the metabolic activation of ethylene glycol to their toxic acid metabolites, the limitations of available laboratory tests, and the indications for treatment with antidotes, with or without hemodialysis.

Methods: A 46-year-old man was admitted to the hospital on the 30 November 2011 with suicidal ethylene glycol poisoning. It was a severe intoxication with serum ethylen glycol concentration above 10 g/l. Initial haemodialysis was urgently started followed by continual veno-venosus haemodialysis (CVVHD). Intravenous ethanol was continuously administered as a competitive inhibitor of alcohol dehydrogenase (ADH). After 48 hours, when serum ethylen glycol concentration was zero, CVVHD had finished, but the patient needed renal replacement therapy because of ongoing kidney failure. The last haemodiafiltration was done on the 10 January 2012, after there had been renal function partially repaired to glomerular filtration (GF) on grade 3a-b, and since the year 2013, glomerular filtraton is on grade 2. On the 12 April 2017, the patient was admitted to the hospital again with suicidal ethylene glycol poisoning (he ingested demonstrably 1l automotive antifreeze), and the initial serum ethylen glycol concentration was 4,7 g/l. Initial haemodiafiltration was started (befor we known serum ethylen glycol concentration), followed by continual veno-venosus haemodiafiltration (CVVHDF) and intravenous ethanol was continuously administered. Metabolic acidosis was not serious, and spontaneous diuresis had been maintained. The next haemodiafiltration was done on the 13 April, followed on the 15 April by continual veno-venosus haemodiadiafiltration (CVVHDF), when the serum ethylen glycol concentration was zero. The patient did not develop a progression of chronic kidney disease, and the last glomerular filtration was 1,4 ml/s (measured GF) or 1,21 ml/s (GF- MDRD).

Results:

Conclusions: According to our experience, early comprehensive treatment of severe ethylene glycol poisoning saves not only the life of the patient, but also, in the optimum case, it may also enable the repair of renal function.

PUB038

Unraveling the Role of BUN as a Marker of Renal Function or Maladaptive Neurohormonal Activity in Patients with Acute Heart Failure Abhilash Koratala,[2] Muhannad Leghrouz,[2] Amir Kazory.[1] *[1]University of Florida, Gainesville, FL; [2]University of Florida, Gainesville, FL.*

Background: It has been proposed that blood urea nitrogen (BUN) could be a marker of exacerbated neurohormonal activity (NA) above and beyond its role in determination of renal function in the setting of acute heart failure (AHF). Changes in weight and daily fluid balance are commonly used to monitor decongestive therapy in these patients; ultrafiltration (UF) has emerged as an option for more efficient fluid removal and alleviation of NA. We sought to determine whether decongestion by UF is correlated with a decrease in BUN as a surrogate for maladaptive NA.

Methods: Articles cited in PubMed database from January 2000 to March 2017 using variable combinations of key words "ultrafiltration", "heart failure", and "decongestion". Original clinical articles evaluating the role of UF in AHF were reviewed and selected. Relevant data including primary outcomes, and decongestion markers were extracted and compared. Using Spearman's rank correlation analysis, the degree of dependence and correlation between weight reduction and fluid removal with changes in BUN was determined

Results: A total of 348 patients in 8 studies were included. The mean age was 65 years and 68% were male. There existed substantial variation across studies in the reporting of surrogates of decongestion. Weight loss ranged from 2.6 to 9.7 Kg (mean 6.2±2.05 Kg) and fluid removal ranged from 2.6 to 12.1 L (mean 8.5±3.0 L). Changes in BUN ranged from +0.8 to +12.54 mg/dl (median +8.5 ± 4.5 mg/dl). There was a negative correlation between changes in BUN and reduction in weight (R= -0.47, 95%, CI of Correlation -0.89-0.35, p=0.24) and with the amount of fluid removal (R= -0.53, 95%, CI of Correlation -0.9-0.27, p=0.17).

Conclusions: Based on the currently available evidence, decongestion by UF is correlated with a rise in BUN level in patients with AHF. Therefore, although BUN could reflect NA in this setting, it can still be used as a marker of renal function that is affected by intravascular volume changes. Since the goal of therapy in AHF is optimal decongestion without overzealous fluid removal, future studies are needed to explore whether combining BUN with clinical markers of decongestion could more precisely guide the process of fluid extraction.

PUB039

Liraglutide-Induced Acute Tubular Necrosis Paris Barkan, Avrum Gillespie. *Temple University Hospital, Philadelphia, PA.*

Background: Liraglutide, a GLP-1 agonist used to treat Diabetes Mellitus, has known gastrointestinal and thyroid side effects, but only few reports of renal toxicity. Given insufficient evidence, Liraglutide can be overlooked as the culprit in a patient presenting with acute renal failure, thereby delaying the diagnosis and decreasing the likelihood of renal recovery.

Methods: A 48 year-old female with a past medical history of CKD III, HIV (CD4 1395), Type II Diabetes Mellitus, and HTN presented to the hospital with one week of progressive dyspnea and lower extremity swelling. Of note the patient was started on liraglutide 1 month prior to admission. Her creatinine on presentation was 6.92 mg/dl from a baseline of 1.5 mg/dl. Her UA was significant for 300 mg/dl protein and urine sediment revealed only rare granular casts. HBV, HCV, C3/C4 were within normal limits. Her HIV RNA viral load was undetectable. A SPEP showed a polyclonal gammopathy and UPEP quantified 460 mg/dl protein of mixed tubular/glomerular origin. ANA was positive in a 1:320 speckled pattern. A renal ultrasound was unremarkable. A renal biopsy revealed moderate to severe acute tubular necrosis in the background of diabetic changes. Immunofluorescence (IF) was negative. Given the finding of ATN and interval work-up, drug reaction to liraglutide was noted as the primary insult. Upon review of her medication list, liraglutide was her only new medication and the only medication that could have induced ATN. Liraglutide was discontinued on admission and she improved with aggressive IV diuresis. Her creatinine 5 weeks after discharge came down to 3.39 from a peak of 7.8.

Results:

Conclusions: This case illustrates the importance of a medication history in identifying a temporal relationship between new drug initiation and the onset of renal failure. This patient had multiple risk factors for renal dysfunction including Diabetes Mellitus, HTN, HIV and morbid obesity. Although rarely reported, Liraglutide-induced AKI should be considered in the differential of a diabetic patient presenting with renal dysfunction when more common etiologies have been excluded. It is particularly important to monitor and recognize this adverse event early as withdrawing the offending agent can prevent progression to End Stage Renal Disease.

PUB040

Atypical Hemolytic Syndrome Post-Transplant Liza Cholin, Jordan Burlen, Hitarth S. Dave, Susan C. Coventry. *University of Louisville, Louisville, KY.*

Background: Introduction: Hemolytic Uremic Syndrome (HUS) is a type of Thrombotic Microangiopathy (TMA); it presents with thrombocytopenia, anemia, and acute renal failure. Atypical HUS (aHUS) accounts for 10% of all HUS cases, and occurs due to defective alternate complement pathway regulation, resulting in injury to endothelial cell lining of small blood vessels. When compared to Shiga-toxin producing Escherichia coli HUS, aHUS has a much poorer prognosis with death and end-stage kidney disease (ESKD) occurring in 53% of patients at three years. **Case Description:**

A 37 year old female with ESKD status post pancreas-kidney transplant presented with gastroenteritis-like symptoms. Laboratory evaluation showed a creatinine of 2.59 (baseline 0.55), hemoglobin of 10.9, platelets of 38, with schistocytes and polychromasis on peripheral smear. Further testing included a low C3 level, low normal C4, elevated lactate dehydrogenase, normal haptoglobin, negative cultures (blood, urine, stool), normal ADAMTS13 activity, and negative Shiga toxin. Renal biopsy revealed thrombi in rare glomerular capillary loops and acute tubular necrosis, with no signs of acute T-cell mediated or antibody mediated rejection. Genetic testing was negative for a specific quantitative or genetic factor leading to complement dysregulation. Patient was treated with hemodialysis and eculizumab. Renal function improved, and she no longer required dialysis at time of discharge.

Methods:

Results:

Conclusions: Discussion: Initial presentation of aHUS can be indistinguishable from other types of TMAs. Once, you have excluded shiga toxin-producing bacterial infection, ADAMTS13 deficiency, and other systemic diseases, then an aHUS diagnosis can be made. Genetic testing is also helpful to determine if it is a familial or sporadic form. Renal biopsy is typically not necessary; however, it can be beneficial if patient is post-transplant to rule out rejection. Treatment includes therapeutic plasma exchange, steroids, eculizumab, and transplantation (MCP-aHUS only). This case was rare, in that the patient had sporadic aHUS precipitated by a viral gastroenteritis.

PUB041

The Impact of Syndrome of Rapid Onset ESRD on Renal Allograft Survival: A 13-Year Mayo Clinic ESRD Cohort Investigation Macaulay A. Onuigbo,[2] Nneoma Agbasi.[1] *[1]NHS, ILFORD, United Kingdom; [2]Mayo Clinic, Rochester, Eau Claire, WI.*

Background: We first described the syndrome of rapid onset end stage renal disease (SORO-ESRD), acute irreversible renal failure, in 2010. The impact on renal allograft survival is unknown.

Methods: A retrospective study of individual patient-level serum creatinine trajectories of ESRD patients on maintenance hemodialysis at Mayo Clinic Rochester for >90 days, 2001-2013.

Results: 149/1461 ESRD patients had SORO-ESRD: 13 RTRs - 4M:9F, 12 white, age 45 (18-83) years. Serum creatinine was 1.4 (0.8 – 1.7) mg/dL the year before dialysis. Initial access in all was a catheter. AKI causing SORO-ESRD was from acute rejection (4), postoperative (2), tubulointerstitial nephritis (2), unknown (2), infection (1), contrast nephropathy (1), BKV nephropathy (1), and cardio-renal syndrome (1). Renal allograft survival - 1469 (277-4939) days. Acute rejection and ATN were common (Table). Time on dialysis - 856 (129-1630) days. 5/13 died - 3 following cardiac arrest; 2 after stopping dialysis. 4/13 were re-transplanted.

Conclusions: SORO-ESRD contributed significantly to late renal allograft loss and return to hemodialysis. Potentially preventable causes of AKI leading to SORO-ESRD were identified. Larger studies are warranted.

AKI and Renal Replacement Therapy after Implantation of Left Ventricular Assist Device Abhilash Koratala,[2] Olanrewaju A. Olaoye,[1] Amir Kazory.[2] *[1]University of Florida, Gainesville, FL; [2]University of Florida, Gainesville, FL.*

Background: Implantable left ventricular assist devices (LVADs) are increasingly used for long-term management of patients with advanced heart failure (AHF) due to their established salutary impact on survival. Renal dysfunction is common in the setting of AHF and is associated with worse outcomes. We sought to explore the available evidence on the incidence of acute kidney injury (AKI) and need for renal replacement therapy (RRT) in AHF patients treated with LVAD.

Methods: Articles cited in PubMed database from January 2000 to April 2017 using key words "left ventricular assist device" and "heart failure" were searched. Articles evaluating LVAD in management of AHF were reviewed. Clinical trials that used continuous flow and contained data on renal parameters were selected. Pertinent data including baseline renal function, definition of AKI, and incidence of AKI were extracted and recorded.

Results: A total of 138 citations were reviewed and after exclusion of duplicate studies or those exclusively evaluating pulsatile flow LVADs, 23 clinical trials with 7733 participants were included. The mean age was 54.8 years, and 76.3% were men. The mean ejection fraction was 17.5%. There existed substantial variation across studies in the degree of baseline renal function and the definition of AKI. The baseline serum creatinine level was 1.46 mg/dl ± 0.16. The incidence of AKI was reported in 16 studies and was between 4 to 45.2% (mean 15.8% ±10.5). The incidence of need for RRT, reported in 12 studies, was between 2 to 38.1% (mean 15.8% ±11).

Conclusions: With the exponential growth of LVAD use, the number of patients with AHF receiving these devices as "destination therapy" is increasing, hence the need for evaluation of long-term impact on end-organ function. We found that renal dysfunction is prevalent in patients referred for LVAD therapy. Moreover, these data suggest that despite treatment of circulatory failure by LVAD and consequent improvement in renal function, a small subset of patients with AHF develop AKI, and a similar proportion require RRT post-operatively. Future studies are needed to identify the population at risk for renal complications after LVAD implantation, and to explore treatment strategies aiming at preservation of renal function in these patients.

PUB043

Tenofovir Induced AKI: A Single Centre Experience Umesh L. *Nephrology, institute of nephrourology, Bangalore, India.*

Background: Tenofovir has been widely prescribed in various first line antiretroviral regimen. It is infrequently associated with renal failure and biopsy findings of proximal tubular injury. We studied the clinical and histopathological findings in 27 patients having tenofovir induced nephrotoxicity

Methods: An observational study over a period of two and half years(from August 2014 to March 2017) in a State run government hospital which included all patients who were seropostive for HIV with renal dysfunction. Renal biopsy was performed whenever indicated.

Results: A total of 27 cases of tubular injury in the setting of tenofovir use were identified. There were 19 men and 8 women with a mean age of 45.03±12.95. Ten of twenty seven patient required hemodialysis. Mean creatitine at the time of biopsy was 5.78±2.71 mg/dl with mean protienuria of 1643.96±1056.44mg/dl. Time duration from TDF use to the time of biopsy ranged from 7 weeks to 13 months with a mean of 7.7 ±5.5months. Glycosuria detected in ten patients (all with normoglycemia), eight of them had phosphaturia. RENAL biopsy showed toxic proximal tubular injury with interstial inflammation which was mild and localized in 14 patients, moderate to severe, and diffuse in remaining 13 patients. Twenty two patients were available for follow up once tenofovir was discontinued and 77.27% of them had complete recovery of renal function at the end of 6 months

Conclusions: This study shows that tenofovir nephrotoxicity is a largely reversible form of toxic acute tubular necrosis which targets the proximal tubules accompanied by interstial inflammation. Hence renal parameters should be closely monitored in these patients.

PUB044

Serum Procalcitonin Level May Predict AKI in ICU Patients with Sepsis Mahmoud H. Imam,[1] Enas Elsebaey ahmed,[3] Amr Marzouk,[2] Amira Mohamady,[3] Rizk sayad rizk Sarhan,[3] Ahmed W. Elshourbagy.[4] *[1]Internal Medicine Department, Benha University, Benha, Egypt; [2]Anesthesia Department, Ain Shams University, Cairo, Egypt; [3]Benha University, Benha, Egypt; [4]banha faculty of medicine, Benha, Egypt.*

Background: Sepsis still has a high incidence even in developed countries. Acute kidney injury (AKI) frequently occurs in significant percentage of septic ICU critically ill patients with decimal prognosis. Early prediction of AKI and early interventions may improve outcome. The aim of this study is to examine if procalcitonin (PCT) can be used for early prediction of AKI septic patients in ICU.

Methods: 67 patients with sepsis were enrolled in this study. On admission, PCT was measured together with serum creatinine, urea, and other inflammatory markers. qSOFA was calculated at the emergency department. Patients were classified into two groups: AKI and non-AKI groups.

Results: PCT had a significantly higher value among patients who developed AKI than non-AKI group (67.04±20.59 ng/ml vs. 36.84±18.36 ng/ml); $p < 0.001$. Also, PCT exhibited a good predictive role for AKI with the ROC area under the curve was. 0859 ($p < 0.001$).

Conclusions: PCT may help in the early prediction of AKI among septic ICU patients.

PUB045

Successful Treatment of Renovascular Hypertension in Takayasu's Arteritis via Stenting: A Two Year Outcome Aparna Natarajan,[1] Julia Schneider,[1] Ivie O. Okundaye.[2] *[1]LUMC, Westmont, IL; [2]Loyola University Medical Center, NEENAH, WI.*

Background: A 31 year -old woman with no prior medical history presents to an outside to the ER for abdominal pain. Physical exam was notable for blood pressure of 190/96 mm Hg and diffuse tenderness to palpation of the abdomen. ESR 88, amylase 146 and lipase 834, UA negative for blood and protein. Patient was started empirically on steroids for autoimmune pancreatitis. Subsequent MRI showed infrarenal aortic wall thickening with extension into left renal artery concerning for aortitis. Upon initiation of lisinopril creatinine doubled to 2.05 mg/dL. A CT angiogram of abdomen revealed duplicated right renal artery, moderate to severe occlusion of bilateral renal arteries and thus suspicion of bilateral renal artery stenosis was confirmed. In addition, CT also showed inflammation around infra- renal aorta, findings suggestive of Takayasu's arteritis. Other possible causes of large vessel vasculitis or infection were ruled out.

Methods: While the patient was started on prednisone and mycophenolic acid to treat vasculitis, she continued to be profoundly hypertensive with little response to antihypertensive agents in three different classes plus diuretics. Renal duplex showed 8.9 cm R and L 11 cm without hydronephrosis. Given complete occlusion of the two right renal arteries and small right kidney size, a decision was made to perform Left renal artery stent placement. Renin levels at the time of the angiogram were 24 ng/mL/hr. In follow up of six weeks after drug-eluting stent placement, she had improvement in blood pressure readings, improvement in inflammatory markers and was able to discontinue most of the antihypertensive agents. Subsequent renal duplex studies demonstrated improved renal velocities (1.7m/sec from 2.6m/sec of left renal artery) which are maintained two years post procedure. Patient is now on maintenance steroid, ace-inhibitor, cellcept 1500mg BID and clopidogrel.

Results:

Conclusions: Takayasu's Arteritis is a rare cause of renal artery stenosis. Endovascular stenting and immunosuppression haves been proposed treatments in prior studies.This case report demonstrates efficacy of this combined approach two years post stent placement for treatment of hypertension and preservation of renal function.

PUB046

Long-Term Clinical Impacts of Cumulative Fluid Balance in Continuous Renal Replacement Therapy Chun Soo Lim, Jung Nam An, Jung Pyo Lee, Yun Kyu Oh. *Seoul National University Boramae Medical Center, Seoul, Republic of Korea.*

Background: Renal functional assessment at 3 months after continuous renal replacement therapy (CRRT) initiation can be useful in predicting long-term mortality and progression to ESRD.

Methods: We investigated the association between fluid balance before and after CRRT initiation and long-term outcomes after acute kidney injury (AKI) episode requiring CRRT. Among 1764 adult AKI patients started on CRRT from 2009 to 2013 in intensive care units in four tertiary academic hospitals in Korea, 331 survivors at 3 months after CRRT initiation were enrolled. Chronic kidney disease (CKD) progression was defined as a worsening renal status assessed at 3 months after CRRT initiation, comprising RRT continuation, an increase in serum creatinine of more than 50%, and a decrease in the estimated glomerular filtration rate of 35% or more than the baseline values.

Results: Cumulative fluid balance during 5 days after CRRT initiation was not associated with CKD progression. However, a positive fluid balance during 24 hours before CRRT initiation had the protective effect for CKD progression [Odds ratio 0.46 (0.23-0.91); $P = 0.026$]. This result was significant after adjustment for gender, age, and baseline serum creatinine. During the median 20.4 (7.5-39.7) months of follow-up, fluid balance was not associated with the long-term mortality.

Conclusions: Cumulative fluid balance after CRRT initiation was not associated with the long-term clinical outcomes. However, positive fluid balance during 24 hours before CRRT initiation was a favorable factor for CKD progression. The monitoring and management of fluid balance before CRRT initiation could be important.

PUB047

Clinical Analysis of Cardiac Surgery Patients with AKI shuqin hu, Hongli Jiang. *Dialysis Center of First Affiliated Hospital of Medicine School, Xi?an Jiaotong University, Xi'an, Shaanxi, China.*

Background: AKI is one of the severe clinical syndromes with the high morbidity and mortality. Due to the difference of geographical and disease distribution, the risk factors of postoperative AKI are still controversial. This research retrospectively analyzes the mortality, morbidity, risk factors and clinical features of Postoperative AKI. Analysis the risk factors in mortality and severity of AKI for improving prognosis and treatment. In order to reduce the morbidity and mortality of AKI after cardiac surgery, it is necessary to identify and intervene the risk factors.

Methods: 575 underwent cardiac surgery in the first affiliated hospital of Xi'an JiaoTong University from July 2015 to June 2016. The definition of AKI was based on the KDIGO clinical practice guideline for AKI. Screening patients with AKI or not who met the inclusion criteria and had complete case histories. We investigated clinical features, general information, laboratory data, basic diseases and prognosis. Logistic regression analysis was used to investigate the risk factors in morbidity and severity of AKI

Results: Results Of the 575 patients, AKI developed in 177(31.78%) patients, whereas (4.17%)had renal replacement therapy. Patients with AKI had higher mortality than patients without AKI (10.17%VS0.5%, P<0.001). AKI occurred mainly the first day after the cardiac surgery, and most of them are stage The highest diagnostic rate (80.23%) of AKI is the first day after the operation. The incidence of AKI at stage 2 and stage 3 is higher in the second day after operation than the first day. Multivariate logistic regression analysis showed that cardiopulmonary bypass, the advanced age, the high level of preoperative blood CystatinC, perioperative infection, intraoperative cardiopulmonary bypass time, were the independent risk factors of AKI after cardiac surgery. Left ventricular ejection fraction (LVEF) <40%, perioperative infection and postoperative arrhythmia were risk factors influencing the severity of AKI

Conclusions: Cardiac surgery induces high morbidity of AKI and mortality and poor prognosis which closely associated with many risk factors. Perioperative infection is not only an independent risk factor for the occurrence of AKI, but also an independent risk factor for the severity of AKI

PUB048

Causes, Clinical Features, and Treatment of Rhabdomyolysis: A Retrospective Analysis Yu Zongchao,[1] Fanna Liu.[2] *[1]nephropathy, The First Affiliated Hospital of Jinan University, Guangzhou, China; [2]The First Affiliated Hospital of Jinan Universtiy, Guangzhou, China.*

Background: RM is a condition of skeletal muscle breakdown where muscle injury causes a release of myoglobin and the muscle enzymes creatine phosphokinase (CPK), lactate dehydrogenase (LDH), and the transaminases. The classic presentation of this condition is muscle aches, weakness, and tea-colored urine. RM is commonly associated with myoglobinuria, and if sufficiently severe, this can result in AKI. Since a systematic review of RM is currently lacking in the literature, we undertook this study of the causes, clinical features, and treatments of RM.

Methods: We retrospectively reviewed the medical charts of patients with confirmed diagnoses of RM from June 2012 to August 2016, who had received care at the First Affiliated Hospital of Ji'nan University, Guangzhou, China.

Results: A total of 48 patients were included in this study (36 males and 12 females). The most common causes of RM among these patients were strenuous exercise (50%) and infection (25%). Muscular weakness (72.92%) and muscular pain (64.58%) were the most common presenting symptoms, followed by fever, dark urine, emesis, and oliguria or anuria. Among the patients, 42 received intravenous (IV) fluid therapy, and none developed acute kidney injury (AKI). The other six patients accepted continuous renal replacement therapy (CRRT), five of whom had an alleviation of their symptoms. One patient was transferred to another hospital for further treatment since the primary disease was dermatomyositis and it was non-responsive to immunotherapy.

Conclusions: RM is a complex condition with non-specific symptoms that can develop from various causes. The syndrome is treatable and has good outcomes. Early and aggressive fluid has been the main intervention for preventing and treating AKI. Renal replacement methods can also play a supportive role, though they are not the first line of treatment for RM-induced AKI. Our results indicate that the most effective treatments are early diagnosis, comprehensive therapy, active prevention, and the timely elimination of complications.

PUB049

Sofa Coagulation Score and Patient Outcomes in Severe AKI: Analysis from the Randomised Evaluation of Normal versus Augmented Level (RENAL) Study Jin Lin,[1,4] Ying Wang,[1] Rinaldo Bellomo,[2] Meili Duan,[3] Martin P. Gallagher.[1] *[1]George Institute for Global Health, Sydney, NSW, Australia; [2]Austin Health, Melbourne, NSW, Australia; [3]Intensive care unit, Beijing Friendship Hospital, Beijing, China; [4]Intensive care unit, Beijing Friendship Hospital, Beijing, China.*

Background: A decline in platelet count is common in critically ill patients with severe AKI. However, there is relatively little data assessing the association of SOFA coagulation scores and clinical outcomes in severe AKI patients receiving continuous RRT.

Methods: We performed a secondary analysis from the Randomised Evaluation of Normal versus Augmented Level of RRT (RENAL) study. The primary endpoint was all-cause mortality at 90 days after randomisation. The secondary outcomes were the length of intensive care unit (ICU) and hospital stay. The association between the SOFA coagulation scores and these outcomes were analysed using multivariate Cox model adjusted for baseline variables.

Results: Among 1465 patients in the RENAL study, the complete SOFA coagulation score data were available in 1280 patients. Among them, 579 patients had high SOFA coagulation scores (defined as ≥1), while 701 patients had normal SOFA coagulation scores (<1). The univariate analysis showed that high SOFA coagulation scores were associated with higher mortality at day 90 (49% versus 38.5%, p=0.0002). There was no significant difference in the length of ICU and hospital stay between these two groups.

In multivariate analysis, the association between high SOFA coagulation scores and increased mortality rate at 90 days remained significant.

Conclusions: In the RENAL study, an approximately 50% of patients had an increase in SOFA coagulation scores during their ICU admission. High SOFA coagulation scores were associated with increased mortality at 90 days.

PUB050

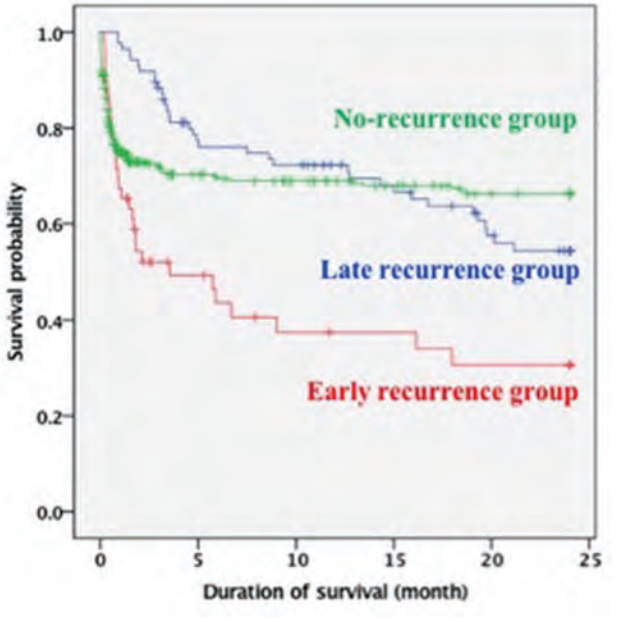
Early Recurrence of AKI Is a Prognostic Factor for All-Cause Mortality Keisuke Sako, Kengo Furuichi, Yasuyuki Shinozaki, Tadashi Toyama, Shinji Kitajima, Akinori Hara, Yasunori Iwata, Norihiko Sakai, Miho Shimizu, Takashi Wada. *Kanazawa university hospital, Tonami, Japan.*

Background: Recurrent acute kidney injury (AKI) is associated to a risk factor for mortality. However, it is unclear whether the period until AKI recurrence may influence mortality. We set up a hypothesis that early recurrence is higher mortality and evaluated the prognosis of recurrent AKI cases by setting 21 days as the cut-off period of AKI recurrence.

Methods: All of the cases were admitted and followed-up at the Kanazawa University Hospital in Japan from November 1, 2006 to October 31, 2007. A total of 21,939 cases were evaluated retrospectively. The primary endpoint was death. The observation time was two years. Recurrent AKI was defined as the re-increase of serum creatinine after the previous AKI episode. Cases developed AKI recurrence less than 21 days were defined as the early recurrence group, and the other cases were defined as the late recurrence group.

Results: Four hundred sixty adult cases (2.1%) developed AKI in two years. One hundred thirty-five cases developed recurrent AKI among them. The number of early recurrence group was 49, and the number of late recurrence group was 86. The rates of all-cause mortality were higher in the early recurrence group (p=0.001; log-rank test; the early recurrence group, 105.5 deaths per 100 person-years; the late recurrence group, 32.7 deaths per 100 person-years; No-recurrence group, 34.4 deaths per 100 person-years).

Conclusions: Patients with recurrent AKI less than 21 days showed poor prognosis. Careful follow-up for at least 21 days after AKI is necessary detect the recurrence of AKI to predict prognosis after AKI.



PUB051

You Only Diagnose What You Think Of – A Case of IgG-4 Related Kidney Disease Mubasshar Rehman,[2] George C. Bonifant,[2] Karim El Hachem,[2] Steven D. Smith,[1] Ira S. Meisels,[3] Purva D. Sharma.[3] *[1]Icahn School of Medicine at Mount Sinai/St Luke's-Roosevelt Hospital Center, New York, NY; [2]Nephrology, Mount Sinai St Luke's Hospital, New York, NY; [3]None, New York, NY.*

Background: IgG4-related disease affects multiple organs and is characterized by fibrosis and a dense lymphoplasmacytic infiltrate rich in IgG4-positive plasma cells. Renal involvement is observed in 15% of cases with tubulointerestitial nephritis being the predominant pathologic finding.

Methods: A 55 year old man with history of hypertension presented for several months of diarrhea, abdominal pain and recent perioral numbness. A non contrast Computed Tomorgraphy of the abdomen revealed normal sized kidneys with mild bilateral pelvic fullness and findings consistent with pancreatitis. His laboratory work up showed a creatinine of 8.7mg/dL, calcium of 6.0 mg/dL, IgG4 of 1470 mg/dL, and a low C3 (33 mg/dL). His creatinine failed to improve with hydration. The urinary sediment was bland. He underwent a kidney biopsy revealing diffuse, severe interstitial and glomerular scarring with marked mononuclear interstitial inflammation including plasma cells, many of which stained positively for IgG4. The patient did not respond to steroids and was started on hemodialysis for uremic symptoms. 6 months prior, he had presented for dry mouth, unintentional weight loss, and chronic diarrhea with negative EGD and colonoscopy. His creatinine was 1.68 mg/dL with 230 mg of albumin/gram of creatinine, findings that were deemed to be hypertension related. No additional work up had been done at that time.

Results:

Conclusions: IgG4- related kidney disease can present with kidney dysfunction, minimal proteinuria and a bland urine sediment. In the right clinical context, we suggest obtaining IgG4 and complement levels with a low threshold for a kidney biopsy. Early recognition and tissue diagnosis can lead to prompt treatment with steroids with or without Rituximab and avoidance of progression to ESRD.

Integrated Endovascular Approach to Treatment of Acute Renal Vein Thrombosis Manifested as Primary Membranous Glomerulopathy Natalia Plotskaya. *Capital Health RMC, Trenton, NJ.*

Background: Renal vein thrombosis (RVT) is a very common complication of nephrotic syndrome, it can be symptomatic and chronic asymptomatic. It is associated with imbalance between procoagulant and anticoagulant factors, endothelial dysfunction. Multiple modality treatment might be required in symptomatic RVT with extension to inferior vena cava.

Methods: A 51 year old male with a long history of hypertension and 4 months lower extremity edema presented with severe sharp left flank pain with radiation to low back for 4 days. He had similar pain in the right flank 2 months ago. Physical examination revealed elevated BP of 190/110 mmHg, left lower abdominal tenderness and moderate lower extremities edema. No family history of kidney disease or hematologic disorders was identified. Laboratory date shown increased creatinine of 1.35 mg/dL for 2 months, decreased albumin of 2.6 g/dL. CT scan of abdomen with intravenous contrast detected left renal vein thrombosis extending into the suprarenal inferior vena cava, also possible extension of thrombus into the left gonadal vein, enlarged and heterogeneous left kidney. Immediately patient was started on heparin drip. Despite of tPA infusion at rate 3 mg/hr for 6.5 hrs follow up left renal venogram still shown large clot. Decision was made to proceed with AngioJet thrombolysis and mechanical removal of residual clot which finally lead to its resolution confirmed by venogram. Next day creatinine decreased to 1.19 mg/dL. On day 5 after intervention nuclear renal scan demonstrated symmetric flow to both kidneys, no evidence of hydronephrosis. Hypercoagulability work up was unremarkable. Isolated elevation of homocysteine 12.5 umol/L and protein S antigen > 200% were noted. Urinalysis shown severe proteinuria of 11. 6 g/24hours. For this reason on day 7 patient underwent successful left kidney biopsy which shown membranous glomerulopathy (MGN) stage1-2. Indirect immunofluorescence staining was positive for phospholipase A2 receptor (PLA2R) which supported primary MGN.

Results:

Conclusions: Acute RVT should be highly suspected in symptomatic patients with acute kidney injury associated with lower extremity edema, sudden flank pain. Timely diagnosis with CT angiography is necessary to access extension of thrombosis and initiate combined intervention to preserve renal function and prevent further thromboembolic event.

PUB053

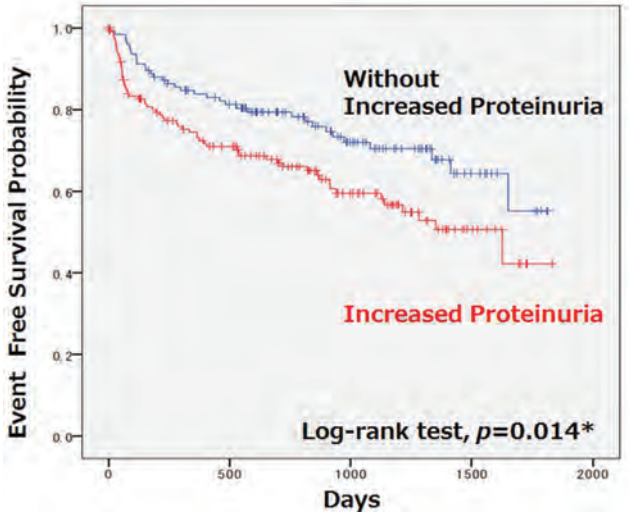
Isolated Increased Proteinuria Predicts Poor Long-Term Outcomes in CKD Patients without Contrast-Induced Nephropathy Raku Son, Takuya Fujimaru, Masahiko Nagahama, Yasuhiro Komatsu. *Nephrology, St. Luke's International Hospital, Tokyo, Japan.*

Background: Contrast-induced nephropathy (CIN) is associated with long-term adverse events. Although CIN is defined only by increased serum creatinine, previous studies have shown that contrast media exposure induces transient proteinuria. However, no study has evaluated the association of isolated increased proteinuria without CIN and clinical outcomes.

Methods: In this single-center, retrospective cohort study, we collected data of chronic kidney disease (CKD) patients who underwent contrast-enhanced CT and received CIN prevention protocol from April 2012 to March 2016 at outpatient clinic. Patients who developed CIN were excluded. Increased proteinuria was defined as post to pre urine protein creatinine (P/C) ratio more than 1. The primary end point was the composite of certain adverse events, including death, stroke, myocardial infarction, end-stage kidney disease, coronary artery intervention and others. Log-rank test and Cox proportional hazard analysis were performed.

Results: Of 291 patients who received CIN prevention protocol, 4 patients were excluded due to CIN. In the rest patients (n=287, age 73.3±10.2, 67.2% of males), 161 patients (56.1%) had increased urine P/C ratio. During the follow-up (1250±46.8 days), 97 patients (33.8%) had adverse events. In Kaplan-Meier survival curves, patients with increased proteinuria showed significantly poor outcomes compared to those without increased proteinuria (p=0.014) (Figure). After adjusting for age, sex, baseline eGFR and urine P/C ratio, hypertension, diabetes mellitus and cardiovascular diseases, increased proteinuria significantly associated with poor long-term outcomes (Hazard ratio 2.00, 95% confidence interval 1.29-3.09).

Conclusions: Isolated increased proteinuria after contrast-enhanced CT predicts poor clinical outcomes in CKD patients even without CIN.



PUB054

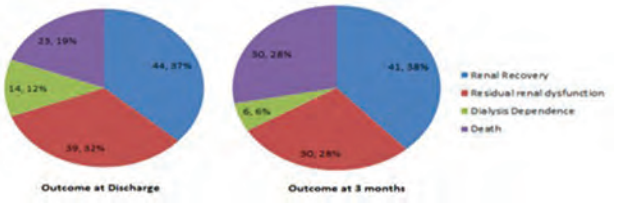
AKI in Intensive Care Unit: A Clinical and Outcome Study Prof narinder P. Singh, Danish Kathuria, Neeru Aggarwal, Anish Gupta. *MAX SUPER SPECIALITY HOSPITAL, DELHI, India.*

Background: Acute kidney injury has both short term as well as long term consequences in critically ill patients. Our study was aim to document the evolving epidemiology of AKI in India.

Methods: A longitudinal study was performed in a tertiary care center in North India among 120 patients with AKI. We enrolled patients who were either admitted in ICU with AKI i.e. community acquired (CA-AKI) or developed AKI during their ICU stay i.e. hospital acquired (HA-AKI). Diagnosis, staging, risk factors assessment and management of enrolled patients was done as prescribed by the KDIGO clinical guidelines for AKI. The outcome was assessed at discharge and at 3 months and classified as favourable (renal recovery) and adverse (residual renal dysfunction, dialysis dependence and death). A statistical analysis was performed, using a Pearson's Chi-square test and paired 't' test.

Results: Out of 120 patients, 87(73%) had de novo AKI while 33 (27%) had acute on CKD. Out of all patients, 55 % had CA-AKI while 45 % developed HA-AKI. Almost half of the subjects (47.5%) had stage I AKI, 27.5% had stage II and remaining quarter of subjects had stage III AKI. Sepsis (60.8 %), circulatory shock (53.3%), age > 65 years (58.3%) were the most prevalent risk factors which were significantly associated with poor outcome (p <0.05). Severity of AKI showed a linear trend with adverse outcome at discharge, which was significant (p 0.025). Clinical outcome at the time of discharge and at 3 months are demonstrated in figure 1. Almost 50 % of the stage I AKI showed complete renal recovery at 3 months as compared to only 25% and 29.6% for stage II and III respectively. Different stages of AKI also showed a graded increase in mortality at 3 months - 19.2% for stage I compared to 35.7% for stage II and 37 % for stage III.

Conclusions: This study demonstrated increasing prevalence of adverse outcome in a linear fashion with increase in the severity of AKI. The epidemiology of AKI in critical care in India has started to resemble high income group countries, in terms of both age distribution as well as etiology.



PUB055

A Case of AKI from Hemophagocytic Lymphohistiocytosis Induced by Ehrlichiosis Olanrewaju A. Olaoye, Saraswathi Gopal. *University of Florida, Division of Nephrology, Gainesville, FL.*

Background: Hemophagocytic Lymphohistiocytosis (HLH) is an aggressive life-threatening syndrome of excessive immune activation occurring from either inherited or acquired defect in cytotoxic T lymphocytes and natural killer cells. Cytokine mediated acute kidney injury has been described to be strongly associated with HLH. Here we present a rare case of HLH associated with severe renal failure due to Erlichiosis chaffeensis

Methods: A 70-year-old African American male with history of diabetes mellitus, benign prostatic hypertrophy and hepatitis C successfully treated with Harvoni presented with generalized weakness, nausea vomiting and abdominal discomfort. Eleven days prior to his hospitalization, he was treated for right forearm cellulitis. On admission, vital signs were significant for a temperature of 39.5oC, pulse rate of 126/min. His labs showed WBC of 2,500/mm^3, hemoglobin of 10.4 g/dL, platelet of 39,000/mm^3, ALT 406 IU/L, AST 1,501 IU/L, ALP 110 IU/L, total bilirubin 0.9 mg/dL, ferritin 27,889 ng/ml and serum creatinine of 6.37 mg/dL (recent baseline was 1.1-1.2 mg/dL). Chest radiograph and pan-culture were not suggestive of an infection. Peripheral smear was unremarkable for schistocytes. Patient developed respiratory and renal failure requiring mechanical ventilation and hemodialysis. Given persistent pancytopenia, a bone marrow biopsy was done which showed hemophagocytic macrophages containing predominantly RBCs and neutrophils. A diagnosis of HLH was made; patient was started on Etoposide and Dexamethasone therapy for immunosuppression. Ehrlichia chaffeensis serology was also obtained, considering recent history of forearm cellulitis., the titers resulted as positive (IgG 1:1204 & IgM <1:16). Patient was treated with Doxycycline for 2 weeks. During the course of doxycycline therapy patient started to recover renal function, hemodialysis was stopped. Three weeks after initiation of doxycycline, he was discharged with a serum creatinine of 1.26 mg/dL

Results:

Conclusions: HLH is a syndrome of cytokine storm leading to multi-organ dysfunction including the kidneys. Early identification is crucial, as immunomodulatory therapy is required to diminish the hyperinflammatory response. Moreover, identifying the underlying cause and initiating specific therapy is imperative as it can reduce the mortality associated with HLH, which is around 50%.

PUB056

Potential Hydralazine-Induced False Positive ANCA Specific for Proteinase 3 (PR3) as a Sentinel Event Mimicking of Granulomatosis with Polyangiitis (GPA) in a Case of Focal Acute Tubular Injury Nader S. Bahri. *Meharry Medical College, Brentwood, TN.*

Background: Rapid declining of renal function accompanied by proteinuria and hematuria in a hypertensive and diabetic individual on hydralazine with work- up showed Positive ANCA serology activity required diagnostic renal biopsy with no evidence of GPA vasculitis with a rare reported presentation.

Methods: A 45 year-old female with a past medical history of hypertension on multiple medications recently on hydralazine, DMT2 with Hb A1C of 7.6, a known case of CKD 3 with the baseline of creatinine 1.29 mg/dl presented in December 2016 with rapid onset shortness of breath with coughing that produced minimal amounts of blood, orthopnea, and swelling. She had a similar presentation back in November 2016 where a CT of her chest was performed that showed scattered alveolar opacities consistent with pneumonitis (Infections versus idiopathic). She subsequently developed rapid declining of renal function (serum creatinine 3.08 mg/dl), Non- nephrotic range proteinuria (protein/creatinine ratio 3.3 g/g) and hematuria which raised diagnosis of pulmonary-renal syndrome and immediate therapy with high dose corticosteroids were initiated. During the work-up ANCA serology activity was positive 1:20 titer confirmed by enzyme immunoassay to confirm ANCA specific for PR3;all other serological analyses were negative and patient was initiated on cyclophosphamide with thinking of granulomatosis and polyangiitis (Wegner's granulomatosis) as main diagnosis. Afterward kidney biopsy demonstrated moderate arterionephrosclerosis with features of accelerated hypertension-related vascular injury, moderate diabetic nephropathy and foal acute tubular injury. These findings didn't support the diagnosis of granulomatosis and polyangiitis(GPA). Hydralazine were suggested as potential cause for False Positive ANCA testing. All previous treatments has stopped and ANCA activity turns negative after withdrawal of

hydralazine. Patient treated for her pneumonia and acute tubular injury with improving condition.

Results:

Conclusions: This case highlights the presentation of false positive testing induced by medications. Hydralazine is a known agent causing of sporadic Pauci-immune Glomerulonephritis via ANCA activity, however in this case the false positive ANCA serology specific for PR3 didn't revealed any pathologic evidence of vasculitis.

PUB057

AKI, Its Risk Factors, and Mortality in Chronic Obstructive Pulmonary Disease Patients Tae won Lee,[2] Ha nee Jang,[5] Hee jung Park,[5] Hyun Seop Cho,[5,6] Eunjin Bae,[1] Se-Ho Chang,[5,6] Hyun-Jung Kim,[4] Dong Jun Park.[3,6] *[1]Gyeongsang National University Changwon Hospita, Changwon, SEOUL, Republic of Korea; [2]Department of Internal Medicine, Gyeongsang National University Changwon Hospital, Changwon-si, Gyeongsangnam-do, Republic of Korea; [3]Gyeongsang National University Hospital, JINJU, Republic of Korea; [4]School of Medicine, Gyeongsang National University, Jinju, Republic of Korea; [5]Department of Internal Medicine, Gyeongsang National University Hospital, Jinju, Gyeongsangnam-do, Republic of Korea; [6]Gyeongsang National University, Institute of Health Sciences, Jinju--si, Gyeongsangnam-do, Republic of Korea.*

Background: Chronic obstructive pulmonary disease (COPD) is an inflammatory airway disease and a major cause of illness and death throughout the world. Inflammation is known to play a major role in the pathophysiology of AKI. We evaluate the impact of acute kidney injury (AKI) on mortality and risk factors in patients with COPD.

Methods: We retrospectively enrolled patients who hospitalized due to COPD acute exacerbation between January 2011 and April 2014. We categorized patients into two groups: with AKI and without AKI. We evaluated factors associated with AKI and effect of AKI on all-cause mortality.

Results: Among the 177 patients, 41 patients (23.2%) had AKI and 30 patients (16.9%) died during follow up period. Patients with AKI tend to lower blood pressure, lower estimated glomerular filtration rate (eGFR) and received invasive mechanical ventilation (MV) at the time of admission. Older age, lower BMI, lower eGFR level, diabetes and AKI were significantly associated with all-cause mortality. In addition, lower eGFR level, diabetes, invasive MV and presence of pneumonia were significantly associated with AKI.

Conclusions: The prevalence of AKI is relatively high in COPD patients and AKI is independent factor of the all-cause mortality. Thus, close monitoring and prevention for AKI is important in COPD patients.

PUB058

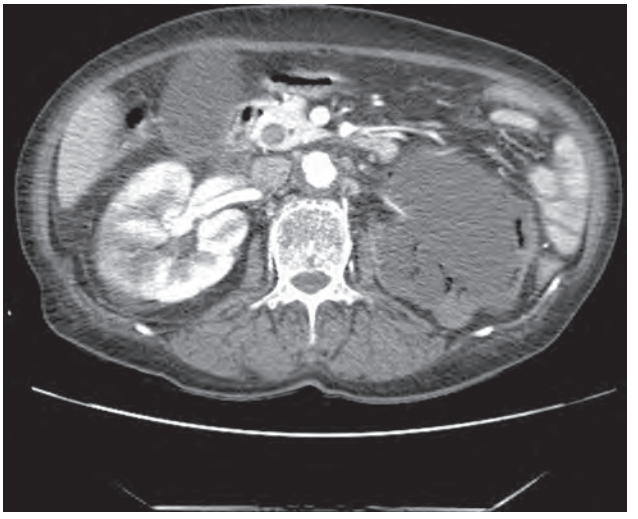
A Case of Urinary Tract Infection: One Kidney Is EPN and the Other Is Simple Pyelonephritis Heeryong Lee, Woochul Lee, Jeong gun Kim. *Good Samsun Hospital, Busan, Busan, Republic of Korea.*

Background: Emphysematous pyelonephritis(EPN) is an acute necrotizing parenchymal and perirenal infection caused by gas-forming organism. EPN is commonly associated with diabetes mellitus, urinary tract obstruction and immunosuppression. In comparison with simple pyelonephritis, EPN is an acute severe necrotizing infection with a mortality rate of up to 25%. The most common pathogens are *Escherichia coli (E. coli)* and *Klebsiella pneumonia*. We report a case of a 78-year-old woman who developed EPN in one kidney and simple pyelonephritis in the other.

Methods: A 78-year-old woman presented to the emergency department with fever, chills, and both flank pain. Her medical history was significant for diabetes mellitus, hypertension. Spot urine reveal pyuria. Abdominal radiography revealed gas collection. And computed tomography (CT) revealed gas collection in the parenchyma and huge hydronephrosis of the left kidney and wedge-shape low attenuation of the right kidney (Panel A). The patient received a diagnosis of emphysematous pyelonephritis of the left kidney and simple pyelonephritis of the right kidney. The patient was started on intravenous piperacillin/tazobactam on arrival. This was then switched to meropenem as blood cultures collected on two separated days grew *E.coli*. After the CT results were confirmed, the percutaneous nephrostomy catheter was inserted. Here she was noted to have pus and air. Antibiotics were maintained for 2 weeks and symptoms and laboratory findings improved. Control abdominal CT revealed more improving state of emphysematous pyelonephritis and hydronephrosis. So she was discharged after catheter removal.

Results:

Conclusions: EPN is caused by gas-forming organism, most commonly *E. coli*. But, Even if the infection is caused by the same organism, it can be expressed as another type of infection in same organ.



PUB059

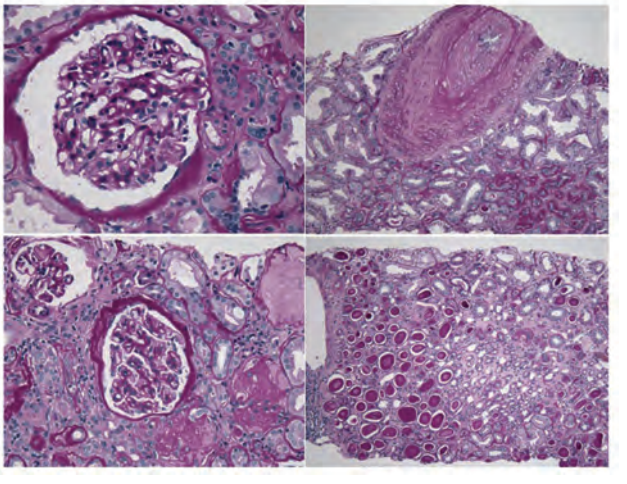
Methylphenidate Associated Antiphospholipid Antibody Syndrome Mediated AKI Neal B. Shah,[4] Helmut G. Rennke,[1] Juan Pablo Domecq Garces,[3] Peter G. Czarnecki,[1] Yanli Ding,[2] David B. Mount.[1] *[1]Brigham and Women's Hospital, West Roxbury, MA; [2]Brigham and Womens Hospital, Boston, MA; [3]Brigham's Women Hospital, Boston, MA; [4]Nephrology, Brigham and Womens Hospital, Boston, MA.*

Background: 70 year Caucasian female admitted for elevated creatinine levels found on routine blood testing.

Methods: 70 y/o F with history of hypertension, CAD and normal pressure hydrocephalus (recent VP shunt placement) was admitted for elevated creatinine 2.3mg/dl. Methylphenidate had been started 1 month prior to admission, for slow mentation; it was held on admission. Physical exam significant for 3/6 systolic murmur radiating to carotid and mild suprapubic tenderness. No edema, anasarca or skin rash. Creatinine remained elevated despite IV saline. She was non-oliguric. Hospital course significant for labile hypertension and two episodes of acute pulmonary edema with systolic BP 200s. Labs remarkable for Hb 9g/dL (previously 12g/dL), BUN was 44mg/dL, Cr 2.3mg/dL. PTT elevated at 49s. Low haptoglobin of 8mg/dl and mild LDH elevation of 329U/L. Peripheral smear had few schistocytes. Urinalysis showed 0-2 RBCs, 3-5WBCs with bacteria, 2+ proteinuria. Urine culture tested positive for E Coli UTI, treated with fosfomycin. Protein creatinine ratio was 3.2. Renal US showed bilateral 9.5cm kidneys and normal echogenicity. Initial serologic workup was unremarkable. Kidney biopsy showed severe arterial and arteriolar sclerosis, marked hypoperfusion, no evidence of deposition disease. Anticardiolipin IgG was elevated at 35.7 CU (normal 0-19); was 19 CU two months prior. She was diagnosed with antiphospholipid syndrome, treatment included IV methylprednisolone followed by 6 week oral prednisone taper, plasmapheresis, and rituximab. BP was well controlled on captopril. Creatinine improved from peak of 2.7 to 1.3mg/dl, with drop in anticardiolipin titer to 8 CU. Haptoglobin and LDH levels normalized.

Results:

Conclusions: Methylphenidate initiation may have been the second hit causing worsening of antiphospholipid syndrome and precipitation of AKI.



Cortex with global glomerulosclerosis, hypoperfused glomeruli & sclerosis of interlobular artery. Outer medulla shows tubular atrophy, cast formation.

PUB060

Low Doses of Perioperative Flurbiprofen Protect Individuals Suffering from AKI Hao Zhang,[1] Qin Liao,[2] Jianwen Wang,[2] Shi-kun Yang.[3] *[1]The Third Xiangya Hospital of Central South University, Changsha, China; [2]The third Xiangya Hospital of Central South University, Changsha, China; [3]The third Xiangya Hospital, Central South University, Changsha, China.*

Background: Flurbiprofen is a new nonsteroidal anti-inflammatory and analgesic drug, it may be associated with AKI but the thoroughly effects are unclear. In this study, we attempt to explore the association between the perioperative using of flurbiprofen and AKI after operation.

Methods: We obtained data from a database of 141467 patients, who underwent operations in the Third Xiangya Hospital of Central South University January 2012 to July 2016, 10774 patients were enrolled for this retrospective study. Acute kidney injury (AKI) was defined as KDIGO guideline. Chi-square test, univariate analysis and Logistic regression analysis were used to determine the risk factors for AKI and evaluate the effects of different does of flurbiprofen on AKI.

Results: There were 2656 cases who used flurbiprofen perioperatively in 10774 cases, the prevalence of postoperative AKI was 6.94% in 10774 cases, the prevalence rate of AKI was5.8% and 7.3% in subjects using flurbiprofen and subjects without using flurbiprofen, respectively. After the does stratification of flurbiprofen, the incidence of AKI in patients with a low dose of flurbiprofen (5.2%) was significantly lower than that of patients without using of flurbiprofen (7.3%) ($P<0.01$), while the incidence of AKI in patients with a high dose of flurbiprofen (11.2%) was significantly higher than that of patients without using of flurbiprofen (7.3%) ($P<0.05$). Multivariate logistic regression analysis showed that the ASA classification, preoperative estimated glomerular filtration rate, excessive bleeding and emergency surgery were independent risk factors for AKI in total patients (OR= 2.4, 4.7, 1.6, 2.1 respectively, $P<0.01$), while using of low dose lurbiprofen (≤150mg) was a protective factor for AKI (OR= 0.4, $P<0.01$). On the other hand, in 2656 patients who used flurbiprofen, multivariate logistic regression analysis showed that the large dose of lurbiprofen, ASA classification, preoperative estimated glomerular filtration rate, excessive bleeding and emergency surgery were independent risk factors for AKI. (OR= 2.9, 3.1, 1.8, 2.4 respectively, $P<0.01$).

Conclusions: Large dose of perioperative flurbiprofen (≥200mg) was an independent risk factors for AKI. Using of low dose lurbiprofen(≤150mg) perioperatively could effectively reduce the incidence of AKI, while a large dose of flurbiprofen could aggravate the incidence of AKI.

PUB061

Incidence of AKI in Acute Decompensated Heart Failure Oisin O Corragain,[3] Avrum Gillespie,[2] Mark G. Weiner.[1] *[1]Lewis Katz School of Medicine at Temple University, Philadelphia, PA; [2]None, Philadelphia, PA; [3]Temple University Hospital, Philadelphia, PA.*

Background: Acute Kidney Injury (AKI) is a significant cause of morbidity and mortality, affecting 27-40% of all patients hospitalized for acute decompensated heart failure (ADHF) in previous literature. Rising creatinine levels in ADHF is often thought to be secondary to Cardio-renal syndrome (CRS), however it is often difficult to differentiate increased creatinine due to CRS from other causes of AKI, mainly tubular damage and acute tubular necrosis (ATN). There is conflicting evidence on outcomes of AKI in ADHF, some showing worse outcomes, while several previous studies have noted a mortality benefit with increased creatinine during diuresis. Early recognition of tubular damage and ATN may prevent progression to AKI Stage 3, need for renal replacement therapy, ICU admission and mortality. The purpose of this study is to characterize the incidence of AKI in patients admitted with ADHF. The specific objectives are to try to predict AKI not due to CRS, assess outcomes with worsened severity of AKI and to identify patients at higher risk of AKI

Methods: We performed a retrospective review of existing data on patients hospitalized with ADHF, involving all patients admitted to Temple University Hospital with a primary or secondary discharge diagnosis of ADHF between August 5th, 2016 (The date of the transition to inpatient Epic Electronic Medical Record from the preceding largely paper based inpatient medical record system) and April 4th 2017.

Results: 230 individual patients with an inpatient diagnosis of ADHF without a diagnosis of End Stage Renal Disease were identified; with a total of 425 admissions identified. 56.9% were male; the average age was 64.7 with a range of 28 to 101. The incidence of AKI based on KDIGO criteria was 50.8% (N=117) for patients, with AKI noted in 55.5% (N=236) of all admissions. Of those with AKI, 84.7% (N=200) had AKI Stage 1, 13.5% (N=32) had Stage 2 and 1.6% (N=4) had Stage 3. 58% (N=138) of admissions with AKI had not resolved by last day of admission.

Conclusions: Not all elevation in creatinine is CRS in ADHF. Future studies will better characterize these patients, identify risk factors for incidence of AKI, and explore the association of discharge AKI with likelihood of readmission.

PUB062

Hidden Beneath the Surface: A Case of Chronic Lymphocytic Leukemia Manifesting as AKI and Pancytopenia Khurram Mehtabdin,[2] Anam Siddiqui,[3] Kenar D. Jhaveri.[1] *[1]Hofstra Northwell School of Medicine-Northwell health system, Great neck, NY; [2]North Shore-LIJ Healthsystem, Great Neck, NY; [3]Northwell, Elmhurst, NY.*

Background: Chronic lymphocytic leukemia is a neoplastic disease of B cells, usually involving hematopoietic organs such as the bone marrow, blood, lymph nodes and spleen. There are rare instances where extra-hematopoietic manifestations can occur. This is a case of a patient with AKI and pancytopenia treated for presumed lupus nephritis despite negative serologies with pulse steroids and subsequently develops worsening leukocytosis.

Methods: A 55 year old female with no past medical history presents with recurrent fevers, polyarthritis and diarrhea. Labs reveal pancytopenia, AKI with peak Cr 5.26mg/dl, hematuria, subnephrotic proteinuria of 1.8 on spot ratio and hypocomplementemia. Chest radiography demonstrated slight left lower lobe pulmonary infiltrates and mediastinal lymphadenopathy. ANA was 1:80 and all other secondary serological testing was negative, (ANCA, anti-GBM, cryoglobulins, hepatitis, HIV). The patient was started on pulse steroids (1gm for 3 days) for presumptive seronegative lupus nephritis with rapid improvement in renal function and resolution of pancytopenia within days. A kidney biopsy was performed during the resolution phase of the AKI. After steroids were started, the patient developed leukocytosis (up to 60 K/uL), with significant lymphocytosis and smudge cells noted on smear. Flow cytometry was consistent with small lymphocytic leukemia, a form of CLL. The bone marrow testing confirmed 20-30% involvement with CLL. The kidney biopsy confirmed resolving interstitial nephritis and tubular damage but was negative for any infiltrative malignant CLL cells.

Results:

Conclusions: This patient's case demonstrates the various manifestations, including both renal and rheumatologic complications of chronic lymphocytic leukemia. Interstitial nephritis has been reported with CLL and can respond to steroids alone albeit treatment of CLL. It is presumed to be a reactive inflammatory process from small pockets of malignant cells. Autoimmune processes have also been reported with CLL. The pancytopenia and clinical manifestation might have been a paraneoplastic autoimmune process seen with CLL. The patient's kidney function is now normal and steroids are being tapered. The physician should be aware of renal insufficiency present in 7.5% of patients at the time of CLL diagnosis and in an additional 16.2% during the course of the disease.

PUB063

Study of Renal Morphological and Structural Changes at Different Ischemic Times and Types of Renal Vascular Pedicle Clamping Angela Mazzeo,[1,2] Miguel A Goes.[1,2] *[1]Hospital Israelita Albert Einstein, Sao Paulo, Brazil; [2]Division of Nephrology, Federal University of São Paulo, São Paulo, Brazil.*

Background: Clinical manifestation of acute renal injury is often seen in patients who underwent interventions such as partial nephrectomies, and renal transplantation during the post-surgical period. Additional factors that may potentiate this condition, such as the severity of the installed condition, the complexity of the surgical procedure and comorbidities, should be considered. Objective: To study renal morphological and structural changes in relation to different ischemic times and types of renal vascular pedicle clamping

Methods: We performed simulating this procedure in which 16 pigs were ramdomized in two groups containing 8 animals each: Group AV; unilateral left clamping of the renal artery and vein with contralateral kidney used as control and Group A - unilateral left renal artery clamping only, with the contralateral kidney also used as control. Serial biopsies of the renal parenchyma were performed at times 0, 10, 20, 30, 40, 50, 60, 70, 80, and 90 minutes after clamping. The tissues were submitted to histopathological analysis to identify structural and morphological alterations

Results: : We observed higher vascular congestion and edema in A group after 10 min, 20 min, 30 min, 40 min and 60 min post ischaemia ($p<0.001$, $p=0.001$, $p=0.02$, $p=0.001$, $p=0.001$; respectively). We observed higher frequency of lesions in Group A for all cellular alterations found (interstitial inflammatory infiltrate, interstitial hemorrhage and cell degeneration) in all times of clamping except for the formation of pigmented cylinders that were only found in the AV Group

Conclusions: the number of lesions derived from ischemia is associated with the duration of the insult. In addition, the AV Group presented a lower frequency of injuries than Group A (it presented a higher number of injuries in a shorter time interval of ischemia)

PUB064

Prevalence and In-Hospital Outcomes of AKI in a University Hospital in Argentina Carlos Federico Varela,[2] Luciana Rubin,[2] Michelangelo Hernan,[2] Maria L. Ocampo,[1] Gustavo Greloni,[2] Daniel Luna,[2] Guillermo Rosa Diez.[2] *[1]Hospital Italiano Buenos Aires, CABA, Argentina; [2]Hospital Italiano de Buenos Aires, CABA, Argentina.*

Background: Comprehensive epidemiologic data on AKI in Argentina has not been written. The aim of our study is to evaluate the epidemiology and clinical outcomes of AKI among hospitalized adults.

Methods: Patients admitted between June 1, 2014 and May 31, 2015 were studied. Inclusion criteria were age above 18 years, the presence of two serum creatinine (Crea) during or 2 month before hospitalization and having stayed hospitalized more than one day. We excluded patients with chronic dialysis requirement and renal transplantation. We used hospital laboratory, admission and discharge databases. AKI was defined and staged according to KDIGO Crea criteria. Using Crea at discharge, we evaluated renal recovery.

Results: We studied 19930 in-hospital episodes. The mean age of patients included was 64±19, 52% were female, median of length of stay (days, LOS) was 4.5 and mortality was 5.6%. AKI prevalence was 11.6% and mortality in this group was 19.8%. AKI patients were older and average of days between first and highest Crea was 2 days. KDIGO stage 1 occurred in 9.2%, stage 2 in 1.6% and stage 3 in 0.8% with a stepwise increase in mortality with increasing AKI severity. ICU patients were 4631(23% of total group) of these had AKI 26%, while ward patients suffering AKI in 7.2%. Contrast media were

administered in 22% vs 9.4% of patients with and without AKI respectively. AKI occurred in 10.1% of patients who undergo cardiac surgery. LOS 9.8 vs 4.1 in patients with and without AKI respectively. In survivors, 73% have recovery of baseline renal function and 27% have partial recovery. In the last group 89.3% have a eGFR under 60ml/min/1.73m2.

Conclusions: As described in literature, AKI is common in hospitalized adults and is associated with significantly higher in-hospital mortality and CKD.

Table: 1. Clinical and demographical data

	All patients 19930 (100%)	AKI 2310 (11.6%)	No AKI 17620 (88.4%)	p value
Age (years)	64.16 ± 19,33	70,4±17	63,3±19	0.001
Gender female %	52.20%	45.60%	53,00%	0.001
LOS (days)	4.5	9.8	4.1	0.001
Mortality %	5.6%	19.80%	3.80%	0.0001
ICU patients %	23.2%	52,2%	19,2%	0.0001

Preexisting AKI Could Be Reversed in a Portion of Patients after Cardiac Surgery Xin Wan,[2] Jing Li,[1] Changchun Cao.[3] *[1]Nanjing First Hospital, Nanjing Medical University, Nanjing, China; [2]Nanjing Hospital Affiliated to Nanjing Medical University (Nanjing First Hospital), Nanjing, China; [3]Sir Run Run Hospital Affiliated to Nanjing Medical University, Nanjing, China.*

Background: Acute kidney injury (AKI) is a common complication after heart surgery. However, in clinical practice, preexisting AKI could also be reversed in some occasions after cardiac surgery, especially in patients with higher level of preoperative creatinine level. In this article, the occurrence, short-term prognosis and influential factors were discussed.

Methods: Five years of retrospective data (2008-2012, n=2832) were collected in the Division of Thoracic and Cardiovascular Surgery, Nanjing First Hospital, Nanjing Medical University. Observation of a decrease of 26.5μmol/L in serum creatinine in patients without renal replacement treatment was seen as the case of released preexisting AKI. Statistical description and binary logistic regression(backward stepwise: Wald)was applied in the study.

Results: After excluding the cases of patients with end-stage renal disease (ESRD) and missing data, 2383 cases were included in the study. Among which, 137 cases (5.7%) of patients were observed with released preexisting AKI. In patients with lower level of preoperative eGFR, the occurrence increased dramatically (from 1.4% to 50%). Compared with the postoperative acute, patients with reversed preexisting AKI suffered from lower mortality (1.5% vs. 2.6%). In the model of logistic regression, male (OR 1.794, 95% CI 1.201 to 2.681), lower level of preoperative eGFR (OR 6.438, 95% CI 4.808 to 8.620), previous cardiac surgery (OR 2.918, 95% CI 1.241 to 6.902) and preoperative use of IABP (OR 5.710, 95% CI 2.103 to 15.102) were the factors prompting the phenomenon. While patients with older age (OR 0.516, 95% CI 0.342 to 0.777), hypertension (OR 0.621, 95% CI 0.396 to 0.974), diabetes (OR 0.399, 95% CI 0.166 to 0.959) and peripheral vascular diseases(OR 0.253, 95% CI 0.135 to 0.471) were harder to reverse from the preexisting AKI. The area under the receiver operating characteristic curve was 0.842 (95% CI 0.826 to 0.856).

Conclusions: Preexisting AKI could be reversed in some occasions after cardiac surgery. Preoperative creatinine is influential but not decisive in postoperative renal prospective. Combination of preoperative state could predict the releasable preexisting AKI accurately, which may provide objective evaluation for the patients with higher level of preoperative serum creatinine.

PUB066

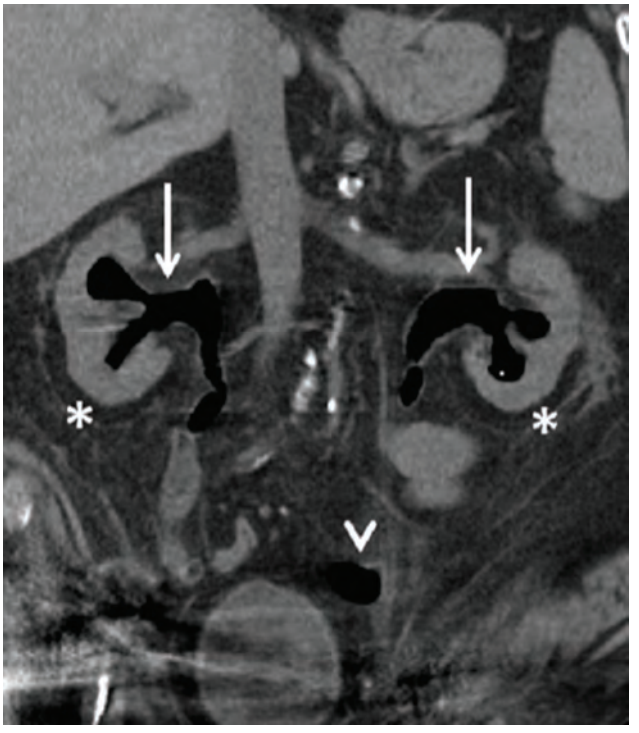
Foley Folleys: Emphysematous Pyelitis from Instrumentation in Obstructive AKI Anna S. Gutman,[1] Shimshon Wiesel,[1] Jonah E. Abraham,[2] Militza K. Kiroycheva.[1] *[1]Staten Island University Hospital, Staten island, NY; [2]Anesthesia, University of Pittsburgh Medical Center, Pittsburgh, PA.*

Background: Emphysematous pyelitis (EP) is a subclass of the life threatening infection, ephysematous pyelonephritis (EPN). We report a case of an 81-year old man, who developed EP after urinary tract (UT) manipulation.

Methods: An 81-year-old man with chronic obstructive nephropathy due to benign prostatic hyperplasia presented to our hospital with worsening kidney function. He was asymptomatic, afebrile, and had stable vital signs. His serum creatinine was 3.1 mg/dL, up from 1.5 mg/dL, and he had mild hematuria, pyuria, and proteinuria. Renal ultrasound showed bilateral hydroureteronephrosis with high post void residual volume, for which a urinary catheter was placed. Repeat ultrasound showed bilateral renal collecting shadowing echogenic foci, and a CT abdomen/pelvis showed air throughout the collecting systems and ureters. He was treated with antibiotics despite a negative urine culture, and a repeat CT showed resolution of the EP.

Results:

Conclusions: EPN is divided into: Class 1 (EP) – gas in the collecting system Class 2 – gas in the renal parenchyma Class 3A – gas/abscess extension to the renal fascia Class 3B – gas/abscess extension to adjacent tissues Class 4 – bilateral EPN or a solitary kidney with EPN Treatment for EPN is individualized, with general guidelines: Class I and II – antibiotics and percutaneous drainage (PCD) if the UT remains obstructed Class III and IV – antibiotics, PCD, and nephrectomy if no improvement For all classes: relief of the UT obstruction Our patient had asymptomatic, class I EPN, likely due to UT manipulation, obstruction, or infection. He improved with antibiotics, and did not require surgical intervention.



CT: air in the renal pelvises extended into the ureters (arrows). Fat-stranding of the bilateral kidneys (asterisks). Air at the left uretero-vesicular junction (arrowhead)

PUB067

Association of the Severity and Recurrence of AKI with Incident CKD in Head and Neck Cancer Patients with High-Dose Cisplatin-Based Chemo-Radiotherapy Akihiko Kato,[2] Naoko Tsuji,[2] Takayuki Tsuji,[1] Naro Ohashi,[1] Hideo Yasuda.[1] *[1]Hamamatsu University School of Medicine, Hamamatsu, Japan; [2]Hamamatsu University Hospital, Hamamatsu, Japan.*

Background: Acute kidney injury (AKI) is a serious complication of cisplatin (CDDP)-based chemotherapy. However, its impact of long-term renal outcome is not clear. We aimed this study to examine the impact of AKI severity and recurrence on renal outcome in head and neck cancer patients with CDDP treatment.

Methods: We identified 52 head and neck cancer patients whose basal estimated glomerular filtration (eGFR) was higher than 60 ml/min/1.73m^2, and who had underwent chemo-radiotherapy including 66-70 Gy with repeated infusion of CDDP of 80 mg/m^2 on days 1, 22, and 43 (age: 60±10 years old, male/female=48/4, basal eGFR: 87±18 (60-143) mL/min/1.73m^2).

Results: Of 52 patients, 24 (46.2%) developed AKI; 14 (26.9%) developed stage 1, 8 (26.9%) developed stage 2, and 2 (3.8%) did stage 3. There were 18 patients who complicated of one episode of AKI, 7 patients who did of 2 episodes, and 1 patient who did of 3 episodes during the chemotherapy. During the 4-month follow-up after the treatment, mean eGFR was decreased to 67±25 (32-182) mL/min/1.73m^2. There were 23 patients (44.2%) who developed incident chronic kidney disease (CKD), 19 of stage G3a and 4 of stage G3b. A multiple regression analysis revealed that basal eGFR was a significant determinant of incident CKD (β=-0.41, $p<0.01$). Especially, of 20 patients whose basal eGFR was lower than 80 mL/min/1.73m^2, 14 (70.0%) patients developed CKD after CDDP treatment. In contrast, AKI stage, number of AKI episode, and timing of AKI onset during the chemotherapy did not relate to the onset of CKD.

Conclusions: The findings suggest that the severity and recurrence of AKI episode during the CDDP-based chemotherapy did not relate to subsequent CKD progression. Rather, a lower basal eGFR (< 80 ml/min/1.73m^2) was a potent risk factor of incident CKD after the CDDP-based chemotherapy.

The Jaffe Reaction Is Not Affected by Acetylcysteine James S. Cain,[2,3] Jack E. Sherman.[1] *[1]Roanoke Valley Governor's School, Roanoke, VA; [2]Nephrology, Carilion Virginia Tech School of Medicine, Roanoke, VA; [3]Valley Nephrology Associates, Roanoke, VA.*

Background: Alkaline picrate creatinine determinations (the Jaffe reaction) are used to measure urine and serum creatinine levels, alternative methods have been proposed to resolve the multiple problems with this venerable technique. A common alternative (Trinder reaction) is subject to negative interference by acetylcysteine (NAc.) NAc is used

to offer nephroprotection from IV contrast and is the subject of numerous investigations. We found no literature clearing the Jaffe reaction from this interference. As researchers rely upon this assay, we studied the effect of NAc on this test.

Methods: Serial dilutions of known concentrations of creatinine were prepared. The samples were analyzed with a negative control using manual and automated kinetic alkaline picrate procedures. Samples with creatinine concentrations of 15, 30, 60, and 120 mg/dl were assayed with added Nac of 0, 200, 100, 50, 25 and 12.5 mg/dl.

Results: In no case did the addition of NAc significantly alter the optical density of the "spiked" test samples compared to their non spiked counterparts, this was confirmed by ANOVA testing

Conclusions: The Jaffe reaction appears to be free of negative or positive interference from NAc. Conclusions drawn from creatinine assays under these conditions can be trusted. This affirms the use of the Jaffe reaction in both clinical and research venues involving NAc in both kinetic and non kinetic assays. The assay has numerous other known interfering substances which need to be considered.

PUB069

Systolic Blood Pressure Predicted One Year Mortality of Patients with Type-3 Cardio-Renal Syndrome Ying Zhou, Chen Yu. *Department of Nephrology, Department of Nephrology, Tongji Hospital, Tongji University School of Medicine, Shanghai, China., Shanghai, China.*

Background: Cardiorenal syndrome (CRS) is the clinical syndrome with heart failure and kidney damage, there is a complex interaction between them. The aim of this study was to investigate the clinical features of acute renocardiac syndrome (cardiorenal syndrome type 3) and prognostic factors in a tertiary referral hospital in Shanghai of China.

Methods: There were 1011 out of 19361 subjects (5.22%) admitted to our internal medicine ward (from January 2015 to December 2015), diagnosed with CRS. There were 33 cases which were diagnosed as type 3 CRS. This was a retrospectively cohort and we analyzed the anthropometric, history, clinical, biochemical and mortality characteristics of them.

Results: During 1-year follow-up, 9(27.3%) patients died. Mean age of these 33 patients was 75.33±11.82 years, 16 (48.4%) were males, 5 (15.2%) were smokers, 8 (24.2%) were diabetic, 25(75.8%) had a history of hypertension, 11 (33.3%) had coronary heart disease, 9 (27.3%) were affected by stroke. They were divided into 2 groups: survival group and dead group. Systolic blood pressure (154.46±30.71 vs 126.78±21.42), hemoglobin [(75.8, 109.0) vs (58.5, 90.0)] and Glutamyl transpeptidase [(18, 40) vs (9.8, 26.5)]levels were higher in survival group than in dead group ($P<0.05$). However, PCT levels were higher in dead group(1.02, 17.10) than in survival group(0.19, 0.66) ($P<0.05$). Multivariate logistic regression analysis suggested that systolic blood pressure independently predicted one year mortality (odds ratio: 0.947; 95% confidence interval [CI]: 0.901 to 0.99; $p = 0.033$).

Conclusions: CRS is common, and one year mortality of patients with type-3 CRS was high. Systolic blood pressure can help predicted one year mortality of patients with type-3 CRS.

Elderly versus Younger Patients in Vasculitis: A Single Centre Experience Vasantha M. Muthuppalaniappan,[2] Philip Davis,[3] Abhishek Dattani,[2] Saurabh Chaudhri.[1] *[1]Stratford, United Kingdom; [2]Barts Health NHS Trust, London, United Kingdom; [3]NHS, London, United Kingdom.*

Background: ANCA associated vasculitis (AAV) is a multi-systemic autoimmune disease primarily of older adults with a peak age between 65 & 74 years old. Without treatment AAV leads to considerable morbidity & mortality. The potential adverse effects of immunosuppressive therapy can be daunting when considering treatment in elderly. Our aim was to evaluate the clinical features & outcomes in elderly patients with AAV in comparison to younger patients at our unit.

Methods: We performed a single centre, retrospective study, observing 1 year survival outcomes & relapse rates in any patient diagnosed with AAV who presented to our renal unit, between Jan 2014-Dec 2015. Patients were divided into elderly group (EG) (≥70 years) and younger group (YG) (<70 years). Data on clinical features, treatment, survival and renal outcome were analysed.

Results: A total of 31 patients (17 male) aged 31-82 (mean age 61.7±14.9) were identified. The EG of 12 patients were compared to the YG of 19 patients.(Table 1) Overall 1 year survival in the YG was 93.8% & 50% in the EG. Mortality increased with age (R^2=.230, p=0.006) & C-reactive protein (R^2 .268, p=0.003). Mortality was raised in the EG with non-standard immunosuppression but large SD affected the p value. 33.3% of patients in the YG and 20% of patients in the EG had at least 1 relapse episode in a year. 26.7% of the younger patients required an average of 1 hospital admission. Each elderly patient had at least 1 hospital admission. Among patients who survived at 1-year, 20% of elderly patients and 13.3% of younger patients required dialysis.

Conclusions: Elderly patients with AAV had a higher mortality rate in comparison to the younger group. Relapses were more frequent in the younger group. Hospitalisations were more frequent in the elderly patients. Age at presentation in the whole group significantly affected survival outcomes.

Table 1

	Young AAV Group <70 years (n=19)	Elderly AAV Group ≥70 years (n=12)
Age at diagnosis mean	53 ± 12	75.8 ± 4.8
Mean BVAS score	21.1 ± 6.5	17.3 ± 6.6
MPO	42.1% (8)	50% (6)
PR3	57.9% (11)	25% (3)
GBM	0	8.3% (1)
Double positivity	0	16.7% (2)
HD at presentation	15.8% (3)	41.7% (5)
Standard immunosuppression	94.7% (18)	50% (6)
Non standard immunosuppression	5.3% (1)	50% (6)

PUB071

Digoxin Toxicity in a Patient with Liver Failure and AKI: Role for CRRT versus Plasmapheresis Aravindan V. Jeyarajasingam,[6] Srikanth Thiruvarudsothy,[3] Anuradha Konkesa,[2] Sushma Munugoti,[5] Smita Mahendrakar,[1] Alluru S. Reddi.[4] *[1]Swedesboro, NJ; [2]Rutgers, Morrisplains, NJ; [3]Rutgers NJMS, Belleville, NJ; [4]Rutgers New Jersey Medical School, Newark, NJ; [5]Rutgers UNIVERSITY, Montclair, NJ; [6]Nephrology, Rutgers NJMS, Newark, NJ.*

Background: Introduction: Digoxin has been used for management of atrial fibrillation (AF) and congestive heart failure (CHF). One of the concerns of digoxin use is its toxicity, particularly in patients with renal failure. We present a patient with AF, decompensated liver failure, superimposed on alcoholic cirrhosis and acute kidney injury (AKI), who was successfully treated with CVVHDF and plasmapheresis for AKI and digoxin toxicity.

Methods: Case Description: A 62-year-old man with past medical history of alcoholic cirrhosis and recently diagnosed AF and CHF was admitted for fatigue and weakness. He was on digoxin, furosemide and spironolactone. On admission, the patient was found to have bradycardia with heart rate of 33 beats/min and digoxin level of 3.6 ng/ml which peaked to 6.2 ng/ml. Serum creatinine was 3.4 mg/dl, which continued to rise, and the patient became anuric. Patient received Digibind and CVVHDF. His heart rate improved to 70s and subsequently dropped to 40s on days 4 and 5. Second episode of digoxin toxicity was suspected with likely digoxin-digibind complex deconjugation, as repeat digoxin level was 1.9 ng/ml. Patient received another dose of digibind on day 6 of the admission and followed by one cycle of plasmapheresis to remove the digoxin – digibind complex. Patient's vitals improved significantly after the plasmapheresis and remained stable during rest of the hospital stay.

Results:

Conclusions: Discussion: Digoxin is a cardiac glycoside that has very narrow therapeutic window; therefore, toxicity is common. It is excreted through kidneys. Owing to large molecular weight of digoxin and digoxin-digibind complex, CVVHDF that was initiated for anuric AKI failed to eliminate this complex. Deconjugation of digoxin-digibind circulating complex in the blood likely caused the second episode of digoxin toxicity with increase in digoxin levels as well as bradycardia. This case suggests that digoxin toxicity can be improved by 1-2 treatments of plasmapheresis when digibind fails to improve digoxin toxicity in patients with AKI and/or CKD.

PUB072

Clinical Characteristics of Sepsis Patients Who Were Treated with Continuous Renal Replacement Therapy A young Cho, In O Sun. *Presbyterian Medical Center, Jeonju, Korea, Jeonju, Republic of Korea.*

Background: Soluble inflammatory mediators are known to exacerbate sepsis-induced acute kidney injury (AKI). Despite the frequent use of continuous renal replacement therapy (CRRT) in the management of sepsis-induced AKI, predictor of mortality remain unclear.

Methods: We enrolled 337 patients who were treated with CRRT due to sepsis at the Presbyterian Medical Center intensive care unit from 2010 to 2014 in the study. We divided these patients into two groups (survivors vs non-survivors) according to 28-day all-cause mortality, compared their clinical characteristics, and analyzed the predictors of survival.

Results: The study included 212 men and 125 women, with a mean age of 67 years (range, 21-92 years). When we compared clinical characteristics of survivors (n=212) and non-survivors (n=125), no differences were identified, with the exception of age, total bilirubin, platelet count, and red blood cell distribution width (RDW). Survivors were younger (64 ± 14 vs 69 ± 12 year, P=0.001) and had high platelet count (180×10^3/ mL vs 134×10^3/ mL, $p<0.01$) than non-survivors. However, survivors had low RDW (14.99 ± 2.1 vs 16.17 ± 3.3, $p<0.01$) and low total bilirubin (1.04 ± 1.45 vs 2.7 ± 6.13, $p<0.01$) than non-survivors. In multivariate logistic regression analysis, age, platelet count and RDW were assessed as prognostic factors to predict 28-day all-cause mortality in sepsis patient who needed CRRT.

Conclusions: Age, platelet count and RDW could be predictors for 28-day all-cause mortality in sepsis patients with CRRT.

PUB073

Use of Point of Care Creatinine Testing to Identify AKI in the Community Setting Joshua Storrar,[1] James Ritchie,[2] Dimitrios J. Poulikakos.[1] *[1]Salford Hospital, Manchester, United Kingdom; [2]Salford Royal Hospital, Manchester, United Kingdom.*

Background: Two thirds of Acute Kidney Injury (AKI) cases detected in hospital are community acquired. Point of care renal function testing in primary care may assist early identification and management of community acquired AKI to improve outcomes. Point of care (POC) creatinine testing has been developed but has not been used in the community routinely. In this study we aimed to evaluate existing creatinine POC testing against our standard laboratory method in order to support its use in the community.

Methods: We obtained POC creatinine (venous or capillary) values with StatSensor (NOVA) and serum creatinine values with Siemens Advia 2400 Jaffe for 89 patients in the hospital setting (either in the Emergency Department, outpatient clinic, ward environment or haemodialysis units). Of the POC samples, 28 were capillary blood and 61 were venous blood. POC samples were obtained at the same time as laboratory samples. We measured the percentage difference in values with the two different methods and performed correlation analysis.

Results: POC creatinine values ranged from 44µmol/L to 985µmol/L and laboratory creatinine values ranged from 43µmol/L to 1201µmol/L. There was a good correlation between POC and laboratory creatinine values (R^2 0.92, p value 0.006), Figure 1. The average percentage difference between POC creatinine and laboratory creatinine was -10%.

Conclusions: We have demonstrated a correlation between POC and laboratory creatinine results. POC testing overall tends to overestimate creatinine values. POC has reasonable agreement with laboratory assays to detect normal and abnormal values. Since AKI is defined based on change in creatinine values caution should be exercised when using POC testing and baseline laboratory values particularly for small fluctuations.

Correlation of point of care creatinine values with laboratory creatinine values

PUB074

The Clinical Implication of Computed Tomography in Predicting Severity of Acute Pyelonephritis Associated AKI A young Cho, In O Sun. *Presbyterian Medical Center, Jeonju, Korea, Jeonju, Republic of Korea.*

Background: The aim of this study is to investigate the incidence and clinical characteristics of acute kidney injury (AKI) in patients with acute pyelonephritis (APN) and evaluate the efficacy of contrast-enhanced computed tomography (CECT).

Methods: From May 2007 to December 2009, we included 541 patients with APN who underwent a CECT examination. We investigated the incidence and clinical characteristics of APN associated AKI using the RIFLE criteria. In addition, we divided these patients into four groups according to renal parenchymal involvement in CT (group 1; less than 25% involvement, group 2; 25% or greater involvement but less than 50% involvement, group 3; 50% or greater involvement but less than 75% involvement, group 4; greater than 75%), and compared their clinical characteristics, incidence of AKI.

Results: The patients included 33 males and 508 females with a mean age of 55 years (range, 18 to 92). The incidence of AKI was 14.4%; of which, 8.0%, 5.4% and 1.0% were classified as Risk, Injury and Failure, respectively. When we compared clinical characteristics among groups, there were no differences except hospital stay. The patients in group 4 have longer hospital stay than other groups (grade 1; 9±5, grade 2; 9±4, grade 3; 9±4, grade 4; 10±5, p=0.008). There was no difference in baseline renal function (70±27 vs 76±27 vs 74±23 vs 74±23, p=0.87) and incidence of AKI among groups (G1: 9.4%, G2: 9.3%, G3: 7.2%, G4: 11.3%).

Conclusions: The incidence of APN-associated AKI was 14.4%. Although CECT is useful to detect severe APN, it seems to be less helpful to predict the AKI in patients with APN.

PUB075

Intravenous Immunoglobulin Associated Nephrotoxicity Umair S. Ahmed. *Lavale, MD.*

Background: Intravenous immunoglobulins (IVIg) are an effective treatment of multiple conditions and are usually well tolerated. We present 3 cases of IVIg associated acute kidney injury (AKI)

Methods: Case 1 56-year-old female, admitted with asymptomatic thrombocytopenia on routine testing. Platelet count on admission was 11,000. Patient was started on prednisone 100 mg daily and received 2 doses of sucrose containing IVIg, 1gm/kg. Serum creatinine on the day of administration of IVIg was 1.0, increasing progressively to 1.60, 2.50 and 2.60 over the next 3 days. No other nephrotoxic insults were identified. Urine evaluation was unremarkable. Serum creatinine 2 weeks later was 1.0 Case 2 53 years old male, admitted with back pain and bilateral lower extremity weakness. Serum creatinine on admission was 0.90. Patient was diagnosed with Guillain-Barre syndrome. A total of 2 g/kg of sucrose containing IVIg was administered over 5 days. Serum creatinine on day of initial IVIg administration was 0.80, increasing 2 days later to 2.0 and peaking at 2.20. Serum creatinine decreased to 1.20 three days after IVIg was completed. No other nephrotoxic insults were identified. Urine evaluation was unremarkable. Case 3 83 years old male, history of chronic kidney disease stage III and diffuse large B-cell lymphoma who presented with asymptomatic thrombocytopenia noted on routine investigations. Serum creatinine on the day of IVIg administration was 1.80 which was his baseline. Serum creatinine increased the day after IVIg infusion to 3.0 and continued to worsen. Patient started manifesting symptoms of uremia and was started on hemodialysis. Renal functions recovered to his baseline function after 4 sessions of hemodialysis.

Results:

Conclusions: Stabilizers are used in IVIg preparations to prevent formation of dimers and polymers, which may result in many of the adverse effects. Stabilizers include sucrose, glucose and sorbitol. Incidence of IVIg related AKI is approximately 6%, and higher with with sucrose-stabilized products. Sucrose administered intravenously enters tubular epithelial cells, causing swelling and cytoplasmic vacuolization of the proximal tubule and osmotic nephrosis. IVIg-associated AKI mostly occurs in patients at increased risk for AKI such as chronic kidney disease, diabetes mellitus, age > 65 years old, volume depletion or concomitant use of nephrotoxic agents.

PUB076

A Case of Oxalate Nephropathy in the Setting of Esophagogastrectomy and High Dietary Oxalate Intake Nawsheen Chowdhury,[2] Margaret O'Shea,[1] Youngjun Park,[3] Shayan Shirazian,[1] Naveed N. Masani.[1] *[1]Winthrop University Hospital, Mineola, NY; [2]Winthrop university hospital, Mineola, NY; [3]Winthrop-University Hospital, Mineola, NY.*

Background: Oxalate nephropathy has been defined as acute kidney injury (AKI) or chronic kidney disease (CKD) that results from tubular deposition of calcium oxalate. It is mostly reported in patients with primary hyperoxaluria, short bowel syndrome, ethylene glycol and high dose vitamin C intake. We present a case of Oxalate induced nephropathy secondary to high oxalate dietary supplement in the setting of esophagogactrectomy.

Methods: A 71-year-old Caucasian male with a history of type 2 diabetes mellitus for 17 years, esophageal cancer, status post gastroesophagectomy three years ago, nephrolithiasis, and stage 3 CKD with a baseline creatinine of 1.4 mg/dL presented to clinic with AKI and creatinine of 4.1 mg/dL. His urinalysis revealed a bland sediment with no protein. Despite discontinuation of his PPI and ACEi his renal failure worsened to a creatinine of 4.5 mg/dL and he was initiated on hemodialysis. The patient underwent renal biopsy that revealed acute tubular injury associated with multiple intratubular crystalline inclusions which are optically clear and produced strong birefringence under polarized light, most consistent with calcium oxalate. After a thorough investigation the patient admits to taking a vegetable supplement that includes Spinach, yams, carrots, broccoli, celery, and kale. After restriction of high oxalate dietary supplement, the patient was able to come off dialysis and now has stable creatinine of 2.9 mg/dL. A random oxalate:creatinine ratio was high at 86.7 mg oxalate/gm creatinine.

Results:

Conclusions: Excessive dietary oxalate intake has been shown to cause oxalate nephropathy. Risk factors for dietary induced oxalate nephropathy include primary hyperoxaluria, ethylene glycol poisoning, secondary hyperoxaluria due to bariatric surgery, inflammatory bowel disease, Orlistat therapy, high dose Vitamin C. In our case it appears that high oxalate supplement in the setting of esophagogastrectomy led to hyperoxaluria and calcium oxalate deposition in the renal tubules. As with other cases of oxalate nephropathy the renal dysfunction improved with removal of the offending agent; our patient is left with significant residual chronic kidney disease, stage IV.

PUB077

AKI Diagnosed by KDIGO Criteria Is an Independent Risk Factor for Mortality in Critically Ill Burned Patients Judith Martins. *HOSPITAL UNIVERSITARIO DE GETAFE, MADRID, Spain.*

Background: INTRODUCTION AND AIMS: Acute kidney injury (AKI) has been associated with increased morbidity and mortality in critically ill patients. However, the impact of AKI in outcomes in critically ill burned patients has not been extensively studied. The aim of our study was to assess the relationship between the diagnosis of AKI and different outcomes in this patient population. .

Methods: MATERIAL AND METHODS: We performed a retrospective analysis of patients admitted to the Intensive Care Burn Unit (ICBU) of our hospital from 1992 to

2012 (n=1635). We included patients with length of UCBU stay ≥ 3 days. We assessed the relationship between the presence of AKI (KDIGO criteria) during the first 7 days of ICBU admission and different outcomes (mortality, infection rate and requirement of renal replacement therapy [RRT]) using a stimative multivariate logistic regression model. The strength of the association was measured by the odds ratio (OR) and the 95% confidence interval. Data are percent or median and interquartile range. A p value < 0.05 was considered statistically significant

Results: RESULTS: A total of 840 patients were evaluated (age 44 [31-61] years; male 601 [72%]; total surface area burned 24% [15%-40%]; non survivors 109 [13%]; RRT 34 patients [4%]). Comorbidities associated were: hypertension 102 (12.2%), diabetes mellitus 35 (4.2%), chronic kidney disease 1 (0.1%). AKI developed in 466 (55.5%) patients. Mortality of patients with AKI versus patients without AKI was 17% and 8%, respectively (p<0.001). In the multivariate analysis, after adjustment for 12 covariates (hypertension, diabetes, chronic kidney disease, heart failure, age, sex, SAPS score, SOFA score for the cardiovascular, coagulation and respiratory components at admission, deep burn surface area and requirement of mechanical ventilation in the first 72 hours) AKI was associated with an increased risk of death (OR 2.22 [1.21-4.08], p=0.010), infection rate (OR 1.36 [1.01-1.84], p=0.044) and requirement of RRT (2.37 [0.99-5.65], p=0.051).

Conclusions: CONCLUSIONS: In our study AKI is common and is independently associated with poor outcomes, including a higher mortality rate, among critically ill burned patients.

PUB078

Hospital Acquired Kidney Injury in Critically Ill Patients Judith Martins. *HOSPITAL UNIVERSITARIO DE GETAFE, MADRID, Spain.*

Background: INTRODUCTION AND AIMS: Hospital acquired acute kidney injury (AKI) is common and is a risk factor for all-cause mortality and chronic kidney disease. Early detection of AKI is important to prevent the progression of AKI and to improve clinical outcomes. The aim of this study was to examine AKI acquired during the stage in the intensive care unit (ICU).

Methods: METHODS: We performed a retrospective cohort study of patients admitted ato the Intensive Care Unit (ICU) between January 2010 and December 2015. We included patients diagnosed AKI using KDIGO criteria during their hospital ICU stay and were evaluated by the nephrology department. Exclusion criteria were: Previous renal function unknown, AKI diagnosed at admission.

Results: RESULTS: We studied 50 patient: mean age was 67,22 years (±11.62), 35 (70%) were male, mean SPAS score was 59,1 (±5,3). The median length of hospital stay was 35.66 ± 27.03 days and ICU stay was 14,62 (± 14.4)days. Comorbidities associated were: hypertension (58%), Diabetes Mellitus (46%) and previous chronic kidney disease (60%). The main causes of the AKI were:40% hypovolemia (volume depletion, arterial hypotension), 22 % sepsis and 20 % of the cases were caused by multifactorial risk factors. 39 patients (78%) patients need renal replacement therapy(RRT). The majority of RRT procedures were with a continuous modality (CRRT). The principal cause to iniciate RRT was fluid overload and the median duration was 4,7 (±8.4)days. 2% of patients required RRT at hospital discharge. Independent risk factors for RRT were: SPAS score >59 and SOFA cardiovascular 4. Kidney function at ICU discharge with estimated glomerular filtration was 50.01 ± 27.1 ml/min and at hospital discharge was 47 ± 23 ml/min. The in-ICU mortality rate was 42.6%. Independent risk factors for hospital mortality were: previous chronic kidney disease, female and SPAPS score >59,17.

Conclusions: CONCLUSIONS: AKI hospital acquired is a frequent complication in critically ill patients. The diagnosis its associated with a high rate of mortality and need of RRT.

PUB079

Outcomes after Hospital Discharge for Dialysis Dependent AKI Patients with End Stage Liver Disease Victoria T. Vo, Roberto Pisoni, Ruth C. Campbell. *Medical University of South Carolina, Charleston, SC.*

Background: Acute kidney injury (AKI) in the setting of end stage liver disease (ESLD) has a high morbidity and mortality. There is little data on outcomes of ESLD patients who develop AKI requiring hemodialysis (AKI-D) who survive to discharge and how many ultimately survive to transplantation. To investigate this further, we conducted a retrospective chart review of ESLD patients who developed AKI-D and required hemodialysis (HD) after hospital discharge.

Methods: Patients with ESLD and AKI-D were identified by ICD-9 codes for intermittent hemodialysis and by admitting service (ESLD service). Patients on HD before the index admission & patients with newly diagnosed end stage renal disease (ESRD) from progressive chronic kidney disease (CKD) were excluded. The protocol was approved by the MUSC IRB.

Results: 54 patients met criteria for analysis. 23 patients died during the index admission and 6 were discharged to hospice. 8 patients were discharged home without HD after recovery of renal function. 17 patients were discharged home on HD. Median age was 52 years (range 28-65 y), 9 (53%) were women. Causes of AKI were acute tubular injury 9 (53%) and hepato-renal syndrome 5 (29%). Causes of ELSD were hepatitis C 5 (29%), NASH 7 (41%), alcohol induced 4 (23%). At the time of analysis, 3 of the 17 (17.6%) patients had undergone liver-kidney transplant (at day 30, 60 and 210), 4 patients were on the kidney-liver transplant list (1 currently waiting, 2 lost to follow up, 1 died), 1 declined further evaluation, and 2 patients were too high risk for listing. 5 people were in the evaluation process and 2 patients were lost to follow up without listing status. Only 1 patient recovered renal function and stopped HD.

Conclusions: AKI-D in ESLD carries a poor prognosis. HD after discharge may serve as a bridge to liver-kidney transplantation in selected patients. Renal recovery was poor.

PUB080

Nursing Perceptions Towards the Care of Patients with Post-Operative AKI Neesh I. Pannu. *University of Alberta, Edmonton, AB, Canada.*

Background: Patients undergoing operative procedures have a high incidence of in-hospital acute kidney injury (AKI) that is often under recognized and associated with adverse outcomes. Surgical teams without nephrology involvement generally manage post surgical AKI. At present, the attitudes and proficiency towards AKI of non-nephrology care providers has not been explored. Our aim was to assess surgical nursing perceptions of post-operative AKI.

Methods: A 14-question survey was provided to registered nurses and licensed practical nurses working on two general surgery wards at the University of Alberta Hospital in Edmonton, AB, Canada. Admitted patient population included trauma patients, and post-operative patients from elective, urgent, or emergent general surgery or urologic operations. Participation in the survey was voluntary, and questions assessed: years of experience, experience in other care environments, comfort level caring for patients with post-operative AKI, agreement with statements concerning the epidemiology, diagnosis, management, and prognosis of post-operative AKI, and attitudes towards performing quality improvement and increasing education around post-operative AKI.

Results: 22 nurses participated, of which, 77% were registered nurses, and 68% had been in practice less than 15 years. Only 36% of nurses had previous care experience in internal medicine wards, the emergency room, or an intensive care unit. The majority of nurses (86%) felt comfortable caring for patients with post-operative AKI. Similarly, most nurses believed that post-operative AKI could lead to irreversible kidney damage (77%), was preventable (95%), and that patients at risk for post-operative AKI could be predicted (81%). Of interest, 68% of nurses felt that the care of post-operative AKI required the involvement of nephrology or medicine consultants. The majority of nurses felt that more could be done to prevent and treat post-operative AKI on their units, and wanted additional education on AKI (72% and 95% respectively).

Conclusions: Although nurses caring for patients with post-operative AKI have minimal exposure to nephrology, they are receptive to nephrologists providing education and guiding quality improvement regarding AKI.

Unusual Cause for Acute Kidney Failure: T-Cell Lymphomatous Infiltration and Impingement D heeraj Kaul,[2] Okwudili Nnaji,[4] Gary R. Briefel,[1] Mary C. Mallappallil,[2] Moro O. Salifu,[3] Ian L. Provancha.[5]

[1]Kings County Hospital, Brooklyn, NY; [2]None, Brooklyn, NY; [3]SUNY Downstate Medical Center, Brooklyn, NY; [4]SUNY downstatemedicsl center, Brooklyn, NY; [5]SUNY Downstate Medical Center, Brooklyn, NY.

Background: Extra-nodal kidney infiltration is an unusual manifestation of T-cell lymphoma. Most patients with lymphoma presenting as extra-nodal disease have B-cell phenotype. Acute kidney injury (AKI) due to lymphomatous infiltration is rare, with the reported incidence of 0.05% in the literature. Lymphomatous infiltration of the kidney occurs late in the disease progress, being very unusual at presentation. We describe a unique case of T-cell lymphoma presenting with AKI with enlarged retroperitoneal lymph nodes causing hydronephrosis and encasement of one of the kidneys, consecutive lymph node biopsy showed T-cell lymphomatous infiltration.

Methods: A 79 year old Hispanic lady from Caribbean descent, with comorbidities such as hypertension, mixed hyperlipidemia, anxiety disorder and stage 3b chronic kidney disease came in for abdominal discomfort 2 weeks after screening colonoscopy and biopsies of colonic polyps. Physical exam showed hypertension of 178/73 mm Hg and normal physical findings. Laboratory studies showed AKI, serum creatinine 4.20, potassium 3.9, lactate dehydrogenase 989 and uric acid 10.4, presumed to be acute spontaneous tumor lysis syndrome. Staging work up with CT scan showed marked retroperitoneal lymphadenopathy, encasement of the right kidney and left kidney hydronephrosis with atrophic changes. Consequently, retroperitoneal lymph node biopsy showed T-cell lymphoma; CD3 positive, C20 and AE1/AE3 negative.

Results:

Conclusions: Review of PubMed Literature of published incidents of cell lymphoma presenting with AKI rendered 258 case reports in humans between 1975 and 2017. Reports described B-cell phenotype lymphoma (100%) the majority seen in immunosuppressed individuals with only a few (12) reports of T-cell lymphoma HTLV-related. Here we present a case of T-cell lymphoma (HTLV-negative) infiltrating and encasing both kidneys presenting as AKI. The unexpected lymphoma presentation warrants need to expand differential diagnosis of AKI.

PUB082

Acute Tumor Lysis Syndrome Caused by Palliative Radiotherapy in a Patient with Metastatic Prostate Cancer Umair S. Ahmed. *Lavale, MD.*

Background: Acute kidney injury as a result of tumor lysis syndrome has been reported in patient with hematological malignancies and can be spontaneous or treatment induced, usually secondary to chemotherapy. We present a case of a patient with

prostate cancer who developed tumor lysis syndrome secondary to radiation therapy and subsequently developed an acute kidney injury.

Methods: Patient is a 67 years old male with a past medical history significant for high grade metastatic prostate cancer who presented to the hospital with abdominal pain, nausea and generalized weakness. He was noted to be hemodynamically stable on admission. Serum creatinine was noted to be 4.80 on admission as compared to a normal baseline serum creatinine. Patient had a history of metastatic prostate cancer and had been treated with six cycles of Taxotere with minimal response. He had also undergone an orchiectomy. Due to severe back pain due to pelvic disease, patient was started one treatment with radium 223 which was 1 week prior to current hospital admission. He had not received prophylactic anti-uric acid treatment. Serum potassium was 6.0, phosphorus was 6.0 while serum uric acid was 35. Patient also had high anion gap metabolic acidosis and was subsequently started on a bicarbonate infusion. He also received 2 doses of IV rasburicase 9 mg. Peak serum creatinine was 6.20 and improved to 1.60. Electrolyte abnormalities resolved. Repeat serum uric acid level was undetectable.

Results:

Conclusions: Tumor lysis syndrome is uncommon after radiation therapy. This case highlights the importance to anticipate the possibility of developing acute kidney injury after radiation therapy which can be minimized by prophylactic administration of Allopurinol.

PUB083

Severity of AKI in Critically Ill Burned Patients Depends on the Diagnostic Criteria Used Judith Martins. *HOSPITAL UNIVERSITARIO DE GETAFE, MADRID, Spain.*

Background: INTRODUCTION AND AIMS: Acute Kidney injury (AKI) is a common and serious complication in burned patients The definition of AKI has been evolving for several years. The latest classification proposed by the Kidney Disease: Improving Global Outcomes (KDIGO) had the aim of unifying the definition of AKI. Following this definition, AKI is diagnosed according to a laboratory criterion (relative changes in serum creatinine [SCr]) and a urine output (UO) criterion. Patients are classified into three different stages. The aim of our study was to investigate the relationship between the criteria used for the diagnosis (laboratory [L], UO [U] or both [L+U]), and different outcomes (Intensive Care Burn Unit [ICBU] mortality and requirement of renal replacement therapy [RRT]) for each AKI stage.

Methods: MATERIAL AND METHODS: We performed a retrospective analysis of patients admitted to the ICBU of our hospital from 1992 to 2012 (n=1635). We included patients with length of UCBU stay ≥ 3 days. We assessed patients for the presence of AKI (KDIGO criteria) for the first 7 days of ICBU admission. We compared the relationship between each stage and different outcomes (mortality and RRT) depending on the criteria used for the diagnosis of AKI (L, U or L+U).

Results: RESULTS: A total of 840 patients were evaluated (age 44 [31-61] years; male 601 [72%]; total surface area burned 24% [15%-40%]; non survivors 109 [13%]; RRT 34 patients [4%]). Comorbidities associated were: hypertension 102 (12.2%), diabetes mellitus 35 (4.2%), chronic kidney disease 1 (0.1%). AKI developed in 458 (54.5%) patients. Patients presented AKI stage I (395 [84%], stage II 52 [11%], and stage III 19 [4%]). For patients diagnosed with L, U or L+U criteria, mortality was, respectively: All stages: 55 (17%), 18 (15%), 4 (24%) (p=0,601); Stage I: 48 (16%), 15 (16%), 1 (20%) (p=0.972); Stage II, 6 (43%), 2 (7%), 2 (20%) (p=0.022) ; and Stage III: 1 (17%), 1 (33%), 1 (50%) (p=0.632). For patients diagnosed with L, U or L+U criteria requirement of RRT was, respectively: All stages 11 (4%), 5 (4%),3 (18%) (p=0.017). Stage I: 8 (3%), 3 (3%),0 (0%) (p=0,891) and stage III: 1 (17%), 1 (33%), 1 (50%) (p=0,632).

Conclusions: CONCLUSIONS: KDIGO defines three stages of AKI of different severity. However, outcomes differ within each stage depending on the criterion met (laboratory versus urine output).

PUB084

Pre Transplant Predictors of Renal Recovery in Patients Undergoing Liver Transplant Sanjeev Gupta,[1] Anastasios Papanagnou,[1] Sharika G. Menon,[2] Savneek S. Chugh.[1] *[1]Westchester Medical Center, Valhalla, NY; [2]Westchester medical center, Valhalla, NY.*

Background: Hepato-Renal Syndrome (HRS) is a life threatening complication of liver cirrhosis. The activation of neurohormonal compensatory mechanisms can lead to intense renal vasoconstriction and resultant renal failure, needing dialysis at times. Liver transplantation was the first therapeutic option to change the prognosis of cirrhotic patients with HRS. Although not all patients post-transplant went into renal recovery. We are presenting a study looking at relationship of total bilirubin with renal recovery.

Methods: We did a retrospective analysis of 40 cirrhotic patients who underwent orthotropic liver transplant (OLT) from 1996 to 2014 with Acute Kidney Injury at our institution. Patients with impaired renal function were classified as having HRS based on the Ascites Club Criteria. The diagnosis of pre-renal azotemia and ATN were based on renal consult notes in the chart. Post-transplant renal function was assessed at day 30.

Results: Total patient population was 40 with mean age; MELD score, total bilirubin, and serum creatinine (SCr) at the time of transplant were 51, 32.4, 15 mg/dl, and 2.58 mg/dl respectively. Mean SCr at day 30 was 1.68 mg/dl with eGFR of 47.4 ml/min/1.73m2. Out of 40 patients, 76.3% were male and 23.7% were female. Patients with bilirubin level of more than 10mg/dl were associated with poor renal recovery with an Odd ratio of renal recovery as 0.5 (P: 0.33).

Conclusions: Renal non-recovery after liver transplantation can be 9-32% but only a limited number of studies have done to look for possible etiology. These studies have shown longer duration of renal dysfunction, repeat liver transplantation, type II DM and age at liver transplantation as predictors of renal non-recovery. In our study we concluded that total bilirubin level greater than 10mg/dl at the time of liver transplant in patients with HRS will have poor renal recovery post liver transplant.

PUB085

Diffuse Alveolar Hemorrhage in Pulmonary-Renal Vasculitides: Successful Resolution with Emergent Adjunctive Plasma Exchange Jan C. Hofmann. *California Pacific Medical Center, San Francisco, CA.*

Background: Antibody mediated diffuse alveolar hemorrhage (DAH) in pulmonary-renal vasculitides is an acute, often life-threatening condition. While high dose immunosuppressive (IS) therapy is paramount in controlling this condition, plasma exchange often proves to be critically important.

Methods: From 1/08-1/17, we evaluated 63 patients (pts) diagnosed with DAH. Of 154 pts with ANCA or anti-GBM antibody renal vasculitis (RV) treated with adjunctive plasma exchange during this 9-year period, 63 pts (41%) were diagnosed with DAH: 28/74 (38%) with MPO positive ANCA RV, 26/60 (43%) pts with Prot3 positive ANCA RV, and 9/20 (45%) pts with anti-GBM RV. Pts were defined as having DAH if the pt had progressive hemoptysis and/or evidence of DAH by bronchoscopy. Median pt age was 54 years (19-85 years old); 37 (59%) pts were female. Majority of pts presented with cough, dypsnea, and hemoptysis; hypoxemia; and diffuse bilateral alveolar opacities. 54/63 (86%) pts underwent bronchoscopy; 46 pts (73%) were intubated. All pts received the following IS regimen: high dose corticosteroids (CS), plasma exchange (PE), and cyclophosphamide (CP) or rituximab (RTM). Pts received CS (methylprednisolone 500-1000 mg IV X 3-5 days) followed by prednisone taper, and CP (500-750 mg/m^2 IV every 4 weeks, or 75-150 mg/day PO, for 3-6 months) or RTM (375 mg/m^2 weekly X 4 weeks). Pts received daily PE treatments (txs) using FFP replacement until DAH resolved.

Results: 55/63 (87%) pts had resolution of DAH ≤7 days after starting IS regimen. Resolution of DAH was defined as: complete or near complete resolution of alveolar bleeding or hemoptysis, and improvement in oxygenation (decrease in FI02 ≥0.30, or increase in SA02 ≥10%), with or without improvement in chest x-ray findings. Mean number of PE txs was 3.7 (2-8 txs). 41/46 (89%) of intubated pts were extubated. 52/63 (83%) pts had significant improvement in oxygenation; 46 (73%) pts had decreased pulmonary infiltrates. 7 (11%) pts died of complications of pneumonia and sepsis.

Conclusions: Diffuse alveolar hemorrhage is an uncommon, but potentially life-threatening complication of pulmonary-renal vasculitides. High dose corticosteroids, cyclophosphamide or rituximab, and plasma exchange are useful treatment modalities and, when initiated promptly, can be highly effective in providing rapid resolution of antibody mediated alveolar hemorrhage.

PUB086

AKI and Cast Nephropathy: Clinicalpathological Features and Associated Outcomes Fernando Manuel G. Pereira,[1] Afonso Santos,[3] Miguel Goncalves,[1] Pedro Pereira Campos,[1] Rita Theias Manso,[1] Karina Soto.[2] *[1]Hospital Fernando Fonseca EPE, Lisbon, Portugal; [2]Hospital Fernando Fonseca EPE and CEDOC Universidade Nova de Lisboa, Lisbon, Portugal; [3]Hospital Prof. Doutor Fernando da Fonseca, Lisbon, Portugal.*

Background: Cast nephropathy is the most common AKI presentation in Multiple Myeloma (MM). Combination of new generation chemotherapy with efficient removal of serum free light chains (FLC) was recently suggested to increase kidney and patient outcomes. Herein we present our experience with 18 patients, presented with AKI and diagnosed as myeloma cast nephropathy (MCN).

Methods: A retrospective analysis of MM patients with clinical and/or pathological diagnosis of MCN referred to Nephrology Department was done. Kidney response was defined by eGFR≥ 30 mL/min/1.73 m^2 and/or dialysis independence at 3 months.

Results: Eighteen patients were included, 62,5% male, mean age 71yo, with mean follow-up 17 mo. Most of them admitted with AKI III, median SCr 7.4mg/dL; proteinuria 4,82 g/d; ACR 0.33G/G at admission; 70% of cases with nephrotoxic agents; 81% needed RRT; 44% also treated with PE and 62,5% with HCO-HD. In 68,7% of patients MM was Lambda (median FLCs 4540), 25% Kappa (27100), one biclonal, and another with heavy and light chains. Mean BM plasma cells was 55%, and most with bone lytic lesions. All were treated with QT, 87,5% based on BTZ. After 1st QT cycle 50% non-recovered kidney function, at the end of follow-up 56% were ESRD. Kidney biopsy was performed in 68,75%. Of them, 82% had MCN confirmed, one case with interstitial nephritis and tubular FLC deposit and another with heavy and light MDD and rare casts. ESRD was related with higher percentage of tubules with casts. Of note, Lambda FLC was related with worse kidney outcome, as well as the high levels of FLC at admission. At the begining 75% had hematological response, with median FLC reduction of 55,30%. Best FLC reduction was 82% in 1,22 months, after 1st QT cycle. However, the frequency of relapses determined a global mortality of 70% in a mean period of 16,5 months, most related to MM (50%) and 25% sepsis-related.

Conclusions: Combined approach with BTZ-based chemotherapy and HCO-HD lead to significant and fast reduction of serum FLC, resulting in early kidney response. However, late MM diagnosis with high FLC levels were related with worse kidney and patient outcomes. Future large multicenter studies are still needed to confirm the benefits of HCO-HD. Severe chronic renal impairment strongly affects survival in patients with MM.

PUB087

Characterisation of Polymere Membranes by MALDI-Mass-Spectrometric Imaging Techniques Joachim Jankowski,[1] Vera Jankowski.[2] *[1]RWTH Aachen, Aachen, Germany; [2]University hospital RWTH Aachen, Aachen, Germany.*

Background: For physical and chemical characterisation of polymers a wide range of analytical methods is available. Techniques like NMR and x-ray are often combined for a detailed characterisation of polymers used in medical applications. Over the last few years, MALDI mass-spectrometry has been developed as a powerful tool for space-resolved analysis, not least because of its mass accuracy and high sensitivity. MALDI imaging techniques combine the potential of mass-spectrometric analysis with imaging as additional spatial information. MALDI imaging enables the visualisation of localisation and distribution of biomolecules, chemical compounds and other molecules on different surfaces.

Methods: In this study, surfaces of polymeric dialyzer membranes, consisting of polysulfone (PS) and polyvinylpyrrolidone (PVP) were investigated, regarding to chemical structure and compound's distribution. Flat membranes as well as hollow fibre membranes were analysed by MALDI imaging. In accordance with polymer's characteristics analysis parameters like laser intensity and laser raster step size were established firstly to optimize signal intensity and spatial resolution. Best signal quantity and quality and spatial resolution were achieved with settings of 60 µJ laser intensity and 50 µm laser raster step size. The mass spectrometric investigation of both polymers showed clear differences in ionisation behaviour.

Results: According to the manufacturing process luminal and abluminal membrane surfaces are characterised by differences in chemical composition and physical characteristics. The MALDI imaging demonstrated that the abluminal membrane surface is more consisting of polysulfone than polyvinylpyrrolidone, the luminal membrane surface displayed more PVP than PS. The addition of PVP as hydrophilic modifier to polysulfone-based membranes increases the biocompatibility of the dialysis membranes. The analysis of polymer distribution is a relevant feature for characterisation of dialysis membranes.

Conclusions: In conclusion, MALDI imaging is a powerful technique for polymer membrane analysis, regarding not only detection and identification of polymers but also localisation and distribution in membrane surfaces.

PUB088

Identifying Hub Genes Associated with Clinical Characteristics in IgA Nephropathy by WGCNA Yan Xu,[1] Chenyu Li.[2] *[1]Affiliated Hospital of Qingdao University, Qingdao, China; [2]Affiliated hospital of qingdao university, Qingdao, China.*

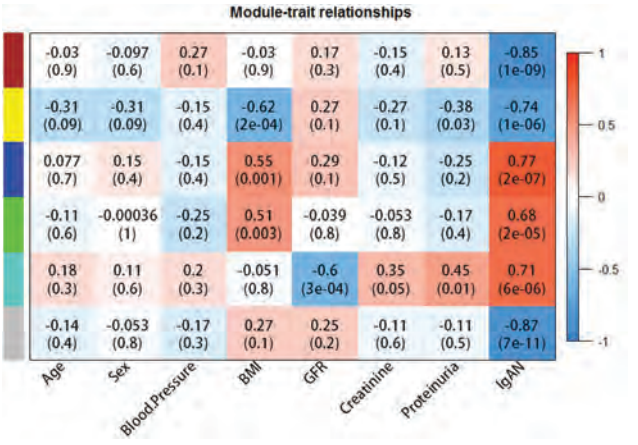
Background: Clinically, IgA nephropathy has a variety of symptoms including paroxysmal gross hematuria, nephritic syndrome and nephrotic syndrome. This study aimed at investigating hub gene and genes modular related to IgA nephropathy clinical characteristics.

Methods: We collected 32 human samples from the European Renal cDNA Bank, used the WGCNA to construct the gene co-expression network and identify the hub genes associated with clinical characteristics. GO and KEGG analysis for hub genes were performed by DAVID, and PPI information was acquired from STRING.

Results: For glomeruli, there were 1470 DEGs containing 10 hub genes associated with age, 8 hub genes associated with sex, and 48 hub genes associated with Bp enrichd in ERK1 and ERK2 cascade, 223 hub genes associated with BMI enrich in organic acid catabolic process, 136 hub genes associated GFR enriched in immune response, 82 hub genes associated with proteinuria enriched in extracellular matrix organization. In tubulointerstitium, there were 480 DEGs containing 6 hub genes associated with age, 15 hub genes associated with sex, and 35 hub genes associated with Bp enrichd in positive regulation of apoptotic process, 87 hub genes associated with GFR enriched in negative regulation of macromolecule metabolic process, 33 hub genes associated with proteinuria enriched in regulation of apoptotic process.

Conclusions: In conclusion, we made a preliminary investigation on molecular mechanisms of relationship between IgA nephropathy and clinical characteristics, and identified hub genes and pathways closely related with BMI, GFR and Proteinuria in IgA nephropathy by a series of bioinformatics analysis.

Funding: Government Support - Non-U.S.



Weighted gene co-expression network analysis in IgA nephropathy glomeruli Each column corresponds to a trait, row to a module eigengene. Each cell contains the corresponding correlation, with color-coded according to the color legend, and P-value.

Novel Vascular Access Device for Hemodialysis Access Eduard Tsyrulnykov,[1] Anil K. Agarwal,[3] Aleksandr V. Obabko.[2] *[1]kenvelo, Mequon, WI; [2]Argonne National Laboratory, Lemont, IL; [3]Ohio State University, Columbus, OH.*

Background: The current methods of cannulation of dialysis access (2 needles) could be ineffective in access with challenging geometry. Proposed single needle cannulation device could be useful in situation where access can accomodate only 1 needle.

Methods: The device consists of a single needle with a dilator with side holes. One of the distinctive features of this device is the use of double dilator (combination of external (element 30) and removable with needle (element 40) internal dilator (elements 45,48 and 30 of image)). There are benefits of using double dilator : 1. Use cannulation needle of smal size. 2. Use of larger size of internal tube advanced into external dilator that will result in higher flow rates of blood through device. Pilot bench and animal studies using this novel VAD for HD were performed between 2005 and 2014. More than 1,200 cannulations were performed in dialysis fistulas in different stages of maturation in animals with medication induced kidney failure. Venous and arterial pressure, blood flow rates, blood recirculation rates, post-treatment bleeding time, and blood urea nitrogen (BUN) clearance were observed and recorded.

Results: The device provides blood flow rate 600 ml/min on radio cephalic fistula. Average post-treatment bleeding time is 3 minutes with applied pressure, blood loss is 3-5 ml. Without applied pressure, bleeding stopped after 10 min and blood loss is 5-10 ml. The decreased level of bleeding is likely due to using smaller size needles. The proposed device develops recirculation 20-30% for the flow rate of 600 ml/min http://www.mcs.anl.gov/~obabko/ed7_te4a.mpeg 2. When flow inside the device is decreased to 450 ml/min, the simulation predict that recirculation will go to zero. http://www.mcs.anl.gov/~obabko/ed8_te4.mpeg

Conclusions: The research presented in this paper suggests that this device could be safely used for dialysis accesses in animals. In the future this device may provide comfort and access for humans. The smaller needle size and increased flow rate will provide additional comfort to patients and possibly increase efficacy of dialysis.

Employing the Lotus Effect for Indwelling Medical Devices Jimmy Ni,[1] Jie Cui.[2] *[1]3J Technologies, Inc., San Diego, CA; [2]Massachusetts General Hospital, Boston, MA.*

Background: Central catheter is the most common hemodialysis access in ESRD patients and associated with increases hospitalization, mortality and healthcare-cost burden. There are many long-term problems of current tunneled catheters especially infection and thrombosis. Thrombotic occlusion occurs in 30-40% of patients, which can occur within 24 hours after insertion or after prolonged continuous successful usage (4, 5). Severe systemic infection occurs in 30% of central catheter-associated bacteremia. When catheter gets infected, patients will need to receive 6 weeks antibiotics[z1], catheter removal, temporary catheter placement and another tunneled catheter reinsertion and a chest X-ray. Center of Disease Control (CDC) estimates the cost of each central line associated infection at $16,550.

Methods: A new type of catheter has been investigated and fabricated, as desired to be efficacious for resolving these problems. We have investigated a cost-effective, long-term, bacteria-resistant, anti-thrombotic interventional medical device on our IP-protected Lotus technology.

Results: The Investigated medical device is based on *Lotus* technology, involving nano-engineered structure array (*Lotus* structure) on the inner surface by a cost-effective, long-lasting micro/nano fabrication method. The catheter is constructed of a monolithic polymer to efficiently carry a bio fluid through an inner surface of a tubular component having a nanostructure array configuration.

Conclusions: We have investigated a cost-effective, long-term, bacteria-resistive, anti-thrombosis interventional medical device on our IP-protected *Lotus* technology. The manufacture process enables it to reform when subject to mechanical molding applied by *Lotus* substrate.

Funding: Commercial Support - 3J Technologies, Inc.

Estimation of Internal Filtration of Two New High Retention Onset Dialyzers Anna Lorenzin,[1] Mauro Neri,[1] Francesco Garzotto,[3] Alessandra Brendolan,[3] Federico Nalesso,[2] Monica Zanella,[3] Nicola Marchionna,[3] Claudio Ronco.[3] *[1]IRRIV, Vicenza, Italy; [2]S.Bortolo Hosp., Vicenza, Italy; [3]St. Bortolo Hospital, Vicenza, Italy.*

Background: During hemodialysis, one of the phenomena contributing to high convective volumes is the internal/backfiltration(IF/BF). In an era of highly permeable and more and more selective membranes, it becomes important to estimate IF/BF volumes for a specific dialyzer and in specific therapy settings. Aim of our study was to in vitro estimate IF volumes by a semiempirical method of two new high retention onset dialyzers in a simulating HD session setting.

Methods: 2 dialyzers were tested: The ranova 400 and 500(Baxter,US). Ultrafiltration coefficients were 48 and 59 ml/h/mmHg respectively. Test was set up in order to collect pressures at inlet and outletof dialyzer compartments in counter-current configuration. Test parameters were:blood flow=300ml/min, dialysate flow=500ml/min, net ultrafiltration=0. Human blood was used. 3 mathematical models were applied:simple linear, double linear and non-linear. The 3rd model considers the blood non-Newtonian and rheological behavior.

Results: Graphs of TMP vs dialyzer length, obtained from the 3 models, are summarized in figure 1. About Theranova400 (Theranova500), single linear model generates an IF volume of 2727ml/h(2906ml/h), but it largely overestimates the result and doesn't match the zero balance condition; double linear model generates 1591ml/h(1815ml/h); the third model, based on assumptions derived previous works in literature, is the most precise and the final volume is equal to 1620 ml/h(1865ml/h).

Conclusions: Geometrical and morphological characteristics of new-generations HD dialyzers and membranes, leading to high permeability and sharp sieving profiles, determine high convective volumes. The convective contribution to the total removal of renal toxins can be increased exploiting internal cross filtration.

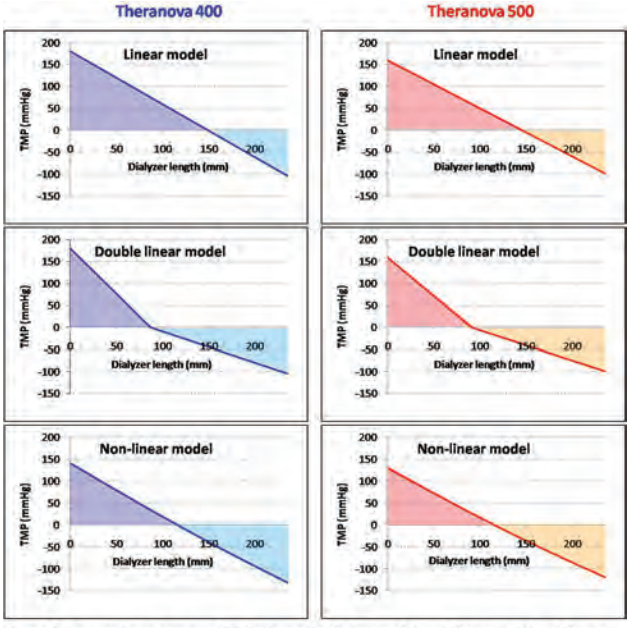

Figure 1. Transmembrane pressures (TMP) estimated inside the two dialyzers, Theranova 400 and Theranova 500, through three different models. The areas under the positive TMP represent the amount of internal filtration (IF), the areas under the negative TMP the amount of backfiltration (BF).

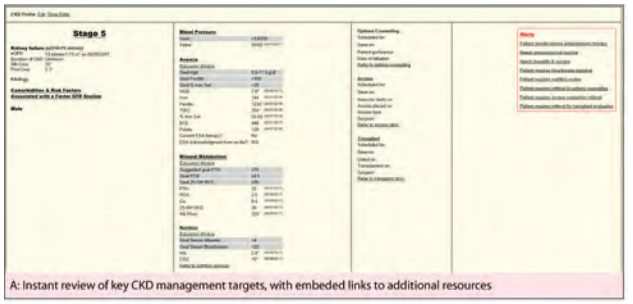
Development of a Digital Dashboard to Streamline CKD Management Nikhil Agrawal,[2] Krzysztof Wierzbicki,[4] Stewart H. Lecker,[2] Andrea Renken,[1] Julie Rockwell,[2] Martin R. Pollak,[3] Ali Poyan-Mehr.[5] *[1]BIDMC, Boston, MA; [2]Beth Israel Deaconess Medical Center, Brookline, MA; [3]Beth Israel Deaconess Medical Center/Harvard Medical School, Boston, MA; [4]Beth Isreal Deaconess Medical Center, Hyde Park, MA; [5]None, Boston, MA.*

Background: In spite of improved safety, and cost-effectiveness over conventional paper-based records, the ever-increasing complexities of electronic health records(EHR) applications and their poor user interface(UI) have been implicated as a major contributor to medical errors, and physician burnout. With the healthcare provider as the end user in mind, we created a streamlined EHR interface to support ambulatory CKD patients care.

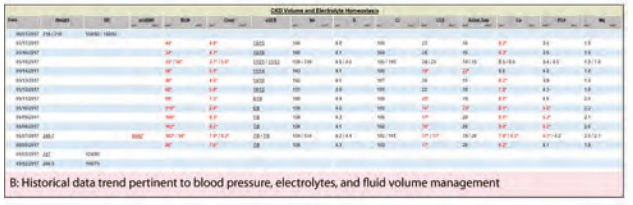
Methods: We formed a multidisciplinary team including an IT specialist, system engineer, nephrologist, nurse, and trainee to develop an electronic dashboard through an an iterative process of UI Design that included: Provider interview, clinical guideline review, definition of the unmet needs, design, prototyping, beta testing, and end user evaluation. Emphasis was placed on user experience and patient needs during the clinic visit.

Results: We have brought all elements pertinent to CKD management under one digital page, referred to as the "CKD Sheet". Provider can access a patient's current state of: Renal function, proteinuria, blood pressure, anemia, iron stores, mineral metabolism, nutritional state, options planning, and transplant evaluation. Each of these 9 categories has built-in educational tools and references. Patient materials (e.g. dietary guides) are readily accessible for print during the visit. Clinical decision support is provided by algorithm-driven alerts for values out of range based on current professional guidelines. Longitudinal data is displayed and grouped by disease systems (e.g. weight, blood pressure, and BNP trended together).

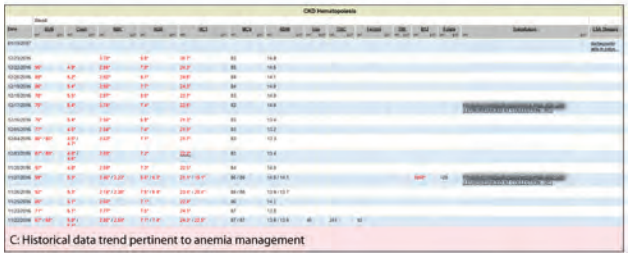
Conclusions: Through an iterative user interface design process and early involvement of end users we have created an EHR-based support tool for the management of patients with CKD.



A: Instant review of key CKD management targets, with embeded links to additional resources



B: Historical data trend pertinent to blood pressure, electrolytes, and fluid volume management



C: Historical data trend pertinent to anemia management

PUB093

Machine Learning Prediction Model of Combined End Point of AKI and New Onset Renal Replacement Therapy (RRT) in ICU Patients Lukasz Kiljanek, Sandeep Aggarwal. *Drexel University College of Medicine, Philadelphia, PA.*

Background: AKI and new onset RRT in ICU patients is associated with significant morbidity and mortality. Prediction of combined endpoint of AKI or need for RRT can potentially improve patient outcomes. To accomplish part of this use of biomarkers, scoring systems and machine learning, have been tried in the past. In our study we attempted the use Gradient Boosting Machine (GBM) - machine learning algorithm to create a AKI and new onset RRT prediction tool using MIMIC III (Medical Information Mart for Intensive Care III) database.

Methods: GBM algorithm from H2O.ai R project library was used to model 2008-2012 MIMIC 3 database. We defined 750 clinical and laboratory variables from first 24 hours after ICU admission. Patients in whom serum creatinine rose by 0.3 mg/dl or more within first 24 hours, with past medical history of dialysis or RRT related events charted within first 24 hours of ICU stay were excluded. Remaining 8893 patients were divided 20 times randomly into training (95% of patients) and testing (5% of patients) datasets. For all patients, minimal serum creatinine within first 24 hours after ICU admission was recorded as baseline. AKI within 24-72 hours after ICU admission was defined as observation of creatinine rise recorded between 24-72 hours by 0.3 mg/dl or more from baseline. New onset RRT was defined as presence of any dialysis related event between 24-72 hours of ICU stay. Average incidence of combined endpoint of AKI or RRT was 82.2 (18%) [95% CI 77.9 - 86.4] for 20 testing sets. Each training dataset was used to build GBM for predicting combined endpoint of AKI or RRT. Each such GBM model was validated on testing dataset. Area under curve (AUC) of receiver-operator characteristics curve (ROC) was recorded.

Results: For 20 testing datasets, AUC of ROC for GBM was 0.79 [95% CI 0.77 - 0.8]. Most important predictors, recorded within first 24 hours of ICU stay, from 1 of 20 runs, with their scaled importances (as per GBM) were : delta creatinine (1), number of pH checks on blood gasses (0.76), last recorded phosphorus (0.4).

Conclusions: In our analysis GBM model showed relatively good accuracy. Our approach can be employed to EMRs in hospitals as an AKI and new onset RRT combined endpoint prediction tool, but more research is warranted to assess clinical applicability and robustness of our methods.

PUB094

Calcitriol Mitigates IL-6 Induced Podocyte Hypermotility via STAT3/MLC Signaling Dian Bao,[2] Fang-Fang He,[4] Hua Su,[1] Chun Zhang.[3] *[1]Huazhong Science and Technology University, Wuhan, China; [2]Union Hospital, Wuhan, China; [3]Union Hospital, Huazhong University of Science and Technology, Wuhan Hubei Provicne, China; [4]Union Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, Hubei, China.*

Background: Podocyte motility contributes to the pathogenesis of foot process effacement and proteinuria during glomerular diseases. Interleukin-6 (IL-6) is a multifunctional inflammatory cytokine and frequently involves in cancer cells invasion and metastasis. It is well-known that calcitriol has anti-inflammatory and immunomodulatory effects besides its classic role in regulation of bone mineral metabolism. Here, we investigated the pathogenic role of IL-6 in podocyte motility as well as the therapeutic effect of calcitriol.

Methods: We cultured conditional immortalized human podocytes and detected podocyte motility by wound healing and transwell assay. Myosin light chain (MLC) or signal transducer and activator of transcription 3 (STAT3) shRNAs were transfected into podocytes by lentivirus transfection system. ML-7 and stattic were employed as inhibitors for the activation of MLC and STAT3 respectively. The expressions of phosphorylated MLC (pMLC), MLC, phosphorylated STAT3 (pSTAT3) and STAT3 were assessed by western blot. The architecture of actin cytoskeleton and focal adhesions were observed by immunofluorescence staining.

Results: We found that IL-6 promotes the expression of pMLC as well as the motility of podocyte in a time-dependent manner. Either genetic deletion or chemical inhibition the phosphorylation of MLC prevents the IL-6 induced podocyte hypermotility, also preserves actin cytoskeleton and focal adhesions of podocyte. Furthermore, our data confirmed that, in IL-6 treated podocyte, STAT3 is an upstream regulator for MLC phosphorylation, and interrupting STAT3 pathway can significantly minimize the hypermotility of podocyte. Calcitriol, widely applied in clinic, markedly attenuates IL-6 induced podocyte hypermotility via blocking STAT3/MLC signaling.

Conclusions: Our data indicated that IL-6 enhances podocyte motility via STAT3/MLC pathway. Whereas calcitriol exertes its protective role by inhibiting this signaling.

Cold Shock Proteins Interfere with TNFα Binding to Its Receptor and Modulate Progranulin-Mediated Inhibition of Signaling Jonathan A. Lindquist, Christopher L. Hessman, Antonia Bock, Sabine Brandt, Peter R. Mertens. *Otto-von-Guericke University, Magdeburg, Germany.*

Background: Inflammation and an influx of immune cells are common elements in the pathogenesis of many diseases including autoimmunity. Amongst the pro-inflammatory cytokines, tumor necrosis factor-α (TNF α) plays a central role due to its ability to amplify the cytokine network. Therefore TNF blocking agents have been developed and demonstrated effectiveness against a number of immune-mediated disorders (rheumatoid arthritis, ankylosing spondylitis, psoriasis). Progranulin (PGRN) is a growth factor that binds to TNF-receptors and interferes with TNFα-mediated signaling. Extracellular PGRN is proteolytically processed into granulins by proteases released from immune cells. PGRN exerts anti-inflammatory effects, whereas granulins are pro-inflammatory. The factors coordinating these ambivalent functions remain unclear.

Methods: We investigated the role of Y-box binding protein-1 (YB-1) as a potential candidate for this immune modulating activity. We identified an interaction between YB-1 and PGRN using a yeast-2-hybrid assay and verified the physical interaction by co-immunoprecipitation. Western blotting and gene expression analysis were used to investigate the influence of YB-1/PGRN on TNF-mediated signaling.

Results: Similar to PGRN, we demonstrate that YB-1 interferes with TNFα binding to its receptors in a dose-dependent manner. Using bone marrow-derived macrophages, we show that YB-1 in combination with PGRN inhibits TNFα-mediated signaling, supporting the functionality in vitro. Costimulation of macrophages with TNF, YB-1, and PGRN reduced MAPK activation as well as NFκB. Using YB-1-deficient cells, we show that NFκB activation was reduced after TNFα-stimulation, confirming that YB-1 is essential for NFκB activation. Recombinant YB-1 reconstitutes this effect, increasing NFκB phosphorylation after TNFα stimulation.

Conclusions: Taken together, we show that YB-1 displays immunomodulatory functions by affecting the binding of TNFα to its receptors and influencing TNFα-mediated signaling, thereby enhancing the anti-inflammatory effect of progranulin. The relevance for chronic kidney disease was already demonstrated, as anti-TNFα therapy significantly decreased disease activity. Given that we observe differential acetylated YB-1 bands in patient urine, we are investigating their relevance for disease activity.

Effect of Novel Phosphate Binder, Ferric Citrate, on Renal Function, Histology, Oxidative Stress, Inflammation and Fibrotic Pathway in Rats with CKD

Wanghui Jing,[1,2] Ane C. Nunes,[1] Mahyar Khazaeli,[1] Nosratola D. Vaziri.[1] *[1]University of California Irvine, Orange, CA; [2]School of Pharmacy, Xi'an Jiaotong University, Xi'an, China.*

Background: CKD commenly result in anemia. Ferric citrate (FC) is a novel phosphate binder which has been shown to increase hemoglobin, serum ferritin, and transferrin saturation. Scince iron overload can accelerate the CKD by promoting by oxidative stress and inflammation, this study was designed to determine the effect of FC administration on the structure and function of kidney in CKD rats.

Methods: Rats were randomized into 5/6 nephrectomized and sham groups. Each group was subdivided into 4% ferric citrate supplemented diet (CTL+FC, CKD+FC) and regular diet (CTL, CKD). After 6 weeks, blood pressue, kidney function, serum phosphorus, hemoglobin, serum iron and renal oxidative, inflammation and fabrosis markers were assessed.

Results: FC administration decreased SBP, BUN, as well as serum phosphate, and raised body weight, serum iron, and Hb. Kidney tissue in CKD rats showed activation of NF-κB, and upregulation of pro-inflammatory, pro-oxidant and pro-fibrotic molecules including MCP-1, iNOS, COX-2, gp91^{phox}, MPO, nitrotyrosine, PAI-1, TGF-β and α-SM actin; reduction in nuclear translocation of Nrf2 and down-regulation of its key target products. FC administration in CKD animals resulted in accumulation of iron in the proximal tubular epithelial cells, and significant attenuation of most molecular markers of oxidative stress, inflammation and fibrosis in renal tissue.

Conclusions: FC administration could improve the renal function in CKD rats, and mitigate CKD-associated upregulation of oxidative, inflammatory, and fibrotic in the remnant kidney. The salutary effect of FC on renal function and structure in CKD rats is presently unknown. However, it might be related to the protective effect of the citrate on proximal tubular epithelial cells.

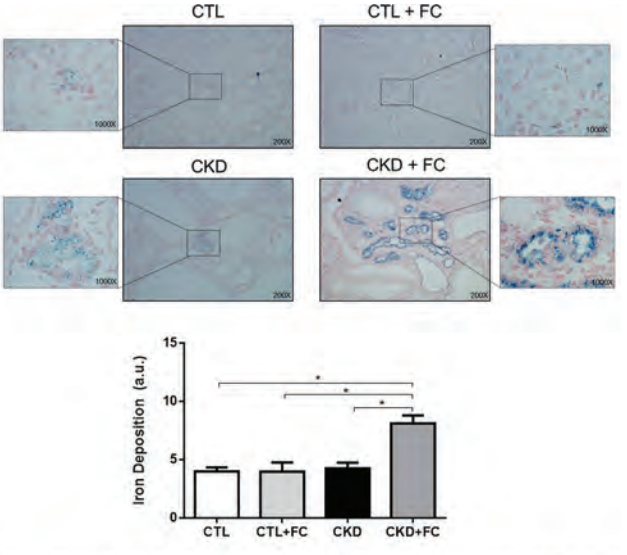

Figure 1. Representative photomicrographs of Prussian Blue stained kidney tissue from CTL (n=5), CTL+FC (n=6), CKD (n=4) and CKD+FC (n=6) treated animals. Data depicting the colon iron deposition in different groups. Data are mean ± SEM. *P<0.05.

The Reactive Oxygen Species Production by Erythrocytes, but Not Cell Death, Is Associated with Anemia in Pre-Dialysis CKD Patients

Andrea N. Moreno-Amaral,[3] Gabriela F. Dias,[4] Natalia Borges Bonan,[1] Ana C. Gadotti,[2] Stephany Van der goot,[6] Alessandro A. Halama,[4] Peter Kotanko,[5] Roberto Pecoits-Filho.[3] *[1]PUC-PR, CURITIBA, Brazil; [2]PUCPR, Curitiba, Brazil; [3]Pontificia Universidade Catolica do Parana, Curitiba, Brazil; [4]Pontifícia Universidade Católica do Paraná, Pinhais, Brazil; [5]Renal Research Institute, New York, NY; [6]Pontificia Universidade Católica do Paraná, Curitiba, Brazil.*

Background: Increased oxidative stress is well-documented in uremic patients. Evaluation of redox status in red blood cells (RBC) has been used as a reliable method to evaluate oxidative stress in patients with chronic kidney disease (CKD). Our aim was to study the associations of RBC death (eryptosis), reactive oxygen species (ROS) generation by RBC, and anemia in pre-dialytic patients at various CKD stages.

Methods: We studied 20 CKD patients (8 CKD 3; 12 CKD 4/5). Pulse oximetry was used to determine arterial oxygen saturation. ROS generation and eryptosis were evaluated by flow cytometry using DCFH-DA probe and Annexin-V binding, respectively.

Results: While ROS production was increased in anemic compared to non-anemic patients, no association between eryptosis and anemia was observed. RBC ROS production or eryptosis were not associated to CKD stages or Oximetry (Table 1).

Conclusions: RBC ROS generation is increased in anemic pre-dialysis CKD patients, indicating its possible role in the pathogenesis of renal anemia.

Follistatin Protects Against Thapsigargin-Induced Apoptosis in Mesangial Cells

Neel Mehta,[1] Agata Gava,[1] Joan C. Krepinsky.[2] *[1]McMaster University, Hamilton, ON, Canada; [2]McMaster University, St. Joseph's Hospital, Hamilton, ON, Canada.*

Background: In numerous glomerular diseases including diabetic nephropathy, glomerular mesangial cell (MC) apoptosis correlates with progressive glomerulosclerosis and albuminuria. Thapsigargin (TG), an endoplasmic reticulum Ca^{2+}-ATPase inhibitor, causes MC apoptosis through increasing $[Ca^{2+}]_i$ and reactive oxygen species (ROS). We have observed that while promoting MC apoptosis, TG also up-regulates the expression of follistatin (FST). FST is a secreted glycoprotein that neutralizes TGFβ super-family members, primarily activins. Since FST inhibits apoptosis and ROS production in numerous cell types, we determined whether FST is protective against TG-induced apoptosis in MC.

Methods: Studies were conducted on primary mouse MC using standard molecular biology techniques including immunoblotting, immunofluorescence and luciferase assays.

Results: TG caused apoptosis in MC that was characterized by elevated caspase 3 cleavage and caspase 3/7 enzymatic activity. TG-mediated apoptosis post-translationally stabilized and increased the expression of FST. Functionally, FST down-regulation augmented, while FST over-expression and exogenous FST pre-treatment protected against TG-induced apoptosis. FST did not exert its protective effects through mediating $[Ca^{2+}]_i$ flux. However, using ROS scavengers, TG-induced apoptosis was found to be dependent on the presence of ROS. Interestingly, while FST protected against TG-induced ROS production, it had no effect on superoxide production. FST is most potently active against Activin A, which has been shown to induce ROS production in other cell types. However, in MC, TG did not increase Activin A production nor did Activin A induce ROS production or apoptosis. Mechanistically, TG induced Smad3 transcriptional activity which was attenuated by FST and the ALK4/5/7 inhibitor SB431542. These data indicate that the protective effects of FST may be explained by its inhibition of activin B, which is being explored in current studies.

Conclusions: In MC, FST protects against TG-induced apoptosis through inhibiting the production of ROS. This is independent of activin A, but may depend on activin B. Future studies will determine whether FST can be used *in vivo* to protect against the progression of glomerular diseases involving MC apoptosis and ROS-mediated injury.

Rapamycin Enhances Repressed Autophagy and Attenuates Aggressive Progression in a Rat Model of IgA Nephropathy

Di Liu, Yexin Liu, Zheng Dong, Hong Liu. *The Second Xiangya Hospital, Central South University, Changsha, China.*

Background: IgA nephropathy (IgAN) has been considered as the most frequent form of primary glomerulonephritis wordwide with a variety of factors involved in the occurrence and development of it. The impact of autophagy in IgAN, however, remains partially unclear. The present study was designed to investigate effects of rapamycin in an IgAN model.

Methods: After establishing an IgAN rat model, SD rats were divided into four groups: control, control+rapamycin, IgAN, IgAN+rapamycin. Proteinuria and the pathological changes and the level of autophagy of kidney were texted. Identify the expression of phosphorylation and total mTOR and s6k1 as well as cyclin D1 in the kidney of rats through Western blot and immunohistochemistry.

Results: We observed a significant reduction in the progression of proteinuria as well as alleviation of pathological lesions in IgAN rats with rapamycin treatment. Besides, autophagy was inhibited while mTOR/S6k1 pathway was activated and expression of cyclin D1 was increased in IgAN. Rapamycin treatment increased autophagy and decreased the expression of cyclin D1.

Conclusions: These results may suggest that mTOR mediated autophagy inhibition may result in mesangial cell proliferation in IgAN. These results may suggest that mTOR mediated autophagy inhibition may result in mesangial cell proliferation in IgAN.

Cryptotanshinone Reduces Angiotensin II Induced Senescence and Autophagy through STAT3/mTOR Signaling in Human Glomerular Mesangial Cells Shuang Yang, Lining Wang, Dan Sun, Xiuying Wang. *The First Hospital of China Medical University, Shenyang, China.*

Background: Angiotensin II induces premature senescence of human glomerular mesangial cells and activation of STAT3. Cryptotanshinone, an active component isolated from Salvia miltiorrhiza Bunge, is an inhibitor of STAT3. The objective of this study is to investigate effect of cryptotanshinone on senescence in human mesangial cells and its mechanism.

Methods: Human glomerular mesangial cells were stimulated with Ang II,then S3I-201(an inhibitor of STAT3)or cryptotanshinone were added into human glomerular mesangial cells

Results: Angiotensin II increased expression of LC3 II and autophagosome formation, decreased expression of p62. Expression of STAT3/mTOR has changed which was correlated with development of cell senescence and autophagy. We also showed that blockage of STAT3 by S3I-201 or cryptotanshinone abrogated the effects of on cellular senescence, on autophagy, on STAT3/mTOR signaling with Angiotensin II.

Conclusions: Cryptotanshinone reduces angiotensin II induced autophagy and senescence, at least in part, by regulating STAT3/mTOR signaling in human glomerular mesangial cells.

PUB101

STAT1 Mediates Cellular Senescence Induced by High Glucose in Human Glomerular Mesangial Cells via Regulation of Autophagy Activity Dan Sun, Lining Wang, Shuang Yang, Xiuying Wang. *The First Hospital of China Medical University, Shenyang, China.*

Background: The signal transducer and activator of transcription 1 (STAT1), which was the first discovered protein in the signal transducers and activators of transcription (STATs), is a latent transcription factor involved in a variety of signal transduction pathways, including cell proliferation, apoptosis, and differentiation. Here, we examined whether the process of senescence would be affected by STAT1 .

Methods: We passaged human mesangial cells (HMC) and induced HMC senescence by high glucose (30mmol/L) after 72h incubation. To explore the mechanism between STAT1 and autophagy that exerts on senescence-associated signal pathway.We inhibited STAT1 by pretreating cell with fludarabine and enhanced autophagy activity with rapamycin to observe the alternation of senescence.

Results: We observed that high glucose induced STAT1 activation, while the activity of autophagy was suppressed and the senescence-associated signal pathway was activated,then senescence expressed. We identify that the expression of p53/p21 pathway was suppressed and senescence was relieved through enhanced autophagy activity, while the senescence expression was relieved by the enhancement activity of autophagy through inhibiting STAT1 by incubation of fludarabine (50umol/L).

Conclusions: STAT1 might mediate cellular senescence induced by high glucose in human glomerular mesangial cells via regulation of autophagy activity.
